A symposium on "Electromagnetic Theory and Antennas", sponsored by the International Scientific Radio Union, the Technical University of Denmark, the Danish Academy of Technical Sciences and the Danish National Committee of the International Scientific Radio Union, will be held in the Technical University of Denmark, Copenhagen, during June 25–30. The programme will include the following topics: propagation of guided and unguided electromagnetic waves in anisotropic media; scattering in random media; propagation along and radiation from modulated structures; properties of partially coherent electromagnetic fields; recent developments in diffraction theory; antennas. Further information can be obtained from the secretary of the symposium, H. Lottrup Knudsen, Øster Voldgade 10 G, Copenhagen K.

FOOD POLICY AND PLANNING IN HUNGRY COUNTRIES

ESTIMATES of the proportion of the world's population that is hungry for all, or the greater part, of the year vary from about 20 to about 70 per cent. The main reasons for this very large margin of uncertainty are two. In the first place, reliable food consumption surveys, far from easy in highly developed countries, are, in most of the underdeveloped countries, extraordinarily difficult to carry out, and the results may be particularly misleading where a major part of a population is engaged in agriculture. In the second place, existing, well-defined standards for adequate nutrition applicable to Western populations have to be interpreted with great care in relation to populations, the individuals of which differ in physical size from Western individuals, or where there is a marked different age distribution, or where many of the individuals carry out quite different types of physical work under different environmental conditions from those in the technologically advanced countries. Nevertheless, to any but the most fleeting Western visitor, it is abundantly obvious that undernutrition is widespread in Far Eastern countries, and malnutrition, especially among young children, is particularly marked.

Pursuing his inquiries further, the observant Western visitor may find that in some at least of these countries the responsible authorities, while cognisant in a distant way that hunger, or even seasonal near-starvation, may afflict a substantial percentage of the people under their charge, scarcely know where to begin in an endeavour to raise nutritional standards.

The fourth Food and Agriculture Organization Regional Conference for Asia and the Far East (1958), recognizing "that the technical issues involved in food policies and planning need to be clarified early from the nutritional angle on a regional basis for the guidance of the governments", recommended to the Director-General of the Organization that a meeting should be convened as soon as possible to consider "the various aspects of the problem of linking the nutritional needs of the people with national policies and plans relating to food and agriculture". The meeting was duly held in Bangkok, Thailand, in June 1960, and its recently published report gives an account of its proceedings and recommendations*. The countries represented at the meeting were India, Thailand, Philippines, Ceylon, Indonesia and Taiwan. Present also were representatives from the World Health Organization, the United Nations International Children's Emergency Fund, the Economic Commission for Asia and the Far East, and a strong group from the Food and Agricultural Organization.

For any country intending to introduce a national policy for nutritional improvement, the essential requirement is reliable information on the actual situation, quantitative and qualitative, of both food production and food consumption in the various districts and among the different socio-economic groups in that country. The first chapter of the report endeavours to make the beginnings of an appraisal of food consumption per head per day, both for the countries represented at the meeting, and also for some of the unrepresented countries, Japan, Korea, Burma and Malaya. The conclusion is reached that "the average levels of food consumption do not appear to be satisfactory", a statement which seems to me, who has seen conditions in part of the Far East, to provide a classical example of meiosis. In fact, if the figures quoted in the report for quantitative food consumption are reliable, the average calorie intake of all except one of these countries is highly unsatisfactory; further, the paragraphs in the same chapter reporting the widespread incidence of deficiency diseases—among which beriberi is reported to be still common in the Philippines, Burma, Viet-Nam and North Thailand—indicate that qualitatively also, many of the Far Eastern diets are seriously inadequate. Another comfortless statement in this chapter is that except in Japan (where per caput fish supplies have more than doubled since the War, and where milk supplies are rapidly increasing) the intake of animal protein has declined in these countries in recent years. The report points out that "clinically-evident cases of malnutrition represent only a fraction of their prevalence. Cases without frank manifestation but with impaired vital functions . . . are usually disregarded, with the result that the magnitude of the problem is hardly realized".

The establishment of food consumption targets, both long-term and medium-term, is dealt with in the second chapter. Among the general principles outlined, one is of especial significance—that in planning for increased food supplies, improved indigenous production should be the basis, a fact which appears still to be only partially recognized in several of the Far Eastern countries. As regards medium-term objectives, a compromise between what is nutritionally desirable and what is economically feasible is recognized as inevitable, though what is economically feasible, in a sovereign country at least, is a matter which is to a large extent under 'indigenous' control.

The third chapter is mainly concerned with improvement in nutrition through food policies and plans. The complex of interrelated factors influencing food consumption and nutrition varies so much from one country to another, or even from one region to another within the same country, that generalizations made in this chapter tend to be so broad as to become truisms. Thus, few can doubt the scarcely epoch-making statement made in the report that the most important economic factor which determines what people eat is their purchasing power. The equally important factors, in several Eastern countries, of religious prohibitions and traditional taboos, which still add gratuitous handicaps to the nutritional burdens at present borne by the humbler citizens in these countries, or bound up as these handicaps are with the difficulties, particularly among the illiterate, of "motivation towards change", receive little emphasis.

The usual, unexceptional recommendations are made—better education in nutrition, home economics, and dietetics, increase in the number and influence of food and nutrition organizations, the need to train individuals who can correlate nutritional needs with agricultural food production from land-

or sea. Few of these individuals exist in the hungry countries at present.

In the fourth and final chapter the need for improved staffing, equipment, status and influence of nutrition research centres in the Far Eastern countries is stressed, and the establishment in each country of a strong committee representing health, agriculture, education, economics and social welfare, capable both of advising the Government and stimulating action along effective lines, is recommended.

Clearly visible through all the cautious phraseology of this report is the general agreement that a significant improvement in most of the Far Eastern countries depends on influencing governments to give indigenous efforts toward the achievement of such improvement both high priority and adequate funds. These efforts would include the far closer correlation of agricultural, economic and nutritional policy, and the training forthwith of adequate numbers of indigenous technologists in these fields.

Truly, the improvement of national diets in the hungry countries is a problem which must depend for its solution on indigenous effort, with, especially in the early stages, specialist assistance, 'know-how' and finance from United Nations agencies and other outside sources. The technical knowledge required is already available in the world; if it is adequately applied, very few indeed of the hungry countries need remain so.

H. D. KAY

TEACHING BIOLOGY IN AMERICAN HIGH SCHOOLS

EARLY in 1959 the American Institute of Biological Sciences, an association of forty-seven societies with an aggregate membership of 84,000, set up the Biological Sciences Curriculum Study under the chairmanship of Prof. Bentley Glass of the Johns Hopkins University. Arnold B. Grobham, of the University of Florida, agreed to serve as full-time director of the project, and space for a permanent headquarters was obtained on the campus of the University of Colorado. With financial support assured by the National Science Foundation, the aim of the Biological Sciences Curriculum Study was to examine the defects of present biology teaching at all levels and the provision of specific programmes and materials to bring biology curricula up to date and to focus them more sharply on what a consensus would hold to be the major objectives of biology teaching.

At the outset, it was decided to begin by tackling the problem of biology at the high-school level. Although the defects of biology teaching in the elementary school or in the colleges may be fully as great, it is in the secondary schools that greatest choice of occupation is made; it is here that one finds the last opportunity to teach the sciences, and specifically biology, to nearly every future citizen. Clearly, much of the difficulty in interesting students in the study of biology at more advanced levels derives from the failure of high-school biology teaching to awaken the interest commensurate with its importance.

A steering committee was formed, comprising some thirty persons, who included not only college and university biologists recognized for their research as well as their interest in education but also high-school teachers of biology, writers of text-books and teachers' hand-books, and high-school administrators. During the course of the first year, the steering committee formulated a general plan of procedure and discussed the problems posed by the existence of an antiquated biology curriculum in the secondary schools. There was general agreement on several key points. Some of the findings of the committee are outlined in a recent issue of the *American Scientist* (49, No. 4; December 1961).

The biological sciences are at present advancing at so rapid a rate as to double the amount of significant knowledge every 10–15 years. While this fact makes it imperative to revise courses and methods of teaching at more and more frequent intervals, it also makes it increasingly impossible to 'cover' in any course all that is significant and that a general citizen might profitably know. Most high-school text-books are twenty years behind the advancing front of knowledge, and in some very significant matters, because of social or religious opposition, fully a century in arrears. Appropriate scientific treatment must be accorded such 'controversial' subjects as organic evolution, the nature of the individual and racial differences, sex, reproduction in the human species, and the problems of population growth and control.

Even worse than the failure to keep biology for the class-room up to date is the prevalent fault of teaching the life sciences (and indeed all others) as constituting essentially a body of established 'true' information, knit by concepts and laws of nature assumed to be unalterable and prescriptive. That observations are always limited, that laws of Nature are mere summations of experience, and that science consequently is for ever adding new observations, modifying its concepts, and refining or replacing its laws of Nature, are principles honoured in the breach. The conception of science as a body of methods of inquiry—involving accurate and confirmable observations, quantitative treatment of data, and controlled experimentation—gets lip service, but rarely, if ever, enters into the experience of the student at the high-school level. In particular, so-called laboratory work has become a travesty of genuine scientific activity.

It is the essence of the life sciences that they are diverse in point of view and methodology. In consequence, there is no single best way to organize a biology course. There is a vast difference between the analytical, physico-chemical approach of the biochemist or biophysicist and the organismal approach of the student of behaviour and the supra-organismal view of the ecologist who must deal with communities and ecosystems. It is both valid and necessary to explore a variety of ways of approaching and organizing the subject-matter of biology.

Whatever the approach and whatever the organization, the essential character of scientific activity and the great biological themes must permeate the treatment. On one hand, the nature of science as an increasingly important element of human history must be stressed. On the other, the warp and woof of the treatment of the subject-matter must consist of the great biological themes such as the interdependence of structure and function, regulation and homeostasis, the genetic continuity of life, its evolution, diversity of type bound up with unity of pattern, and the relation of organism to environment. These must be treated at all levels of organization, from the molecular level to that of the ecosystem, and at all levels of process, from the chemical reaction through the growth and development of the individual to the evolutionary changes with time.

General education must provide each citizen with an understanding of the nature of the scientific process that has become the source of the most radical social changes and the principal strength and resource of every modern nation. This is of the gravest importance in a democracy, where every ultimate decision rests with the people. This conclusion calls for a thorough and radical change in the nature of most up-to-date science teaching.

A sound understanding of biology is the educational right of everyone who in later years will have to cope with individual problems of health and nutrition, with family problems of sex and reproduction and parenthood, and with the citizen's problems of the wisest management of natural resources, the biological hazards of nuclear radiations in peace and war, and the extent of Governmental support of science as the primary source of national strength and wealth. It was agreed by the steering committee that biology in the high school curriculum might best remain at the tenth grade level, where it is now conventionally taught and where the great majority of students take it, rather than be shifted to a later year where it would have the advantage of following instruction in physics and chemistry but would be taken by a small minority of high school students.

The steering committee adopted the objective of preparing materials for a biology course that would be suitable for all high-school students, irrespective of ability or future plans. This choice did not exclude the possibility of preparing, in addition, biology courses designed either for selected groups of younger students or for those more advanced.

During the summer of 1960 the first drafts of three distinct biology courses, including text-books, laboratory manuals and teachers' guides, were prepared by three teams of writers and supporting staffs to produce the 'yellow', 'blue' and 'green' versions, short names for courses on the respective genetic and developmental, biochemical and physiological, and ecological and evolutionary approaches. In the summer of 1961, a revision of the texts and laboratory work was made.

These books are supported by a teachers' handbook, a set of volumes which includes, among numerous other aids to the teacher, a discussion of the background, emphases, and the aims of the Biological Sciences Curriculum Study, and the distinctions between the three versions and conventional high school courses.

The separate volume of *Biological Investigations for Secondary School Students* presents 100 biological problems at present unsolved, selected and edited for the use of the truly gifted student, from hundreds of suggestions submitted by research biologists in the United States. Each problem is outlined with sufficient detail for the student to begin a long-term project. Copies of this volume, the text-books, laboratory manuals, teachers' guides and the teachers' handbook are obtainable from the American Institute of Biological Sciences, 2000 P Street, N.W., Washington 6, D.C.

YOUTH SERVICES IN BRITAIN

In opening a debate on the youth service in the House of Lords on February 21, Lord Stonham, while critical of the scale of the Government's contribution of less than £1 million to be distributed among nearly 5 million young people during the year, congratulated the Minister of Education on the action taken to implement the recommendations of the Albemarle report. The National College for Training Youth Leaders was opened at Leicester in January 1961; 84 students completed the course last year, 140 more had started, and there was already a waiting list for next year's course. The Youth Service Development Council had met 14 times since it was founded, usually with the Minister of Education in the chair; the requirements for the status of qualified youth leaders were announced last July and a salary scale ranging from £680 to £1,000 a year was agreed. For the period 1960–63 the Minister had authorized starts on building projects to a value of £7 million, including furnishing and equipment, four-fifths for local authorities and one-fifth for voluntary bodies, and £535,000 had been paid to voluntary organizations in each of the past two years.

For the Government, the Lord Chancellor, Lord Kilmuir, stated that direct financing of the Youth Service by the Exchequer had increased from £229,000 in 1959–60 to £775,000 in the current year. Under the building programme some 750 new and expanded youth clubs and centres were being provided and there was good reason to believe that the Albemarle target of 1,300 full-time qualified youth leaders would be achieved by 1966. Besides the National College, there were full-time courses of training at University College, Swansea, and West Hill Training College, Birmingham, and 10 teacher-training colleges had introduced training for youth leadership as an optional part of their three-year course. Proposals to a value of about £14 million had been submitted in respect of building programmes and because of this the Minister had had to introduce a system of local priorities, irrespective of whether the jobs were to be undertaken by local educational authorities or by voluntary bodies. There had been two conferences of senior Government experts on youth questions: one in Paris, in March 1960, and the other in Brussels, in March 1961; and there would be a third in Strasbourg in March 1962; as well as one at Leicester in April on training full-time leaders. A continuous exchange of information and technical assistance was developing on all matters connected with the youth service and there was the prospect of establishing at Strasbourg in the next two years a European Youth Centre concerned with training senior youth leaders, organizers and administrators, through courses of six months, as well as providing shorter courses and research activities.

In replying on the debate, Lord Newton added that the Youth Service Development's Council publication *Youth Service* had now a circulation of 23,000 and that the grants to national voluntary organizations for 1961–62 totalled £236,000 for 35 organizations. Grants for special developments in experimental work amounted so far to £57,000 and included grants to the Youth Theatre, to the Council for Nature, for appointment of an officer to attract more young people to the work of the Council's conservation corps, and to the National Association of Youth Clubs and the Young Women's Christian Association for research into techniques of approaching and attracting potential delinquent 'unclubables'. Voluntary Service Overseas had been financially assisted through the Department of Technical Co-operation. At the time of the Albemarle report local education authorities were employing directly, or contributing to the salaries of, some 700 full-time youth leaders. By the middle of 1961 this total had increased by at least 100, and authorities and voluntary bodies had plans to employ another 450 over the next three years, while the number of youth officers and organizers employed by local education authorities had increased from 350 to 425 and would probably increase by another 50 in the next three years.

THE CARNEGIE TRUST FOR THE UNIVERSITIES OF SCOTLAND

THE sixtieth annual report of the Executive Committee to the Trustees of the Carnegie Trust for the Universities of Scotland for the year 1960–61 * records payments of more than £135,000 to universities and other institutes under the quinquennial arrangements, in addition to expenditure on schemes directly administered by the Trust. The major projects have been, in the University of St. Andrews, £9,881 for a building for the Biology Department at Queen's College, Dundee, and £5,055 for the Bell-Pettigrew Museum at St. Salvator's College; at the University of Glasgow, £36,400 for the Stevenson Physical Education Centre and £5,700 for the new Arts Faculty building; £26,325 for the Physics Department building at the University of Aberdeen; and £25,000 for the Holland House Hall of Residence at the University of Edinburgh.

Early in 1961 assurances were given to the universities that the University Grants Committee would not expect them to contribute from their own resources to approved building programmes for 1962 and 1963 and to the provisional programmes for 1964 and 1965. Accordingly, the Trust has informed the universities that during the quinquennium 1962–67 it would not make grants to remedy any deficiency in the Treasury Grants for teaching buildings as it had done in the 1957–62 quinquennium. The provision of new teaching buildings is regarded as a Government responsibility, and in the new quinquennium the Trustees consider that in student residences, playing fields, unions, staff common rooms, etc., there is a large field in which they can substantially help the Scottish universities to supply the proper amenities of university life, provision of which would otherwise be seriously delayed if made at all. In the quinquennium 1962–67, the Executive Committee has decided to release from resources £250,000 for capital expenditure on approved schemes, while retaining normal recurring grants at an annual level of £60,000. Of the allocation from reserves, £72,000 each will be available to the Universities of Glasgow and Edinburgh, £48,000 each to St. Andrews and Aberdeen, and £10,000 to the Royal College of Science and Technology, Glasgow.

Expenditure on the research scheme exceeded £60,000, subventions in aid of publication of works of scholarship increasing to £3,167 (excluding two special provisions made in the previous year), and from October 1961, Glasgow and Edinburgh are each to receive £3,000 annually, and St. Andrews and Aberdeen £2,000 annually, to facilitate travel in connexion with research by members of the staff of the universities. The usual notes on the work of Fellows, Senior Scholars and Scholars during the session 1960–61 are given in an appendix, together with lists of research grants and of publications.

The system of assistance to students with fees continued without significant change from its modified form when the Scottish Education Department altered its bursary regulations in 1957. The number of beneficiaries fell from 538 in 1959–60 to 455, and payments from £18,185 to £15,575, and the Trust's scheme will continue to be administered on the same principles as before until the results of the new Government scheme, following the acceptance of many of the recommendations of the Advisory Committee on Awards to Students, can be properly assessed. Repayments by beneficiaries fell to £1,482 by thirty beneficiaries, compared with £2,069 by thirty-nine in 1959–60. In the summer of 1961, a system of vacation awards to students who had shown exceptional merit at their university, which had been tried in one faculty in 1960, was extended to all faculties at each of the Scottish universities. In all, sixty-one awards were made, totalling £2,640, to senior students generally either about to enter their final year or about to go on to research immediately after first graduation. In arts most awards in 1961 were used to enable their recipients to study a special topic, or to pursue language or other studies at a foreign university. This scheme has been a great success and it may be desirable to increase expenditure on it.

HAZARDS OF DUST

THE stage is set for action when, in a time of rapid social change, a recently nationalized industry which employs nearly three-quarters of a million men is found to be also manufacturing hundreds of cases of an industrial disease. If, in addition, the Nation depends fundamentally on the product of this industry which possesses, therefore, a trade union of great power, then in the colloquial phrase "something will happen".

After an initial few years of feeling its way through situations, some of which were almost laughable—such as when the embryo medical research programme was directed by a former professor of physics—the National Coal Board has now come to be equipped with strong medical and scientific services managed by hard-headed men who know what they are about.

A report, entitled, *The Study of the Composition of Respirable Dust in the Pneumoconiosis Field Research*, comes from the scientific service alone*. It summarizes the considerations which have led up to the present views on the study of the composition of airborne dust in coalmines. It discusses how the collieries should be selected for dust sampling and the statistical design of the sampling method. The use of a thimble versus a thermal precipitator technique for sampling is balanced up and the writers come down on the side of the thermal precipitator. They then summarize what is known about the coal and mineral content of airborne coalmine dust and the techniques necessary for its analysis. For this, they suggest that a phase-contrast method be used with an optical microscope. The man-hours necessary for dust surveys of different types are calculated, and the relation of the physics and chemistry of coalmine dust to the human disease of pneumoconiosis is considered.

The authors realize that what they are talking about are shadow pictures of men's chests rather than functional disease, and they feel that the X-ray absorptions of dusts of differently ranked coals should be studied. They also point to a fundamental gap in our knowledge of the pathological effects of dust on the animal cell by suggesting that this should be investigated experimentally. These are merely two of the more interesting ideas from a number of projects for future work.

But it must be admitted that it is not easy to get the sense out of this report and the abstract says nothing about what is really between the covers.

Another report, entitled, *The Relation between Pneumoconiosis and Environmental Conditions*, describes the most impressive survey of its kind which has ever been carried out anywhere in the world*. The chest X-ray appearances of more than 30,000 coalworkers have been set against all the different types of work which they had carried out up to the time the pictures were taken. The survey took in 26 different collieries chosen to cover the range of relevant geographical and environmental conditions. The sample of men was nearly 95 per cent complete.

This extensive national study shows that there are wide variations in the prevalence of pneumoconiosis and in its relation to the age of the mineworker, but with regional similarities; that the higher the rank of coal the greater the prevalence of chest X-ray abnormality; and that underground coal-getters are the occupational group most at risk. There is now, therefore, for the first time a pneumoconiosis prevalence map for the coalfields. Apart from this, the work has confirmed what was known or strongly suspected already, and the authors reasonably look forward to concentrating the survey in the future, in an attempt to answer the 'why' rather than the 'what' of the problem.

This is a clearly presented document with 31 tables of data in the body of the report, as well as many more in the appendixes, in which there are also 23 well-drawn coloured charts.

As a source-book of data on dust disease in British coalmines it is a *sine qua non*. R. C. BROWNE

SCIENCE IN THE PACIFIC

SPONSORED by the National Science Foundation (Washington, D.C.), a new series of *International Science Information Studies* examines the main scientific publications, research facilities and information services of selected countries of the world. The first three volumes have been written by Mr. John O. Sutter and are devoted to four Pacific nations, namely, the Republic of Indonesia, the Federation of Malaya, the State of Singapore, and the Republic of Viet-Nam*.

The object of the series is to help in overcoming some of the obstacles to communication between scientists brought about by distance, language and different cultural patterns Each volume starts with a brief account of the geographic, political and economic background of the area and then describes the facilities available for education in science, concluding with an account of scientific research and information activities in the country. In appendixes, factual information is given about research institutes, libraries, translation services and scientific publications.

Mr. Sutter's investigations show that in Malaya and Singapore there are forty-four scientific or semi-scientific serial or periodical publications, ranging in content from descriptions of original research to material of a popular science type. In the Republic of Viet-Nam, there are relatively few periodicals of a scientific nature, though French-established institutes publish articles on oceanography, medicine (Pasteur) and rubber research. In Indonesia, there is an ever-increasing flow of publications, some of which contain papers on original research. Before the Second World War these were in Dutch, but now they are in Indonesian with some articles in English or with English summaries.

POSSIBLE MECHANISM OF OLFACTION

By DR. ANDREW DRAVNIEKS

Armour Research Foundation of Illinois Institute of Technology, Chicago

OLFACTORY receptors detect the presence of 10^5–10^7 molecules of certain odorivectors per cm.^{3} of air, discriminate between small differences in the molecular structures of these odorivectors, and convey the observations to the nerves in the form of electrical potential pulses several tens of mV. strong. Such action may be possible by a selective utilization of dispersion (London–van der Waals) forces, together with some dipole interactions, in absorption on ferroelectric substrates. Circumstantial evidence may be enumerated.

Relative rapidity of appearance and disappearance of the olfactory sensation leads to the conclusion, from estimates by the absolute rate theory, that the energies of adsorption must be in the range of 5–15 kcal. and that the activation energy must be not more than a few kcal. From a typical isotherm[1], only low coverages ($\ll 0{\cdot}01$) can result on a receptor surface. Even if every adsorbed molecule would produce a dipole change of 2–4 Debye, much higher than thus far observed[2], the resultant surface potential change would be only a fraction of a mV.

However, an amplification of such change is possible on a ferroelectric substrate. Below the Curie point, and before a spontaneous polarization occurs, a mechanical strain exists in the ferroelectric lattice. If the odorivector molecules adsorb on a number of sites, the polarizing field of the permanent or induced dipoles of the osmophoric groups serves to nucleate the lattice shear. This triggers the ferroelectric transformation throughout the ferroelectric domain and results in a spontaneous polarization. The probability of triggering within a given time interval will be proportional to the number of the adsorbed molecules per domain. The resulting Barkhausen pulse[3] may serve as a source of a large signal to the olfactory nerve. The receptor may be restored to the non-ferroelectric lattice form periodically by a metabolic process, followed by a descent back into a strained state as the final preparation for a new pulse. The odorivector molecules may remain on the surface during all parts of the cycle, or else the ferroelectric shear transformation may destroy the specificity of the adsorption sites and cause a temporary decrease in coverage.

The indications that ferroelectric substances occur in organisms have been enumerated by Athestaedt[4]. Some of the more recently discovered ferroelectrics such as guanidine and glycine sulphates and thiourea approach organic structures. It appears likely that co-operative charge separation may occur in proteinic structures.

Inspection of the energy term in the adsorption isotherm[1] shows that a difference of 1–2 kcal. in the energy of adsorption may change the coverage and consequently the probability of triggering in the low-coverage range by a factor of 10–100. At a coverage below a certain threshold the pulses will be too infrequent or too indistinct. Above certain coverage the pulses may be too frequent to be transmitted by the nerves; this would occur also with substances that are adsorbed strongly and unspecifically, such as most molecules with a molecular weight above 300, which usually have no odour[5]. Thus, the selectivity may be based on a sensitivity of the proposed pulsing mechanism to a band of adsorption energies somewhere in the 5–15 kcal. range but by itself only 1–2 kcal. wide. With several receptors[6,7], each tuned to a different adsorption energy band, differentiation between odours becomes possible. Other sub-differentiation may be based on discrimination of the frequency of pulsing.

The energy of adsorption necessary to reach the required energy band may be collected from the dipole and the dispersion-type interactions. Here, many correlations pointed out by various olfactory theories fall in place at least qualitatively.

The bond dipole moments for the functional groups range between 1·4 and 3·5 Debye, and since they are located on the periphery of the molecule, they can interact strongly with the highly polarizable site of the ferroelectric substrate. Two point dipoles at a distance $r = 3$ Å. would interact with an energy of 4·5 kcal., and when the actual dimensions of the dipoles are commensurable with the separation distance, this value may be 50–100 per cent higher[8]. Thus, Müller's dipole theory[9] and various theories of the molecular shape[10-13] elaborated by Beets[14,15] in his profile-functional-group concept, all fall into proper perspective, since the stericity of the whole molecule determines the closest distance of approach between the molecule and receptor dipoles and also influences the effective moment of the functional group.

On the other hand, the critical additional increments in the adsorption energy, to shift its value into the pulse-stimulating band, can be supplied by the frequency-sensitive dispersion forces[16]. This provides a link to the phenomenological aspects of the vibrational theories. Wright's[17,18] objections that Dyson's[19-21] osmic frequencies are energetically implausible would not apply in utilization of these vibrators—together with the interactions of dispersion electrons—for generation of additional attractive energy between the odorivector and the oscillators in the receptor surface. Even if the oscillators are at the lowest quantum-level, they possess a zero-energy $1/2h\nu$ and are considered responsible for the van der Waals interactions in solid lattices[22]. Since the dispersion interactions are additive, with the energy proportional to r^{-6}, many of the oscillators in the odorivector will contribute to the total adsorption energy, but those located in the peripheral functional groups would contribute most significantly. Hence some but not consistent[23] correlation between Raman spectra and the odour; in some cases the dispersion interaction caused by the osmic frequency vibrator may not be critical in shifting the adsorption energy into the specific band. London[24] has given mathematical framework for adsorption by dispersion forces for the case of a spherical molecule and an infinite surface with a quasi-continuous arrangement of oscillators. For explanation of the specificity in olfactory adsorption this simple picture must be elaborated by consideration of interactions between specific oscillators in molecules of a complex shape and distinguishable specific oscillators in the receptor surface; probably even the directions of oscillations must be considered.

It is possible that some receptors may utilize hydrogen bonding[25] as one of the sources of adsorption energy.

Even Zwaardemaker's findings[26] on generation of spray electricity by solution of odorivectors tie loosely into the picture of the dispersion-force adsorption, since the ionization energies of adsorbed molecules enter a form of London's equation[24]; but on the other hand, co-determine the ease of charge separation in rupturing the double layer at surface on which the molecules are adsorbed.

Thus we propose that ferroelectric receptor surfaces cycled through the spontaneous polarization threshold may serve as transducers for a selective sorting-out of adsorbable odorivectors. The energy of adsorption would determine the delay and consequently the frequency of the Barkhausen pulses if the act of depolarization by an outside energy source is fast enough. The odorivectors will be recognized principally by the pulse frequency. In olfaction, similar mechanism coupled to transmitting nerves responsive only to a limited range of frequencies may be functioning.

I am attempting to demonstrate experimentally the relation between the adsorption and the ferroelectric effects in inorganic systems.

THERMAL EXPANSION MEASUREMENTS ON GRAPHITE–BROMINE COMPOUNDS

By J. E. BROCKLEHURST

United Kingdom Atomic Energy Authority, Reactor Materials Laboratory, Culcheth, Warrington, Lancs.

LARGE increases in the thermal expansion coefficient of graphite have been observed on the addition of small quantities of bromine. When graphite is exposed to an atmosphere containing bromine vapour at room temperature, lamellar graphite–bromine compounds are formed. Bromine enters the graphite lattice by diffusion between the layer planes, and under given pressure–temperature conditions, the limiting composition is dependent on the degree of perfection of the graphite structure. Changes in both single crystal and bulk graphite dimensions on bromination are reported in the literature. X-ray analysis of the limiting composition of near-perfect crystals[1] shows a large increase in the *c* dimension of the graphite structure due to the presence of bromine layers between the graphite layer planes. The increase in bulk graphite dimensions has been determined with varying bromine content[2]. The contribution of the *c*-axis expansion to that of the bulk polycrystalline graphite in any given direction will depend on the orientation of the crystallites and the amount of microporosity reducing the effect of the single crystal expansion.

Desorption at room temperature by removal of the bromine atmosphere leaves a residual bromine content. These residual compounds have been observed by several authors, and are discussed by Ubbelohde and Lewis[3]. The bromine may be held by normal lamellar bonding with outward diffusion paths blocked, or at defects in the graphite structure. This article presents results on the effect of this residual bromine on the thermal expansion of a number of graphite specimens.

The effect was observed on two types of artificial extruded graphites, *A* and *B*, differing in their orientation characteristics and basic raw materials, but graphitized at very similar temperatures. Thermal expansion measurements were made in a silica dilatometer over the range room temperature to 700° C. on specimens cut parallel and perpendicular to the extrusion axis. The specimens were suspended from a calibrated quartz spring for brominating, and length and weight increases were followed with a cathetometer. Table 1 shows the maximum values of strain and bromine composition (atomic ratio Br/C × 100) for the initial bromination of these specimens, and the effect of heat treatments on the residual compound obtained after allowing the brominated

specimens to stand in air at room temperature for several days. The residual bromine content was found to be only partially removed on heating to 700° C. under vacuum.

Thermal expansion measurements on the brominated specimens (Figs. 1 and 2) show a large increase over the virgin sample even below 300° C., but above this temperature, the thermal expansion-rate increases rapidly to a much higher value. The length returns to about the original (residual) value on cooling, and repeat runs show a lower expansion coefficient together with some loss of bromine.

Measurements were also made on a specimen of a pressed natural graphite compact cut parallel to the pressing direction and containing a small quantity of residual bromine. This material is of high density and well orientated, giving a high contribution of the *c*-axis in the parallel direction. It should therefore give a good indication of single crystal behaviour. There was no significant change in thermal expansion coefficient up to about 300° C. (Fig. 3), but a rapid increase was again observed above this temperature. No prior heat treatment was given to this specimen after bromination and a large fraction of the bromine content was removed during the first thermal expansion run. A second run showed the same characteristics as the first with a lower expansion rate above 300° C.

The results from the natural compact show that below 300° C., the thermal expansion coefficient of the residual bromine compound is the same as that of graphite when the bromine concentration is low. Above 300° C. the thermal expansion coefficient of the bromine compound is higher than that of natural graphite, and increases with bromine concentration.

The thermal expansion coefficients of the artificial graphite residual compounds are higher than those of the original graphites even below 300° C. Helium density measurements show that the artificial graphites contain closed porosity, whereas the natural graphite does not. It is this porosity which accommodates part of the *c*-axis expansion, thus making the volume thermal expansion coefficient of the artefacts much less than that of a single graphite crystal. However, in the bromine residue compounds formed from the artificial graphites, the *c*-axis has expanded and closed some of the microporosity. It is considered that the closure of this porosity makes the artificial

Table 2. Comparison of Volume Thermal Expansion Coefficients of Natural Graphite Crystals and Artificial Graphite Residual Bromine Compounds

Graphite	Volume expansion coefficient ($\times 10^6$) (500°–600° C.)
A (residue compound)	240–330
B (residue compound)	180
Single crystal (ref. 4)	29

graphite–bromine compounds less able to accommodate further thermally induced *c*-axis expansion, and this is at least partially responsible for the higher thermal expansion coefficients observed in these compounds below 300° C. Above 300° C., as in the case of the natural compact, the thermal expansion coefficients of the artificial graphite residual compounds are much larger than that of a normal graphite crystal, and increase with bromine concentration.

This fact is well illustrated in Table 2, where mean volume thermal expansion coefficients of the artificial graphite–bromine compounds, over the temperature range 500°–600° C., are compared with that of a single graphite crystal using the data of Nelson and Riley[4].

One further point emerges from Table 2 and the data presented in Figs. 1 and 2. The volume thermal expansion coefficient of graphite *B* is higher than that of graphite *A*, yet the volume thermal expansion coefficients of the residual bromine compounds of graphite *A* are higher than that of compound *B* when the two types of graphite contain similar quantities of bromine. This indicates that the residual bromine compounds formed in the two artificial graphites are not identical.

ROLE OF *OLPIDIUM* IN THE TRANSMISSION OF BIG VEIN DISEASE OF LETTUCE

By Dr. J. A. TOMLINSON and R. G. GARRETT

National Vegetable Research Station, Wellesbourne, Warwick

THE symptoms of big vein (yellow vein banding, sometimes with leaf puckering) are similar to those commonly associated with certain types of plant virus infection. Probably mainly because of the symptoms and since the disease was known to be soil-borne it was formerly thought to be caused by a soil-borne virus[1]. Numerous attempts have been made to isolate viruses from the roots of infected plants, but the only one frequently isolated was tobacco necrosis virus[2–4], which consistently failed to induce big vein symptoms when inoculated into healthy plants. Tests of mechanical transmission with leaf sap[5] and transmissions by aphids[6] and eelworms[5] were also negative.

In 1958, it was found[7,8] that the roots of big vein affected plants were invariably infected with a species of *Olpidium* and that zoospores of the fungus taken from such plants would induce the disease if they infected the roots of healthy plants. These investigations suggested that root infection by the fungus was the sole cause of the disease. Many workers have doubted this, however, because the fungus is confined to the surface cells of the roots and because the leaf symptoms are unlike those normally associated with *Olpidium* infection (stunting and wilting of the plants —usually slight[9], but occasionally severe[10]).

New evidence that the cause of big vein was of a virus-like nature was obtained when the disease was transmitted by grafting the tops of plants together in the absence of root infection by *Olpidium*[11,12]. It has also been reported[11] that Haeske[13] obtained transmission with *Cuscuta gronovii* Willd.

Further evidence is now presented that this virus-like causal agent is introduced into the plants by the fungus.

The investigation became possible when an *Olpidium*, indistinguishable in morphology and extent of root invasion from that present in the roots of big vein affected plants, was found in the roots of normal lettuce plants growing at this Station. In numerous serial transfers to healthy lettuce the fungus consistently failed to induce big vein. It was accordingly used in two experiments to determine the role of *Olpidium* in the transmission of the disease. This was done by culturing it for three weeks in the roots of plants affected with big vein, but originally having no *Olpidium* in their roots, and then transferring it to other lettuce plants on which the occurrence of big-vein symptoms could be assessed. Details of the experiments are as follows.

In one experiment, nodal cuttings were rooted from the stems of a wild *Lactuca* sp. (U.S. Department of Agriculture Plant Introduction Service No. 177418) and grown in pots of autoclaved soil. Twelve of them were taken from plants showing big vein symptoms and 8 were from healthy plants, and none had *Olpidium* in their roots. A 'healthy' isolate of *Olpidium* was inoculated into the roots of these plants by pouring on the soil a zoospore suspension obtained by immersing in water the roots of a healthy *Lactuca* plant infected with such an isolate (treatment 1). Similar cuttings, 12 with big vein and 8 healthy, were kept as controls and were not inoculated with *Olpidium*, and the roots of 8 further healthy cuttings were inoculated with zoospores of a 'big vein' *Olpidium* isolate (that is, one known to induce big vein symptoms). Precautions were taken against chance infection with *Olpidium*.

After 3 weeks each of the 48 cuttings in the experiment was removed from its pot and its roots were examined for the presence of *Olpidium*. The fungus was present only in the inoculated roots. Several 2-cm. portions from the root system of each plant were then detached, washed free from soil and placed in a vial of tap water for 10 min. Zoospores were released from the inoculated roots. All the roots were then removed and five 10-day-old *Lactuca* seedlings were stood in each vial for 24 hr. The seedlings were then grown in autoclaved soil for 10 weeks and examined for root infection by *Olpidium* and for the presence of big vein symptoms on their

Table 1. TRANSMISSION OF BIG VEIN BY *Olpidium* CULTURED IN THE ROOTS OF AFFECTED PLANTS

Treatment No.	Derivation of suspensions: Type of *Olpidium*	Derivation of suspensions: Status of culture plant	No. of test seedlings	Effect on seedlings: With *Olpidium* infection: No. with big vein	With *Olpidium* infection: No. without big vein	Without *Olpidium* infection: No. with big vein	Without *Olpidium* infection: No. without big vein

5	'Big vein'	Healthy	27	24	0	0	3

* Infection from 8/12 separate suspensions

leaves. The results of these observations are shown in Table 1.

The result of treatment 1 shows that the zoospores liberated from the roots of the culture plants showing big vein transmitted the disease to 21/25 of the seedlings they infected. These zoospores, however, had arisen from a fungus which, when inoculated into the culture plants 3 weeks previously, would not transmit big vein and which still would not transmit the disease after being cultured in the roots of healthy cuttings (treatment 2). The result of treatment 3 shows that transmission from the roots of big vein affected plants did not occur in the absence of *Olpidium*.

The design of another experiment was similar to that of the first, but plants showing big vein were obtained by grafting scions from *Lactuca* plants affected with big vein on to healthy *Lactuca* stocks, which then developed leaf symptoms of the disease. Similar plants grafted with healthy scions were used as controls. Eight weeks elapsed between grafting and the inoculation of the plants with *Olpidium*. The results of this experiment are shown in Table 2.

The results of treatment 1 are much less conclusive than those of the corresponding treatment in the first experiment, but some transmission was obtained. It is thus apparent that the graft-transmissible causal agent of big vein was also transmitted by *Olpidium*. It is thought likely that the difference between the two results is related to the fact that when cuttings from big vein plants were used the roots developed from infected tissue, whereas most of the roots of the grafted plants developed while the plants were healthy. The proportion of roots from which the disease could be transmitted may therefore have been low.

Table 2. TRANSMISSION OF BIG VEIN BY *Olpidium* CULTURED IN THE ROOTS OF AFFECTED GRAFTED PLANTS

Treatment No.	Derivation of suspensions: Type of *Olpidium*	Derivation of suspensions: Status of grafted culture plant	No. of test seedlings	Effect on seedlings: With *Olpidium* infection: No. with big vein	With *Olpidium* infection: No. without big vein	Without *Olpidium* infection: No. with big vein	Without *Olpidium* infection: No. without big vein

2	'Healthy'	Healthy	15	0	15	0	0
3	Nil	Big vein	24	0	0	0	24
4	Nil	Healthy	21	0	0	0	21
5	'Big vein'	Healthy	27	18	0	0	9

* Infection from 2/5 separate suspensions.

To test for the presence of tobacco necrosis virus the primary leaves of young cowpea plants were inoculated with macerates of the roots of samples of plants from every treatment (except No. 4) in both experiments (total 27 plants). All these inoculations were negative.

Several explanations of the observed results are possible, but it is considered likely that the graft-transmissible agent of big vein (possibly a virus) was carried by the zoospores of *Olpidium*, either externally or internally, from the infected roots of the culture plants to the healthy roots of the test plants. The fact that the roots of the culture plants and the *Olpidium* zoospores released by them were in the test suspensions at the same time makes it possible, however, that the roots exuded the infectious agent into the water and the subsequent *Olpidium* invasion of the roots of the test plants provided entry points for the infectious agent. Teakle[14] has reported that the entry of tobacco necrosis virus into lettuce roots may be facilitated by the concurrent invasion of the roots by *Olpidium*. In our opinion, however, the tobacco necrosis virus is not the causal agent of big vein. Further experiments are in progress to determine the exact mode of transmission of the disease.

A CONSTANT PATTERN OF GROWTH IN YOUNG APPLE TREES

By D. H. MAGGS

East Malling Research Station, Kent

HATTON[1] has described the rootstock effect in apples where, by using suitable rootstocks, trees of the same scion variety may be produced which differ up to ten-fold in their annual increments and four-fold in accumulated crop[2]. A similar, though smaller, scion effect may be produced by growing a range of scion varieties on a single rootstock variety[3]. Because of the wide range of possible experimental effects, such material is suitable for analysing the growth (in a broad sense) of woody species[4]. In such species the large and always increasing woody skeleton presents a complicating factor not encountered with annual or herbaceous crops, for its growth may account for more than 50 per cent of the annual increment[5]. The pattern of growth of the successive annual growth regions of this skeleton is obviously an important consideration in determining the most efficient form of tree for fruit production. and also in

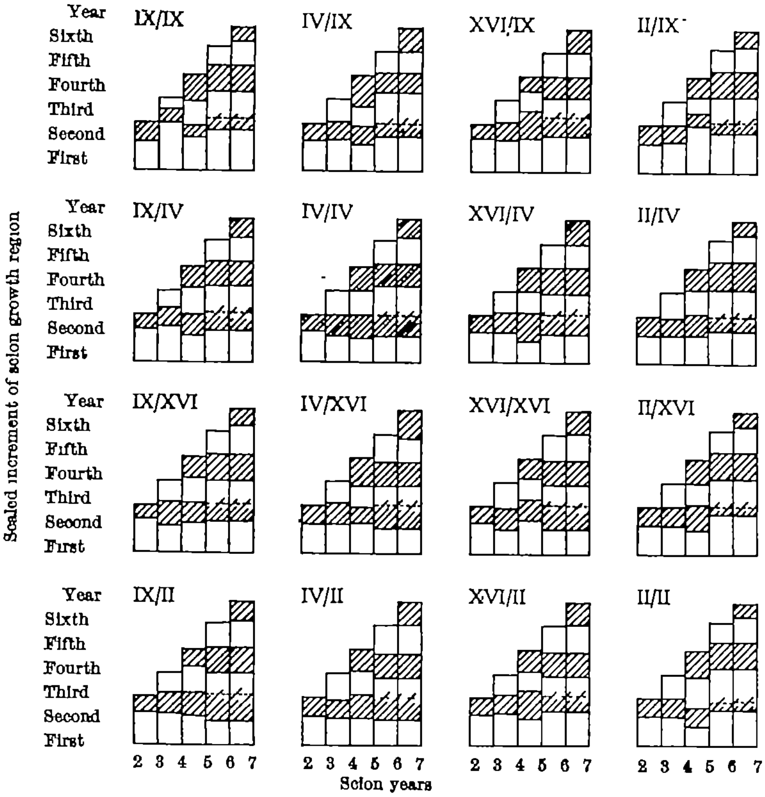

Fig. 1. The distribution of increment to the growth regions for each of the 16 rootstock/scion combinations. The combinations are indicated by Roman numerals, those in the rows having the same rootstock and in the columns the same scions.

crops where the skeleton itself forms the main economic product such as timber and various bark crops. Duff *et al.*[6], in their interesting analyses of 'pattern' and 'configuration' in *Pinus resinosa*, have suggested how external and intrinsic factors interact to determine the amount of cambial activity at a given site, but the fraction of the total increment involved in each region cannot be estimated from their data.

The term 'annual growth region' may be clarified by the following example: in a ten-year-old tree all the current extending shoots form the tenth-year annual growth region, and the total annual woody increment is made up of the extension and thickening of this tenth-year annual growth region plus the tenth-year's thickening on the ninth-, eighth- . . . first-year growth regions. It follows that there are as many of these growth regions as there are years of tree growth. The increments of each region can be determined by the difference between samples of trees analysed at the beginning and end of the growing season. Thus, although the determination of the pattern of growth increments to the woody regions of the tree is not difficult in theory, it does not appear to have been previously attempted, probably because of the length of time required and failure to realize the experimental potentialities of clonally propagated rootstocks. I report in this article a result from such an experiment.

The experiment has already been described in detail[7]; briefly, its main part consisted of adequately replicated plantings of the sixteen rootstock-scion combinations formed by grafting together in pairs the four apple rootstock varieties *M*.II, *M*.IV, *M*.IX and *M*.XVI, used both as rootstocks and as scions. Of these varieties, *M*.IX is slow growing and, as a rootstock, dwarfing, and *M*.XVI is fast growing and invigorating; the other two are intermediate, *M*.II approaching or even surpassing *M*.XVI but maturing to a smaller tree. The experiment lasted seven years, during which time fifteen sets of samples were dug up for the determination of the dry weights of the parts. Replication was six-fold at each sampling. Since the first year's scion growth was complicated by the removal of the rootstock's shoot system, only the five-year period from the end of the first-year's scion growth to the final harvest will be considered. To avoid excessive soil disturbance in the later samplings, root weights were then estimated from sub-samples of certain treatments. Pending a closer analysis of this estimation, root weights have been omitted, and the data refer to scions only.

The total increase in scion dry weight from the second to seventh year of scion growth is given in Table 1. It will be noticed that the heaviest treatment weighed eight times as much as the lightest, and that differences between rootstocks were more marked and consistent than between scions. The differences between treatments were initiated early in the experiment and augmented gradually by similar differences from year to year without any consistent interaction of rootstock and scion variety.

To compare the distribution of the increment of one combination with that of another, some form of scaling must be used, and for this the annual growth region is taken as the unit. For example, the woody increment during the second year of scion growth can occur on two growth regions—the second-year extension shoots and the thickening of the first-year's shoots. The woody increment is therefore scaled to two units, and the two components adjusted proportionally to their weights to add up to this; the distributions for other periods are calculated similarly. The scaled increments for the individual combinations for each period are given in Fig. 1. No samples were taken between the fourth and sixth years, and in order to compute the distribution over that period, the increment for the two-year period was scaled to eleven units (5 + 6), 2/11 being assigned to each of the first five growth regions and 1/11 to the sixth, since it was only present for one year. It was not possible to separate satisfactorily the second and third year growth regions at the final sample, and in the diagrams the separation between them for the final interval has been indicated as the average of the first three intervals.

Table 1. INCREASE IN SCION DRY WEIGHT (KGM.) 2ND–7TH YEAR OF SCION GROWTH

Rootstock	Scion *M*.IX	*M*.IV	*M*.XVI	*M*.II	Rootstock mean
M.IX	0·8	1·4	0·9	1·2	1·08
M.IV	2·0	5·2	3·4	4·5	3·78
M.XVI	2·3	3·5	3·8	4·8	3·60
M.II	3·6	4·5	6·1	6·7	5·23
Scion mean	2 18	3 65	3·55	4·30	3·42

The most remarkable features of the results are the similarity of the patterns for all treatments, despite the large differences in absolute increment, and the uniformity of the distribution from year to year. The larger fraction received by the first-year region and the smaller by the second can be explained as the response to pruning the rootstock shoots just prior to the outgrowth of the first-year scion shoot; the result of this was that this shoot made extra growth[8], resulting in a permanent increase in the cambial surface for that region. In the second year the extension growth was perforce proportionately less, but it is noteworthy that these proportions were generally maintained in subsequent years.

The constancy of the pattern from year to year, despite differences in season, indicates a close relation between extension growth and cambial activity. The relation is likely to be complex, depending itself on the relations between growth-rate and taper of the individual shoots, lengths and number of shoots in successive years, and the thickening of successively older regions. Data bearing on these points are now being examined. These results covered only the first seven years of growth, and it cannot be assumed that the constant distribution will apply throughout the life-cycle of the three.

A SPERM FACTOR AFFECTING THE RECEPTIVITY OF *DROSOPHILA MELANOGASTER* FEMALES

By AUBREY MANNING

Department of Zoology, University of Edinburgh

ONCE a virgin female *Drosophila* has mated she is usually unwilling to accept another male for some time. The length of this refractory period varies between species and probably between different strains of the same species. Smith[1] has shown that *D. subobscura* females rarely mate a second time, and has partly analysed the mechanism behind the change from receptive virgin to unreceptive fertilized female. He finds that the act of copulation itself prevents further mating for a period of 4–24 hr., but females become receptive again unless the copulation has provided them with sperm. If they have been adequately inseminated they remain unreceptive for the rest of their lives, even after their supply of sperm has become exhausted by egg-laying. Thus, although some factor from the sperm 'switches off' the receptivity mechanism, the subsequent absence of sperm does not lead to its being switched on again.

Drosophila melanogaster females are known to re-mate rather readily. If left with males in small vials they will often mate again on the day following their first mating. However rape is quite common in this species, and such rapid re-mating probably does not mean that normal receptivity returns after one or two days. Accordingly, I have repeated some of Smith's analysis using *D. melanogaster*.

A large batch of virgin females was fertilized when 3 days old, by which age their ovaries are fully grown and they are at their peak of receptivity[2]. They were kept in groups of 25, each in a well-yeasted vial and were shaken into a fresh vial every day. Under such conditions they lay eggs abundantly and continuously for many days. On each day subsequent to fertilization a batch of 50 was tested for receptivity. They were shaken into a half-pint milk bottle with 50 males (always 4 or 5 days old) for a period of 30 min. and pairs were removed as they began to copulate. Males court very vigorously in the test bottle, but unreceptive females have more chance to avoid them than if confined in a vial.

As a kind of base-line, 3-day-old virgin females in the same test show 30–35 pairs mated within 5 min. and 40–45 within the whole 30-min. period. Table 1 shows the comparable figures at different times after fertilization. Measured in this way, receptivity is virtually zero for 4 days, but after this the number of females accepting males rises and 9 days after fertilization the population is once more as receptive as when it consisted of 3-day-old virgins.

Table 1. NUMBER OF FEMALES ACCEPTING MALES DURING A 30-MIN. TEST, 50 FLIES OF EACH SEX, ON SUCCESSIVE DAYS AFTER FERTILIZATION

Days after fertilization	1	2	3	4	5	6	7	8	9	10	11
No. ♀♀ mated within 5 min.	0	0	2	2	5	7	10	22	32	31	28
No. ♀♀ mated within 30 min.	0	0	2	2	16	26	21	36	37	43	40

This recovery of receptivity is unlikely to be due to any ovarial changes. Throughout this period the ovaries remain in full production; gross examination reveals no change in size or composition and the females go on laying eggs without pause. Nor is it likely to be an effect of ageing so that, for example, flies go through cycles of receptiveness every 9 days. The receptivity of virgins gradually declines from their peak at 3 days and females do not inevitably become receptive 9 days after fertilization. I delayed the onset of egg-laying in females by keeping them on a diet of 1/5 *M* sucrose alone from soon after eclosion. Bodenstein[3] has shown that *melanogaster* females can mature a few eggs without access to protein as adults, but their ovaries remain very small and very few eggs are laid after fertilization. Such females when fertilized at 3 days old are just as receptive as normally fed flies, but they do not become receptive again after 9 days. They remain totally unreceptive for at least a fortnight, which was as long as observations were continued. Their receptivity returns after a week of normal diet with the accompanying rapid growth of the ovaries and onset of egg-laying.

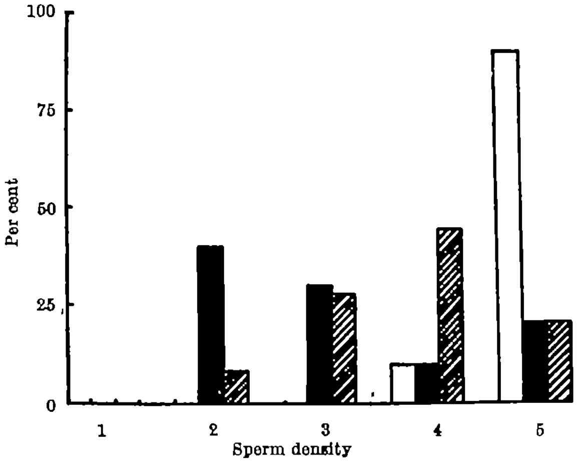

Fig. 1. Percentage of females, 6 days post fertilization, which have various densities of sperm remaining. Density ranges from 1, seminal receptacle full, to 5, empty. *A* (white), 10 ♀♀ which were receptive to ♂♂; *B* (black), 10 ♀♀ which were unreceptive; *C* (shaded), random sample of 25 ♀♀, also 6 days post fertilization

It is impossible to separate the effects of egg-laying from those of sperm-exhaustion, for they inevitably go together. Nevertheless, it is reasonable to suppose that, unlike *subobscura*, the receptivity of *melanogaster* females returns when that factor from the sperm which switched it off disappears when the sperm are all gone. As regards the switching-off mechanism, I have been able to confirm Smith's results and find that *melanogaster* females mated to males which cannot ejaculate sperm become receptive again within a day. Certainly, at the time when receptivity is returning to fertilized females, an increasing proportion of them prove, on dissection, to have used up all their sperm.

More direct support for this hypothesis was obtained by dissecting females after the daily receptivity tests and comparing the amounts of sperm remaining in those which mated quickly with that in females which remained unreceptive throughout. Even with the receptive females which do mate again, the original quantity of sperm which they held can be ascertained provided they are quickly separated from their second mates. No sperm is ejaculated during the first 10 min. of the 15–20-min. copulation period[4]. Only the seminal receptacle of females was examined, for the spermathecæ are often obscured by fat and sperm difficult to see. The sperm density was allocated to one of five grades, roughly estimated and ranging from 1, completely full, to 5, empty, with at most only a single sperm visible here and there.

Fig. 1 shows, as a typical example, the frequencies of the different grades of sperm density among females 6 days after fertilization. Three groups are distinguished : *A*, the first 10 females to accept males in the course of the 30-min. test, (they did so within about 6 min.); *B*, 10 females which remained unmated throughout ; *C*, a sample of 25 females the behaviour of which was not measured, also 6 days post-fertilization. It is clear that, compared with the random sample of females, a higher proportion of the receptive ones have exhausted their supply of sperm, while those that remain unmated tend to be those with most sperm left.

There are two ways by which insemination could lead to the receptivity mechanism being switched off, and sperm exhaustion lead to its being switched on again. The female's seminal receptacle is innervated[5], and the sperm may thus signal their presence because of the synchronized lashing movement which they maintain. Alternatively, some chemical may be produced, either by the sperm themselves or by their interaction with the female tissues, which operates via the hæmolymph on the nervous system. It is hoped to distinguish between these two possibilities by further experiment, but present evidence favours the chemical explanation. Fig. 1 shows that a few females which have exhausted their sperm are still not receptive, and the proportion of such cases rises with successive days, though the total number of unreceptive females gets less. This would suggest that a female does not become receptive immediately her supply of sperm is exhausted; it probably takes a day before the receptivity mechanism is switched on again. Changes due to neural factors alone usually happen quickly, but this delay is understandable if the concentration of some inhibitor chemical has to fall below a certain level. The measure used for the return of receptivity is rather crude, but it does not seem that the gradual depletion of her supply of sperm leads to a gradual increase in a female's receptiveness. She remains unreceptive, but then within about a day becomes fully receptive again. This suggests that if a chemical is produced, it is produced continuously and maintains an adequate concentration over quite a wide range of sperm density. It falls below the threshold concentration only when the supply of sperm is almost entirely exhausted.

GROWTH OF FOOT-AND-MOUTH DISEASE VIRUS IN A FIBROBLASTIC CELL LINE DERIVED FROM HAMSTER KIDNEYS

By G. N. MOWAT and W. G. CHAPMAN
Research Institute (Animal Virus Diseases), Pirbright, Surrey

THE use of cell lines for the growth and assay of the virus of foot-and-mouth disease has been limited. Schwobel and Siedentopf[1] described the cell line *ENS*.53, which was derived three years previously from pig kidney tissue. Satisfactory growth of virus was obtained, but cytopathic effects were absent unless high concentrations of virus were used. The authors stated that the cell line was, therefore, not suitable for the detection of small amounts of virus.

Thorne and Cartwright[2], working at this Institute, used the cell line developed by Stice (Cutter Laboratories, California) in experiments on the adsorption of virus. They found this line to be of low sensitivity for the virus strain which they studied. Other investigations at this Institute by Martin confirmed the low levels of sensitivity to other virus strains and Burrows, working with the two-hundredth passage, found that by this time the cell line was completely insensitive.

Attempts at this Institute to establish cell lines from pig kidney tissue have resulted so far in cells of fibroblastic appearance, which were insensitive to foot-and-mouth disease virus.

Recently, we have shown that a line originating from baby hamster kidney, designated *BHK* 21, is capable of supporting virus growth. These cells were isolated in the Institute of Virology, Glasgow, and have been described by Macpherson and Stoker[3].

For the experiments described, cells were grown as monolayer cultures in 4-oz. prescription bottles, Roux bottles and Petri dishes. The growth medium used was Eagle's basic medium, modified to contain twice the normal concentration of amino-acids and vitamins, plus 10 per cent autoclaved tryptose phosphate broth and 10 per cent unheated bovine serum. Following infection with foot-and-mouth disease virus, a cytopathic effect was observed similar to that seen with infected primary cultures of pig kidney cells. The cells became rounded and granular and detached from the glass surface. Infection with cattle-passaged virus produced a well-marked cytopathic effect in 24 hr., but destruction of the cell sheet was not complete in some experiments until approximately 72 hr. after infection. With virus adapted to pig kidney cells (204th passage) which was passaged 11 times through *BHK* 21 cells, cytopathic effect was observed 4 hr. after infection and the cell sheet was almost completely destroyed 4 hr. later.

The increase in virus concentration was followed in infected cultures from which unadsorbed virus had been removed and the cell sheet washed five times with phosphate-buffered saline. A sample of the medium was taken immediately (0 hr. sample) and further samples after convenient time-intervals. The virus was titrated in unweaned mice and the titre expressed as $\log_{10}$ mouse ID_{50}/ml. The results of a typical experiment are given in Table 1. The viruses used were: (*a*) a type *SAT* 1 attenuated vaccine strain (*RV*.11); modified by passage in mice, and (*b*) a type *C* strain adapted to pig kidney cells. Both viruses were produced in high titre, the cell sheets being almost completely destroyed after 72 hr. The results of a similar experiment comparing the growth of a type *SAT* 1 cattle strain of virus in primary cultures of pig kidney cells and *BHK* 21 cells are given in Table 2. Virus was produced more rapidly from pig kidney cells and the cell sheet was destroyed in less than 24 hr., whereas with *BHK* 21 cells, although the maximum titre was obtained 22 hr. later than with pig kidney cells, the yield of virus was apparently ten-fold greater. The *BHK* 21 cultures contained many more cells than the primary pig kidney cultures. It cannot be presumed that the higher yield of virus with these cells could be attributed to a greater number of cycles of virus multiplication until the results of a more detailed investigation of the quantitative aspects of the virus-cell system, now being undertaken, become available.

31	7·0	—
48	7·0	—

N.D., not detected.

The formation of plaques in an infected monolayer with an agar overlay has also been observed. Virus adapted to *BHK* 21 cells produced plaques of up to 7-mm diameter, 2 days after infection. Plaques have also been observed after infection of these cells with virus adapted to pig kidney cells, unmodified cattle virus and two strains adapted to mice. Virus titrations and neutralization tests of immune sera have also been made by means of cell metabolic inhibition tests with these cells. Owing to their rapid metabolism, results have been obtained after 3 days, which compares favourably with the 4–5-day period necessary with pig kidney cells.

These preliminary investigations with the *BHK* 21 cell line indicate that it will probably be of considerable value in foot-and-mouth disease research. This cell line has the desirable characteristics of rapid growth combined with the production of densely packed sheets of cells. Cultures grown in Roux bottles have yielded up to 1·5 × 10^8 cells, which is approximately five-fold more than might be expected from a similar culture of pig kidney cells. With strains of virus well adapted to these cells it should be possible to produce very high-titre virus preparations.

In addition to the use for virus assay purposes, it is likely that these cells will also be of value in the preparation of both inactivated and live attenuated virus vaccines. At present, live foot-and-mouth disease virus vaccines are prepared at this Institute from the tissues of unweaned mice infected with attenuated strains developed by serial passage in mice. If these mouse attenuated strains of virus could be grown in tissue culture, many of the problems associated with vaccine production would be overcome. So far, primary cultures of pig kidney cells have not proved satisfactory in that the virus titres produced were low. The results in Table 1 indicate that at least one virus strain modified by passage through mice can be grown in *BHK* 21 cells to titres acceptable for vaccine production ($10^{7.5}$ ID_{50}/ml.) without further adaptation to these cells.

Although it has been known since 1937 that hamsters are susceptible to foot-and-mouth disease there is no information on the cultivation of the virus in cells derived from hamster tissues.

Hayflick and Moorhead[4] have reported on the establishment of 25 strains of diploid fibroblasts derived from human fœtuses. These cell strains the development of adaptive behaviour in rats (descriptions in preparation).

The modified Aronson keyboard (Fig. 1) carries twenty typewriter keys individually connected to switches activating the Laupheimer converter. Devices to lock and to clear keys are provided.

The Laupheimer converter registers, accumulates and transmits pulses from the keyboard, or from switches activated by an animal, to a tape-punch. The pulses produce a single input-item, called a 'bit'. Thirty-six bits equal one 'data-word' (Fig. 2, top). The 36 bits of each word are accumulated in an appropriate binary register, transferred into a distribution (serialization) register, and transmitted to the punch at the rate of one, two or three words per second, thus producing a tape with serially punched words. 1–36 punches appear in any given word. A column of bits is called a 'character'. For compatibility with the IBM 1620 computer, the converter automatically inserts a 'parity' punch as needed so that each character contains an odd number of punches, and also automatically punches the thirty-sixth bit in each word to designate the end of that word.

A special switch (Fig. 1) permits the converter to record 'tagging' information (for example, the date, animal, group). From a Friden tape reader, the converter can receive pulses which it punches as tag words to record information about stimulus or time. Through a programmed tape in the reader, the converter can also stop the reader. A standard Friden, 8-channel, motorized punch, model No. 2, is used.

Atsl admits both a simple ordering of the data as to latencies, frequencies, durations, sequences and concomitances of behaviour items, and (by re-ordering measures of counts and intervals between items) the elucidation of complex relations among items. Statistical techniques can be programmed sequentially or simultaneously with the reduction of data. Data from the experiment for which *Atsl* was developed[5] have thus been prepared for publication.

Atsl permits investigation of many aspects of behaviour simultaneously, both by concurrently recording animal-generated and observer-generated data and by increasing the number of recorded items. A complete list of behavioural items of empirically proved significance can thus be obtained as a valuable basis for the specialized investigation of selected independent and dependent variables of such important behavioural phenomena as animal orientation, motivation and development.

This work was supported by grants Nos. *M*–1441 (*C*1 and *C*2) of the National Institute of Mental Health and by the Council Research Fund of the American Museum of Natural History.

We thank Dr. Wolf Helmreich of IBM and Mr. Ken King of the Watson Laboratory for their co-operation.

MECHANISMS OF NON-DISJUNCTION IN MAN

By JOHN S. S. STEWART

Department of Surgery, Queen's College, Dundee

SINCE my previous communication[1], further advances in human cytogenetics have provided information about mechanisms of non-disjunction in man.

Primary Meiotic Non-Disjunction

Types of Primary Meiotic Non-Disjunction. Meiotic non-disjunction in a subject with a normal karyotype may be regarded as primary, and three types of primary meiotic non-disjunction may be recognized. The term 'non-disjunction' is used to describe the abnormal behaviour of sex chromosomes during meiosis although the cause may be non-conjunction or failure of pairing rather than failure of separation of chromosomes or chromatids.

Simple non-disjunction. Simple non-disjunction during the first or second meiotic division of oogenesis may give exceptional gametes of nullo-X- or XX-bearing oocytes and hence abnormal zygotes of XO, YO, XXX or XXY sex chromosome constitution. Similarly, simple non-disjunction during spermatogenesis may give exceptional gametes of nullo-X- (sperm with no sex chromosome, either X or Y), XY-, XX- or YY-bearing sperm and hence abnormal zygotes of XO, XXY, XXX or XYY sex chromosome constitution.

Double non-disjunction. Double non-disjunction, consisting of simple non-disjunction both in the male and in the female, may therefore give abnormal zygotes of OO, YY, $XXXY$, $XXXX$ or $XXYY$ sex chromosome constitution.

Successive non-disjunction. Successive non-disjunction during consecutive meiotic divisions of oogenesis may give new types of exceptional gametes: XXX- and $XXXX$-bearing oocytes and hence $XXXY$, $XXXXY$, $XXXX$ and $XXXXX$ zygotes. Similarly successive non-disjunction during spermatogenesis may give XXY- XYY- or $XXYY$-bearing sperm with $XXXY$, $XXYY$, or $XXXYY$ zygotes. Several types of normal and abnormal zygotes are thus possible in consequence of non-disjunction at one or other or both meiotic divisions of oogenesis, of spermatogenesis, or of both together (Table 1).

Investigation of Primary Meiotic Non-Disjunction. Reported examples of heteroploidy in man include cases with sex chromosome constitution XXY[2–5], XO[6,8,9], $XXYY$[10], and $XXXXY$[11,12]. The XO and XXY karyotypes together with colour blindness

Table 1. POSSIBLE GAMETES AND ZYGOTES WHICH MAY RESULT FROM NORMAL AND ABNORMAL BEHAVIOUR OF THE SEX CHROMOSOMES AT ONE OR BOTH MEIOTIC DIVISIONS OF OOGENESIS OR SPERMATOGENESIS OR BOTH

Female gametes	Male gametes								
	O	X	Y	XY	XX	YY	XXY	XYY	$XXYY$

THE *ATSL*: AN OBSERVER-TO-COMPUTER SYSTEM FOR A MULTIVARIATE APPROACH TO BEHAVIOURAL STUDY

By Dr. E. TOBACH, Dr. T. C. SCHNEIRLA and Dr. L. R. ARONSON
Department of Animal Behavior, American Museum of Natural History, New York
AND
R. LAUPHEIMER
Institute of Mathematical Sciences, New York University

MOST techniques for the analytical study of behaviour are restrictive in the number and aspects of items studied. The animal's whole behaviour should be appraised, for under different conditions not only the behavioural items but also their significance, priority and interrelations change. To permit such an appraisal, the Aronson keyboard was devised in our laboratory[1].

This keyboard consists of a bank of microswitches, each microswitch representing one behavioural item and wired to a pen on an operations recorder. Thus, a trained observer can record as many as forty items while continuously viewing the subject[1]. Although this improves the scope and efficiency of data-collection and recording, analysis of records is time-consuming.

Accordingly, beginning in 1956, the possible modifications were investigated. One result was the development of the Laupheimer converter, which couples the keyboard to a standard tape-punch to produce a paper-tape usable in the IBM 1620 computer. The modified Aronson keyboard, the Laupheimer converter, a paper-tape punch and a computer comprise the data-collection and recording system which we term the *Atsl*. The data obtained through *Atsl* can be processed by a digital computer with appropriate programming, and *Atsl* can be used in any behavioural experiment, utilizing either observer-generated or animal-generated data or both. (At the Institute of Animal Behavior, Rutgers University (director, D. S. Lehrman) a modified version of *Atsl* is in use.) Fig. 1 shows the Aronson keyboard and the Laupheimer converter, two of the components of *Atsl*, as devised and constructed for a project investigating

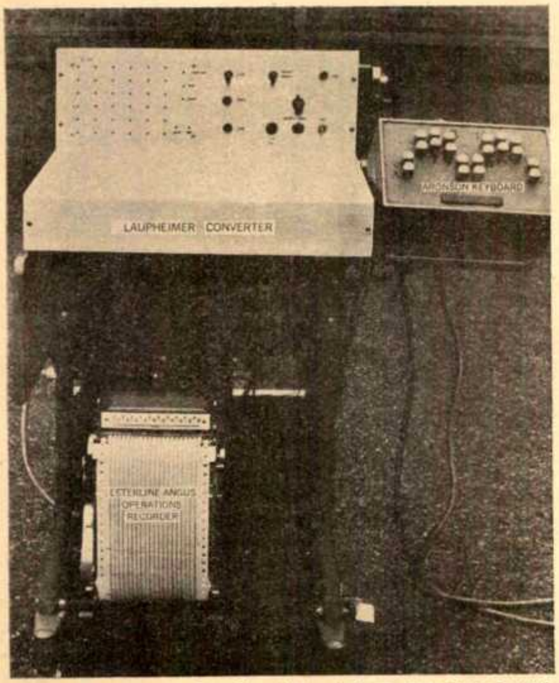

Fig. 1. Aronson keyboard and Laupheimer converter of *Atsl*. The operations-recorder is optional

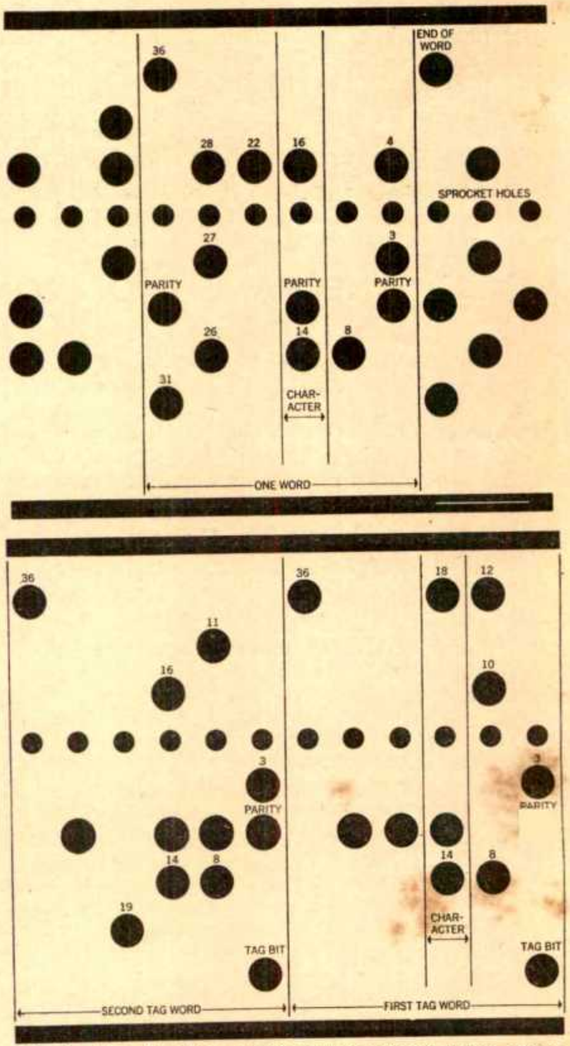

Fig. 2. Top, data-tape showing bits (numbered holes), parity bits and end-of-word bit. Characters are punched seriatim. The first 3½ characters represent observer-generated data for one animal: bit 3, stimulus; bits 4, 8, location; bit 14, 'nosing'; bit 16, 'rising'. The remaining 2½ characters represent animal-generated data from another animal in a respiration chamber; bit 22, consumption of 1 c.c. of oxygen; bits 26, 27, 28, 31, animal's location. Bottom, tag words. The first word gives the date, May (bits 10, 12), 17 (bits 14, 18), 1961 (bit 8). The second tag word gives the time of observation

Fig. 2. The entry ('piggy-back') of fluorescent-labelled rabbit γ-globulin into guinea pig polymorphonuclear leucocytes at rest and during phagocytosis. *A*, resting cells, no particles present; *B*, polystyrene spherules introduced at zero time. Experiment terminated 45 min. later. (Approximate magnification, × 380)

after the equilibration period. In the case of the starch experiments, autologous serum was added to the leucocyte suspension. The ratio of starch or polystyrene particles to leucocytes was in the order of 10 : 1.

It has been reported by McKinley *et al.*[6] that malonate will inhibit the respiratory activity of leucocytic homogenates while it will not affect the respiratory activity of intact leucocytes. The inability of malonate to suppress intact leucocytic respiration has been attributed to its failure to permeate the cell. Thus, the effect of three different concentrations of malonate on leukæmic leucocytes in the absence and presence of particles was studied and is shown in Fig. 1. Leucocytic respiration in the absence of particles is essentially unaffected. However, in the presence of particles the increased respiratory activity associated with phagocytosis is completely inhibited with 10^{-1} *M* malonate. At lower concentrations of malonate the inhibition is evident but to a lesser degree. Pre-incubation of leucocytes with malonate, before addition of particles, followed by washing of the cells to remove exogenous inhibitor, resulted in increased oxidation normally associated with phagocytosis. This further indicates that the malonate does not penetrate in the absence of particles.

Fluorescent-labelled rabbit γ-globulin was found to be present in cells only to a slight degree after incubation with guinea pig polymorphonuclear leucocytes and was thus used in order to obtain visual evidence for the 'piggy-back' phenomenon. The fluorescent material was added with the polystyrene spherules to the leucocyte suspension. Controls lacking particles were run simultaneously. After a 45-min. incubation period, the contents of the flask were removed, washed twice, and aliquots were placed on slides to air dry. They were then examined for fluorescence using ultra-violet microscopy.

The marked increase in fluorescence observed following the addition of fluorescent rabbit γ-globulin to phagocytizing cells is shown in Fig. 2*B*. The almost complete absence of fluorescence in the non-phagocytizing leucocytes can be seen in Fig. 2*A*. The fluorescent material did not enter the cell by coating the polystyrene spherule as we have been unable to show fluorescence surrounding or associated with the spherule after their incubation with only the fluorescent γ-globulin and subsequent washing and examination for fluorescence.

The possibility that malonate is not entering the cell in a 'piggy-back' fashion along with the particle, but instead acting on or near the cell surface, is of course realized. However, the indication that phagocytizing cells are able to concentrate fluorescent-labelled γ-globulin whereas non-phagocytizing cells are not, suggests that both markers are entering the cells along with the particle in the same membranous vesicle.

These observations, that malonate and fluorescent-labelled rabbit γ-globulin cannot enter a cell unless the cell is engulfing particulate material, are of interest. The evidence suggests that these substances do not enter a cell to any marked degree unless the cell is ingesting particles. Presumably the material is entering the cell along with the particle within the membranous vesicle surrounding the particles; the membrane is then thought to disintegrate releasing the particle and material. Thus, material, initially impermeable, can gain entrance to the cytoplasm with the particulate substance. This phenomenon may offer a new approach in permeability studies and may provide information concerning the nature of the cell membrane.

Further, this 'piggy-back' phagocytosis may offer an additional dimension in the field of chemotherapy. Agents unable to enter a cell can be made to do so and perhaps exert a chemotherapeutic effect that ordinarily would not be possible due to impermeability.

This work was supported by research grants from the National Science Foundation (*G*19531) and the National Institutes of Health (*C*5307 and *A*2168).

maintained their diploid karyotype for approximately 50 passages and showed a wide spectrum of sensitivity to different viruses similar to that of primary cultures[3] of the tissues of origin. Macpherson and Stoker have shown the *BHK* 21 cells to be diploid and it is possible that a situation analogous to that of the human diploid cell strains exists if primary cultures of baby hamster kidney cells are also shown to be sensitive to foot-and-mouth disease virus.

We have also examined a clone of *BHK* 21 cells (clone No. 13) received from Macpherson and Stoker which appears to be as sensitive to foot-and-mouth disease virus as the original sample of uncloned cells. All future investigations will be made with the cloned cells. Investigations are now proceeding into methods of large-scale cell production and the growth of high-titre virus.

We thank Prof. M. G. P. Stoker and Dr. I. A. Macpherson for suggesting and supplying the *BHK* 21 cells and also for much valuable information.

'PIGGY-BACK' PHAGOCYTOSIS

By Dr. A. J. SBARRA, Dr. W. SHIRLEY and W. A. BARDAWIL

Department of Pathology and Medical Research, St. Margaret's Hospital
and Tufts University Medical School, Boston 25, Mass.

ACTIVE transport, passive transport, phagocytosis or pinocytosis are terms used for describing different processes whereby substances are able to penetrate cells. In this communication we present evidence suggesting a new phenomenon for the entrance of impermeable compounds into cells. This mechanism of penetration appears to involve entrance with macromolecules and is referred to as the 'piggy-back' phenomenon[1,2]. Conceivably many agents, some potentially chemotherapeutic, are without effect because of their inability to enter a cell. Experiments have been designed to show that some substances which ordinarily would not enter a cell can be made to do so under phagocytic conditions.

Guinea pig polymorphonuclear leucocytes prepared according to the method of Sbarra and Karnovsky[3,4] and normal human and leukæmic leucocytes prepared by the method of Christlieb *et al.*[5] were used.

Guinea pigs weighing 300–400 gm., usually males, were injected with 15 ml. of a 12 per cent sterile suspension of sodium caseinate. 16–18 hr. later the peritoneal exudates were prepared by washing the peritoneal cavity with 40–50 ml. of saline. The cells were collected in 50-ml. celluloid tubes and centrifuged at 50*g* for 10 min. in the cold. They were then re-suspended in a desired volume of phosphate-free Krebs–Ringer solution. Aliquots were measured for total cellular phosphorus. Phosphorus determinations were found to be a more reliable measure of cellular protoplasm than the conventional counting methods (100γ of cellular phosphorus represents 5·53 × 10⁷ cells[3]). Phosphate buffer was now added to yield a suspension of cells in the usual Krebs–Ringer phosphate medium buffered at *p*H 7·4.

Human leucocytes were obtained from apparently healthy laboratory personnel and leukæmic cells from patients suffering from chronic myelogenous leukæmia. 50 ml. of venous blood was drawn directly into a 50-ml. 'luer-lok' syringe, containing 1·5 ml. heparin plus 2·5 ml. of 'Dextran' solution. The syringe was placed vertically in the cold with the 'luer-lok' side up; the major portion of the erythrocytes settled out after 45 min. The supernatant fluid containing the leucocytes was then expressed from the syringe into celluloid tubes. The cells were collected by centrifugation for 10 min. at 50*g*, and the sediment washed once with Krebs–Ringer phosphate medium and brought up to a desired volume. Autologous serum was obtained from the subject donating the leucocytes. Leucocyte counts were made by conventional counting methods.

The phagocytic experiments were carried out in the conventional Warburg manometric apparatus at 37° C. Krebs–Ringer phosphate medium was the suspending medium. Insoluble starch granules of *Amaranthus cruenthus* and polystyrene spherules, 1·171μ in diameter, were used as particles. Starch particles or polystyrene spherules suspended in Krebs–Ringer phosphate medium, 30 μmoles of glucose, and either malonate in different concentrations (10^{-1}–10^{-3} *M*) or fluorescent-labelled rabbit γ-globulin were added to the leucocytic suspension from the side-arms

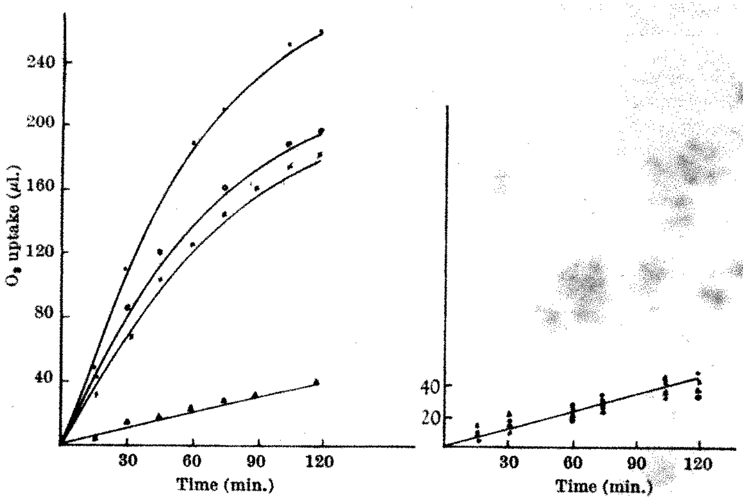

Fig. 1. Leakage of malonate into phagocytizing leukæmic cells. Left, particles present; right, particles absent. ●, 0; ○, 1×10^{-3} *M*; ×, 1×10^{-3} *M*; ▲, 1×10^{-1} *M* malonate

Table 2. EXPECTED RELATIVE FREQUENCY OF ABNORMAL GAMETES PRODUCED BY SIMPLE MEIOTIC NON-DISJUNCTION OF THE SEX CHROMOSOMES AND THE RESULTING ZYGOTES

Stage of gametogenesis affected: First (1 deg.) or second (2 deg.) meiotic division	Relative frequency of abnormal Gametes				Zygotes				
	O	XX	XY	YY	XO	YO	XXX	XXY	XYY
Oogenesis 1 deg.	2	2	—	—	1	1	1	1	--
Spermatogenesis 1 deg.	2	—	2	—	2	—	—	2	—
Oogenesis 2 deg.	2	2	—	—	1	1	1	1	--
Spermatogenesis 2 deg.	2	1	--	1	2	—	1	—	1

studies[13,14] provided the first evidence of meiotic non-disjunction[7,15]. The $XXYY$ karyotype provided evidence of non-disjunction at the second meiotic division of spermatogenesis, and the $XXXXY$ karyotype provided evidence of non-disjunction at successive meiotic divisions, probably of oogenesis. It is probable that several or all of the possible mechanisms occur in man. These mechanisms may be further investigated by studies of colour blindness, parental age, and of the incidence of abnormal karyotypes.

Colour Blindness. Since it was pointed out[7,16] that the incidence of colour blindness in the chromosomal intersexes is consistent with meiotic non-disjunction, it has been agreed[1,16] that simple non-disjunction may occur either at the first or at the second meiotic division although the absolute or relative frequencies of these are not known. Investigations of colour blindness thus provide evidence about the frequency of non-disjunction at the first and second divisions of oogenesis and spermatogenesis and about the position of the colour blindness locus relative to the centromere[17]. An appropriate model for simple primary non-disjunction, in circumstances which may not be so very artificial, is perhaps provided by a study of recessive homozygosis in irradiated *Drosophila*[18].

Parental Age. Since the previous communication[1] was submitted further detailed data[19] have supported a maternal age effect in Klinefelter's syndrome but not in Turner's syndrome. These new results shed further light on the mechanism of meiotic non-disjunction and invite an explanation. There may, for example, be selective loss of nullo-X gametes in the polar bodies during oogenesis. It seems likely that a maternal age effect could be influenced by the relative frequency of non-disjunction, in males and females, in the first and second divisions of oogenesis and by loss, either of gametes before fertilization or of zygotes before birth. Several or all of these mechanisms may operate. It is also possible that the population sampled may not be homogeneous. Thus cases of chromatin-positive Klinefelter's syndrome may include examples with an XXY or $XXYY$ sex chromosome constitution. This would not, however, invalidate the conclusion[13] that more than one X chromosome was present. for the X chromosomes of XXY and $XXYY$ subjects may sometimes be of independent origin in the same way as the X chromosomes of the female normally are. In cases of chromatin-negative Turner's syndrome, however, more serious objections arise, for there is evidence of frequent mosaicism in such subjects[20]. This alone might account for the apparent lack of maternal age effect in Turner's syndrome, but it raises the problem of the relative infrequency of XO zygotes. This in turn might be largely explained by reduced viability of these zygotes since congenital abnormalities are commonly found in Turner's syndrome.

Incidence of Abnormal Karyotypes. As a first approximation the relative frequency of abnormal karyotypes, produced in consequence of simple primary non-disjunction, may be calculated on the assumption that non-disjunction is as frequent during the first and second divisions and as frequent during oogenesis as spermatogenesis (Table 2). Hence an observed excess of XXY zygotes would suggest that most exceptional zygotes arise in consequence of a defect of the first meiotic division of spermatogenesis and an excess of XXX zygotes would suggest a more frequent defect at the second meiotic division of spermatogenesis. Available data on the nuclear sex of infants at birth[21,22] are insufficient for a firm conclusion but suggest that XXY karyotypes may be more common than XXX karyotypes.

The probabilities for aneuploid zygotes with more than two sex chromosomes are more difficult to assess since these may arise in different ways. An added difficulty is their infrequency, which makes detection laborious, even in selected populations; but the incidence in such populations may be of value if most or all of the abnormal zygotes are included in the sample. It is therefore of value to establish the frequency of such karyotypes in oligophrenic populations and to establish, in subjects with each karyotype, the incidence of oligophrenia. The expected relative frequencies of abnormal karyotypes may be calculated (Table 3).

It seems likely that one abnormality may predispose to further abnormalities. Thus, successive non-disjunction may be more common than double non-disjunction. This supposition could be investigated by determination of the relative frequency of abnormal karyotypes in the general or selected populations and by seeking a possible maternal age effect in the subjects discovered. Such studies might also provide information about the frequency of successive non-disjunction in oogenesis and spermatogenesis.

Alternative Mechanisms during Meiosis

In all cases of heteroploidy the possibility of familial cases[23] must, of course, be considered. In familial examples the non-disjunction would be regarded as secondary if it arises in heteroploid subjects.

Other mechanisms entirely different from meiotic non-disjunction might operate. A hypohaploid gamete might be produced by simple elimination of a chromosome without simultaneous occurrence of a hyperhaploid sister gamete. Likewise a hyperhaploid gamete might be produced by simple duplication of a chromosome although colour blindness studies[13] provide evidence that this does not occur in every case.

Table 3. EXPECTED RELATIVE FREQUENCY OF ABNORMAL GAMETES WITH MORE THAN TWO SEX CHROMOSOMES PRODUCED BY SUCCESSIVE MEIOTIC NON-DISJUNCTION OF THE SEX CHROMOSOMES AND THE RESULTING ZYGOTES

	Relative frequency of abnormal Gametes					Zygotes					
	XXX	XXY	XYY	$XXXX$	$XXYY$	$XXXY$	$XXXX$	$XXYY$	$XXXXX$	$XXXYY$	$XXXXY$
Oogenesis	2	—	—	—	—	1	1	—	—	—	—
Spermatogenesis	—	1	1	—	—	1	—	1	—	—	—
Oogenesis	—	—	—	2	—	—	--	—	1	—	1
Spermatogenesis	--	—	—	—	2	—	--	1	—	1	—

Mitotic Non-Disjunction

Mechanisms of mitotic non-disjunction may be investigated in a way similar to that used for meiotic non-disjunction.

Karyotype Analysis. Karyotype analysis should provide much information about mechanisms of mitotic non-disjunction. Non-disjunction at the first mitotic division in subjects with a normal (XX, YY) or abnormal (XO, XXX, XXY) karyotype may produce various types of mosaicism (Table 4) and non-disjunction at a later mitotic division would produce, in addition, clones of cells with the same karyotype as the original zygote. It is unlikely, however, that all cell clones would be of equal viability and some might be rapidly eliminated. Several examples of mosaicism, established or suspected, have been reported. An XXX/XO mosaic[24] was apparently due to non-disjunction at an early mitotic division, perhaps the first, since no XX cells were found. In XX/XO mosaics[20] the mode of origin is less clear. They might arise from XX zygotes due either to non-disjunction at the second or subsequent division with loss of XXX cells or to simple elimination of one X chromosome. Alternatively XX/XO mosaics might arise from XO zygotes in consequence of non-disjunction at the second or later division with loss of OO cells. Similarly an XXY/XY mosaic[3] might arise from XY or XXY zygotes with loss of YO or $XXYY$ cells. The reports of viable XXX[23,24] and $XXYY$[10] subjects are perhaps evidence against the XX and XXY origin of XX/XO and XXY/XY mosaics, respectively.

Colour Blindness. A normal or increased incidence of colour blindness would be expected in mosaics derived from normal (XX or XY) zygotes, but the colour blindness might not always be regular[17]. In general, a higher incidence of colour blindness would be associated with non-disjunction during early mitotic divisions. In mosaics derived from XXY zygotes the incidence would lie between that found in normal males and females and in XX/XO mosaics derived from XO zygotes a male or higher incidence of colour blindness would be expected. The incidence of colour blindness in the fathers of colour-blind subjects with gonadal dysgenesis should also be recorded. A high incidence of colour blindness, a little more than 52 per cent, would be expected in the fathers of colour-blind mosaics derived from XX zygotes. This estimate is based on a colour blindness gene frequency of 8 per cent. Colour blindness would be present in half the fathers of simple heterozygotes and in all the fathers of double heterozygotes and of homozygotes. The frequency of colour blindness in the fathers of colour-blind mosaics derived from XO zygotes would vary with the frequency of non-disjunction in the male and female. It would be 54 per cent if these were equal, for half the fathers would pass on their colour blindness gene and 4 per cent of the others would by chance be colour blind.

Parental Age and Incidence. No maternal age effect would be expected in cases of mitotic non-disjunction unless they were derived from a heteroploid zygote. Studies to determine the relative frequencies might be of value, although the many variable factors, including selection of cases, differential viability and possible association of abnormalities, would make interpretation especially difficult.

Although the mechanisms of non-disjunction in man are complex it is possible to elucidate these mechanisms with appropriate techniques. The collection of much further data is necessary.

Table 4. Some of the Possible Mosaics which may result from Simple Non-disjunction at the First Mitotic Division

Non-disjunction at subsequent mitotic divisions would include, in addition, clones of cells with the same karyotype as the original zygote and, perhaps also, clones of cells with more complex karyotypes

Original zygote	Some possible mosaics
XX	XXX/XO
XY	XXY/YO ; XYY/XO
XO	XX/OO
XXX	$XXXX/XX$
XXY	$XX/XXYY$; XXX/XYY $XXXX/YY$; $XXXY/XY$

CENTROMERES, SITES OF AFFINITY AND GENE LOCI ON THE CHROMOSOMES OF *SACCHAROMYCES*

By Prof. CARL C. LINDEGREN, GERTRUDE LINDEGREN, ERNEST SHULT and YUH LIN HWANG

Biological Research Laboratory, Southern Illinois University, Carbondale

IN the course of constructing chromosome maps by tetrad analysis, two structural features may be encountered; centromeres and (less frequently) sites of affinity. The former may be used for identifying and enumerating the different chromosomes of an organism on the principle that each chromosome possesses one centromere. Sites of affinity, in turn, may be used as a distinguishing feature of certain linkage groups which have not yet been assigned to a chromosome by the centromere criterion. The procedure for locating a centromere was first established by Lindegren[1] for ordered tetrads, later adapted by Lindegren[2] to unordered tetrads[3]. The method is based on the fact that centromeres segregate reductionally at the first division. Sites of affinity, on the other hand, arise in connexion with exceptions to the rule of independent assortment of non-homologous chromosomes. Investigations of a variety of organisms[4–10] indicate that, in certain cases, regions located on different chromosomes pass to the same first division poles with high frequency. Genes located near these regions or sites may appear to be linked. In certain circumstances these sites can be located in a chromosome map.

The first chromosome maps of *Saccharomyces*[11–14] have been recently extended[15,16] and the present article concerns new relationships of centromeres, sites of affinity and gene-loci, demonstrated by hybridizing cultures from a variety of sources[14–18]. The problem of identifying genes in *Saccharomyces* has been complicated by the fact that some distinctly different mutants (which complement and re-combine) have been designated identically by different workers. A temporary device for distinguishing mutants by letters (*L* for Lindegren, *O* for Oshima) as well as by numbers, is adopted in this article; the main emphasis is on giving distinct names to distinct mutants. Table 1 lists the source and the symbols of 18 recently located mutants. New maps have been constructed which include 16 newly located genes together with 34 previously locáted genes.

Table 1. THE SOURCES AND DESIGNATIONS OF 18 DIFFERENT RECENTLY LOCATED GENES

Gene symbols					
Lindegren	Magni	Hawthorne Mortimer	Oshima	Chromosome	Phenotype
**ly*-L					Lysineless
**hi*-L					Histidineless
**su*-L					Non-fermenter sucrose
ar-37	**ar*-3	*ar*-7			Arginineless
**mt*-30					Methionineless
**va*-1					Valineless
mt-02			**mt*-2	X	Methionineless
mt-03			**mt*-3	VI	Methionineless
ar-16	**ar*-1	*ar*-6		V	Arginineless
**mt*-5				V	Methionineless
**le*-2	*le*-4	*le*-2		III	Leucineless
hi-0			**hi*	III	Histidineless
ly-0			**ly*	II	Lysineless
**mt*-55				VI	Methionineless
**ad-L*				II	Adenineless
**bz*				V	Benzimidazole sensitive
**tre*				II	Non-fermenter trehalose
ty-2		**ty*-2			Tyrosineless

* The asterisk before a symbol means that the mutant used in this work was obtained from the author whose name heads the column. The symbols finally used in the map appear in the left column

Linkage is usually indicated by a significant excess of *PD* over *NPD* tetrads, and this is measured by χ^2 on the hypothesis: *PD* = *NPD*. Tetrad distributions are represented by three consecutive numbers, thus 28–4–43 means that for a given pair of genes, 28 parental ditype, 4 non-parental ditype, and 43 tetratype tetrads were observed. For such a distribution, $\chi^2 = (28-4)^2/(28+4) = 24^2/32 = 18$, and linkage would be indicated.

Chromosome II. The gene, *ga*-1 (non-fermenter of galactose) is linked to the centromere of chromosome II[12]. The gene *ly*-2 is 45 Perkins's units[19] distal to *ga*-1[15] and *ly*-0 is also distal to *ga*-1[16]. Although the data suggest that *ly*-0 is farther from *ga*-1 than *ly*-2, the possibility that these represent the same locus cannot be excluded. Current data on linkage of *ac*-1 (actidione sensitivity) and *ga*-1 from this laboratory reveal a total tetrad distribution of 269–11–149, and in family 201, it has been proved that the centromere lies between *ac*-1 and *ga*-1, *ac*-1 being 15 stranes from the centromere[20]. The genes *tre* (trehalose fermentation) and *ad-L* (an adenineless locus) also exhibit linkage with this group (Table 2). The gene order is *ac*-1, centromere, *ga*-1, *tre*, *ad-L*, but *tre* and *ad-L* are not shown on the map because their relations with *ly*-2 have not yet been worked out.

Table 2. TETRAD DISTRIBUTIONS FOR GENES LOCATED ON CHROMOSOME II

The total tetrad distributions are drawn only from families heterozygous for *ac*-1, *ga*-1, *tre*, and *ad-L*, simultaneously. χ^2 gives the value of chi-square for the hypothesis that $PD = NPD$. $\chi^2 > 6\ 2$ indicates linkage

Gene combination	*PD*	*NPD*	*T*	χ^2
ac-1, *ga*-1	194	7	88	174·0
ac-1, *tre*	41	29	96	2 0
ac-1, *ad-L*	56	45	191	1·2
ga-1, *tre*	61	22	95	18 3
ga-1, *ad-L*	63	49	186	1·7
tre, *ad-L*	91	15	63	54 5

Chromosome III. The mating type locus and *hi*-4 are located on opposite arms of chromosone III and the gene *thr*-4 is distal to mating type[15]. A histidineless mutant (*hi*-0)[16] is also linked to the mating type locus. The tetrad distribution for *hi*-0 and mating type is 537–30–432. Complementation studies show that the loci, *hi*-4 and *hi*-0 are different. The gene *le*-2, isolated in this laboratory, is linked both to mating type and to *hi*-0 and fails to complement with Magni's *le*-4[17]. (Hawthorne and Mortimer's *le*-2 also fails to complement Magni's *le*-4 and may be identical to our *le*-2.) Tetrad distributions totalled from miscellaneous crosses show mating type and *le*-2 to be linked: 132–3–104. Tetrad distributions from hybrids heterozygous for both *hi*-0 and *le*-2 indicated that *le*-2 and *hi*-0 were linked in the order, *hi*-0, *le*-2, mating type. The tetrad distributions were 37–0–11 (*hi*-0 and *le*-2), 26–3–20 (*hi*-0 and α), and 30–0–18 (*le*-2 and α).

Centromere of chromosome III was located between *le*-2 and mating type, by data from families 200 and 201, in which the centromere-linked genes *ur*-3, and *ch*-1 could also be followed (Table 3). The gene, *le*-2 is approximately 7·4 stranes from its centromere, while mating type is approximately 22 stranes from its centromere[20]. The latter figure compares well

Table 3. DATA CONCERNING THE LOCATION OF THE CENTROMERE ON CHROMOSOME III

The value, *z*, is the normal curve parameter for the hypothesis that the relative tetratype frequency is 2/3. In each case, *T* is significantly below 2/3 the total number of tetrads

Gene combination	Tetrad distributions for centromere-linked markers

LINDEGRENS' GENE
HAWTHORNE AND MORTIMER'S GENE
OSHIMA'S GENE
10 STRANDS

Fig. 1. Chromosome maps of *Saccharomyces*. This map is based on data drawn from a number of different sources (refs. 10–16 and 20) as well as the more recent results presented in this article. The map contains 10 chromosomes, 4 chromosome segments carrying sites of affinity and 3 chromosome segments which have not yet exhibited linkage with either a centromere or a preferentially segregating site. Centromeres are depicted as round circles containing the numeral of the chromosome it characterizes. Sites of affinity (when they could be located) are represented by a black diamond. Sites on segments *A*, *B* and *C*, preferentially segregate with a point near *ch*-1 on chromosome V, while that on segment *D* preferentially segregates with a point near *ar*-4 on chromosome VII

with 19 [15], 24 [21], and 20·9–25·7 [14]. Data from family 227 show *hi*-4 distal to *le*-2 and in family 241 (*hi*-4 × *hi*-0), 12 *PD* tetrads were obtained. (One *NPD* tetrad was also obtained, but the two histidine-independent progeny grew slowly and may reflect either mutation or a slight 'leakiness' in *hi*-4. In general, crosses carrying *hi*-4 give poorer germination of spores.) Although the relative order of *hi*-0 and *hi*-4 has not been determined (if indeed they do recombine) the total gene arrangement for chromosome III is (*hi*-4, *hi*-0), *le*-2, centromere, mating type, *thr*-4.

Chromosome V. In chromosome V the sequence *ur*-3, centromere, (*ch*-1, *ca*-1), *nc*, *hi*-1, *is*-1, *an*-1 and *co* has been established[14]. Subsequent data from families 131 and 132 showed that the gene *bz* (benzimidazole-sensitive) was closely linked to *ch*-1 and *ca*-1 (*bz*-*ch* : 39–1–11, *bz*-*ca*: 49–0–16). The relative order of these loci was determined in two crosses, families 200 and 201, as centromere, *bz*, *ca*-1 and *ch*-1 [20].

The gene *ar*-16 has exhibited strong linkage with *hi*-1, and in a series of crosses heterozygous for *ar*-16, *ch*-1, *hi*-1, *is*-1 and *an*-1 the tetrad distributions given in Table 4 were obtained. The gene order indicated is *ch*-1, *hi*-1, *ar*-16, *is*-1, *an*-1, establishing the total sequence: *ur*-3, centromere, *bz*, *ca*-1, *ch*-1, *nc*, *hi*-1, *ar*-16, *is*-1, *an*-1 and *co*.

The gene *mt*-5, which controls the synthesis of methionine, is tightly linked to the genes *is*-1 and

is-1, *an*-1	28	0	8

an-1. The tetrad distributions obtained from family 302 for the gene pair *mt*-5 and *is*-1 is 31–1–4, and for the gene pair *mt*-5 and *an*-1 is 35–0–1. These tetrad distributions suggest that the gene *mt*-5 is probably distal to *an*-1.

Chromosome VI. Tetrad data obtained by Dr. Oshima[16] showed that *mt*-03 is approximately 25 stranes from a centromere. The total tetrad distribution of *mt*-03 with *hi*-2 is 18–1–20, showing that *mt*-03 lies on chromosome VI distal to *hi*-2. Another methionineless mutant, *mt*-24 fails to complement with *mt*-03. The total tetrad distribution for *hi*-2 and *mt*-24 is 32–1–24. In a cross, *mt*-24 × *mt*-03, no methionine-independent progeny were obtained in nine tetrads, indicating that these loci are close together, if not identical. A second methionineless mutant, *mt*-55, complements with *mt*-03 (and *mt*-24), but also suggests linkage with *hi*-2 on chromosome VI (family 265, tetrad distribution 4–0–1). No methionineless-independent offspring were obtained in 20 asci from a *mt*-03 × *mt*-55 hybrid, indicating that these two methionine loci lie very close together. Thus, an overall sequence in chromosome VI is: centromere-*hi*-2-(*mt*-03, *mt*-55).

Chromosome VIII. The following order of the genes and the centromere on chromosome VIII has been proposed[15]: centromere, *p*-1, *ar*-4, *thr*-4, *cu*-1. Recent results[10] show that *cu*-1 lies on a distinct chromosome arm which segregates preferentially with chromosome VIII.

Identification of a 'new' chromosome. The genes *mt*-02 and *mt*-03 are complementary, and tetrad results obtained by Dr. Oshima[16] indicate that these loci are on two different chromosomes distinct from chromosomes I, II, III and V. The gene *mt*-02 is 7 stranes from its centromere, and *mt*-03 is 25 stranes from its centromere on chromosome VI.

Table 5 presents the total tetrad distribution of *mt*-02 with the centromere markers of chromosomes I–IX, drawn from data obtained in this laboratory. The strong *F*-distributions with *ad*-1, *ga*-1, mating type, *tr*-1, *ur*-3 and *le*-1 show conclusively that the *mt*-02 chromosome is distinct from chromosomes I, II, III, IV, V and VII.

The problem of locating *mt*-02 with regard to *hi*-2 (chromosome VI) and *ar*-4 (chromosome VIII) involves a somewhat more sophisticated argument. The gene, *hi*-2, is 18 Perkins's units from its centromere[15]. Consequently, if *mt*-02 were on chromosome VI, its distance from *hi*-2 would be either 11 or 25 stranes. (At this magnitude, Perkins's units and stranes are approximately equal.) In either case, one would expect linkage to be manifest in the tetrad distribution for *mt*-02 and *hi*-2. Assuming the distance of 25 stranes, one would expect the tetrad distribution for *mt*-02 and *hi*-2 to be 25·748–0·820–14·432 rather than 10–9–22, the observed distribution. The observed value of $PD/(PD + NPD)$ differs from the expected value with $z = 11{\cdot}32$ and $P < 10^{-10}$. Thus one must reject the hypothesis that *mt*-02 is located on chromosome VI, opposite the centromere from *hi*-2. This also entails rejection of the hypothesis that *mt*-02 is on chromosome VI at all, for if *mt*-02 were on the same arm with *hi*-2 they would lie approximately 11 stranes apart and the expected linkage would be even 'tighter' than that rejected above.

If *mt*-02 were located on chromosome VIII, it should show linkage with *ar*-4, which is also 7 Perkins's units from its centromere. The assumption that they lie on opposite sides of the centromere would place

them approximately 14 stranes apart so that the expected tetrad distribution (in 130 tetrads) would be 99·32–0·91–29·77. This differs radically from 38–39–53, with $PD/(PD + NPD)$ achieving the observed value with probability far less than 10^{-12}. If *ar*-4 and *mt*-02 were on the same side of the centromere, linkage would be nearly complete, which obviously it is not. Thus *mt*-02 does not lie on chromosome VIII.

The genes *hi*-6 and *ly*-1 lie on opposite sides of centromere of chromosome IX at 17 and 29 Perkins's units respectively[15]. Thus, if *mt*-02, which is 7 stranes from a centromere were on chromosome IX, it would have to lie between *hi*-6 and *ly*-1. Consequently the Trow[22] formula:

(1) $1 - 2f(hi\text{-}6,\ mt\text{-}02) \times 1 - 2f(mt\text{-}02,\ ly\text{-}1) = 1 - 2f(hi\text{-}6,\ ly\text{-}1)$ should hold. The symbol $f(A, B)$ denotes the frequency of recombination between genes A and B). The tetrad distribution 75–8–130 for *hi*-6 and *ly*-1 was accumulated from miscellaneous crosses (Table 10 [14]), so that $1-2f = (75-8)/(75 + 8 + 130) = 0{\cdot}315$. The two tetrad distributions listed in Table 5, 11–14–31 (*hi*-6 and *mt*-02) and 19–15–45 (*mt*-02 and *ly*-1), yield the expected fraction $(-0{\cdot}054) \times (0{\cdot}051) = 0{\cdot}002754$. Since f is normally distributed, so is $1-2f$, and the two values can be compared by the z test, with N equal to the number of tetrads. (In tetrad data, the genotypes of the spores do not appear independently. Consequently N cannot be taken as the number of cultures in a normal-curve test. Since $1-2f = a_1 - a_2$ (a_1 and a_2 are relative frequencies of PD and NPD tetrads) $PD - NPD$ is a normally distributed parameter in a sample of size $N = PD + NPD + T$.) In a sample of size 213, the proportion 0·343 differs from the expected proportion 0·002754, with $z > 70$, and with p attaining a fantastically small value. Correction for the fact that the parameters, f(*hi*-6, *mt*-02) and f(*mt*-02, *ly*-1), which were used in calculating the theoretical value, are themselves also random variables with associated variances, could not possibly raise p even within range of the 1 per cent level. Consequently, the hypothesis that *mt*-02 lies on chromosome IX must be rejected.

A methionineless gene *me*-2 [16] was placed on chromosome X largely on the basis 163/273 = 59·7 per cent second division segregation in ordered tetrads. This differs from 2/3 only at the 2 per cent level. In their data, *me*-2 exhibits 473/744 = 63·6 per cent tetratype tetrads, with the markers *ad*-1, *ga*-1, *tr*-1, *le*-1 and *p*-1, all lying within 8 units of their respective centromeres. In data obtained from this laboratory *me*-2 exhibits 82/129 = 63·6 per cent tetratype tetrads with *ga*-1, *tr*-1, *ur*-3, *le*-1 and *ar*-4 (also, all lying within 8 units of a centromere). Thus the data from ordered asci are sub-significant, and segregational data are completely negative with regard to *me*-2 being centromere linked. Furthermore, there are no data indicating that *me*-2 lies on a chromosome distinct from chromosomes I–IX, and its location on 'chromosome X' must be considered premature. However, the gene, *mt*-02, lies only 7 units from its centromere, on a chromosome known to be distinct from chromosomes I–IX. We therefore propose to designate this chromosome, chromosome X.

The chromosome segment carrying ly-L. The gene *ly-L* cannot be identified with either *ly*-0 (with which it complements) or *ly*-2, since both of the latter exhibit linkage with *ga*-1, while *ly-L* does not. The tetrad distributions of *ga*-1 with *ly*-2 [15], *ly*-0 [14] are 32–6–95 (*ga*-1 and *ly*-2), 148–44–454 (*ga*-1 and *ly*-0) and 132–150–683 (*ga*-1 and *ly-L*). However, there does appear to be some association between *ly-L* both with genes located near centromere V and genes on segments which segregate preferentially with centromere V (Table 6). This association does not necessarily prove that *ly-L* is located on chromosome V, since the significant excess of parental over non-parental ditype tetrads could result from preferential segregation of a site of affinity located somewhere near the *ly-L* gene.

This inference is supported by: (*a*) the fact that the weak linkage of the *ly-L* with chromosome V genes varies erratically from family to family since parental preferential segregation may not obtain in all families (namely, family 110); (*b*) the fact that other loci, *cu*-2, *th*-1 and possibly *py*-1, are known to lie on chromosome arms which segregate preferentially with the genes, *bz*, *ca* and *ch*-1 on chromosome V [9,22]; (*c*) the fact that the cumulative linkage effect does not appear with markers *ur*-3 and *is*-1 which lie on opposite sides of the short *bz-ca-ch* linkage group on chromosome V (Table 7), indicating preferential segregation toward points interior to the *ur*-3, *ch*-1, *is*-1 group on chromosome V.

A chromosome segment. The gene *ty*-2 controls the synthesis of tyrosine, and is also associated with a phenylalanine requirement. (Three other cases are known in yeast in which a mutant locus is associated with a multiple biochemical requirement: *is*-2 (isoleucineless, valineless), *po*-1 ('polyaromatic': tyrosine, phenylalanine and anthranilic acid requirements), and *glt*-1 (glutamicless, lactate negative). Linkage between *ty*-2 and *cu*-1 was evident in several families, although the amount of crossing-over varies considerably between families. The total tetrad distribution is 25–6–43. The segment preferentially segregates with chromosome VIII. The points of highest affinity lie near *cu*-1 on the segment distal to *ar*-4 on chromosome VIII [19].

Linkage groups in two segments not located near centromeres or sites of affinity. The mutant *mt*-30 complements with all the other methionineless cultures (*me*-2, *mt*-02, *mt*-03, *mt*-55 and *mt*-5) and exhibits linkage with *ar*-37; the total tetrad distribution from two hybrids was 26–0–8. A valineless mutant, *va*-1, exhibits linkage with *mg* (α-methyl glucoside fermentation). The total distribution accumulated from six hybrids is 22–7–66. The gene *cd*, controlling resistance to 0·01–0·02 per cent cadmium[23], lies about 25 stranes from *mg*. The total tetrad distribution for *cd-mg* is 77–8–58, but the order of these genes with respect to *va*-1 is not known.

We thank Drs. Oshima, Magni, Hawthorne and Mortimer for many of the mutant loci used in this work, and particularly to Dr. Oshima for permission to quote a portion of his unpublished data.

This work was supported by research grant *C*–4682, from the U.S. Public Health Service.

HIGH BACKGROUND RADIATION ON A SMALL ISLAND

By R. N. WEIR

Queen Elizabeth Central Hospital, Federal Ministry of
Health, Blantyre, Rhodesia and Nyasaland

THERE is, at this time, a great deal of interest in the effects of exposure to a high background radiation in animal and plant life. Various interested organizations claim to be searching for groups of people, suitable for comparative studies, living under identical conditions—one group exposed to radiation and the other not exposed. This article is intended to indicate the value of a full-scale biological survey of Chilwa Island in Nyasaland by an organization capable of dealing with the problem.

Geology

Chilwa Island is situated near the south-western shore of Lake Chilwa, twenty miles east of Zomba, the administrative capital of Nyasaland. The island, which measures about two miles across, is the largest and most northerly of an irregular chain of volcanic carbonatite necks adjacent to the eastern border of southern Nyasaland with Portuguese East Africa

The superior resistance to tropical weathering of the carbonatites on Chilwa Island, relative to the older Basement Complex Rocks, have led to the formation of a steep ring-like feature. This topographic feature has been breached by erosion on its western side and a natural amphitheatre has been formed which bounds a flat arena of alluvium and eluvium of terra rossa type.

A geological survey of Chilwa Island in 1952 revealed marked radioactive anomalies at three localities (Garson and W. Campbell Smith, 1958). These were: (1) the floor of the Chirima arena in the area of Chirima Village; (2) the summit plateau; (3) dyke-like carbonatitic bodies on slopes above the Chirima arena.

The primary area of interest in this article is the Chirima arena because the other two areas are uninhabited and covered for much of the year by dense vegetation. The arena has an area of approximately 120 acres. Gamma-ray intensity is highest in an elongated zone, roughly parallel to the northern and southern margin of the arena. Channel samples collected from this area by D. Ostle and J. Taylor of the Atomic Energy Division (1954) indicate an equivalent urania content of between 0·020 and 0·031 per cent, confirming the isorad map produced during the 1952 investigation. It is clear that the radioactive anomaly in the arena is due to the accumulation of radioactive debris derived from the radioactive dykes on the carbonatite slopes. These dykes contain up to 2·14 per cent thoria.

Laboratory investigations at the Atomic Energy Division were directed towards the identification of the radioactive minerals, and the determination of the phase status of the radioelements. The source of the radioactivity in the rocks was found to be mainly in patches of goethite and to a minor extent in tiny grains of pyrochlore.

It was also found that thorium was predominant over uranium in a soil sample, and that most of the γ- and β-radiation must be attributed to the presence of disintegration products of original radioelements which remained fixed in the soils after the latter were leached away. These disintegration products were believed to be decay products of uranium, ionium and radium, which, having no source of replenishment, disintegrated further to elements of shorter half-life periods. This is further indicated by the fact that there is an observed decrease in the degree of radioactive equilibrium as bed-rock is approached. In view of the relationship between the high radiometric anomaly in the Chirima arena and physiological factors described here it is important that future research should establish the exact nature of these short half-life elements.

Further analyses of samples from the Chirima arena are being carried out to determine the presence of cæsium-137/strontium-90 and iodine-131.

Pilot Survey

Following the report of the geological survey of Chilwa Island carried out in 1952 by M. S. Garson and W. Campbell Smith, it was decided to investigate the effects of this high background radiation on the health of the population. The background radiation was estimated to be approximately thirty times normal. Accordingly a small team, consisting of Mr. R. A. Clift, a Government medical laboratory technician, a medical assistant to act as an interpreter and I, spent three days on Chilwa Island in November, 1954, carrying out a preliminary survey.

The geography of the island has already been mentioned, but a few words should be included here about the distribution of the population. There are approximately 1,000 inhabitants living in 21 villages spread out around the flat perimeter of the island. There are no villages on the peaks. Each village has about 45–50 men, women and children governed by a village headman. A census of the people is said to have been held in 1948. Everyone on the island was vaccinated against smallpox in 1951. The island is small and infested with malaria-carrying mosquitoes.

Fishing is the main occupation of the islanders although some tend cattle which have been brought over from the mainland.

The lake provides bilharzia-infected water for all domestic purposes.

Two villages lie within the area known as the Chirima Arena. That nearest the centre of the arena was chosen as the test village. Chief Nkumbira's village, which lies outside the area of radioactivity, was chosen as the control village.

The total white cell counts and hæmoglobin estimations were used as indicators. As the hæmoglobin estimations were of doubtful value they will be excluded from this report.

Capillary blood from the finger was used for all the estimations.

All the persons in the test series except three had lived in the arena since birth. The three exceptions had lived there for 2, 12 and 17 years respectively. None of the control series had lived in the Chirima Arena.

Difference of means = 1·54 (1)

Standard of error of (1)

$$= \sqrt{\frac{(2·7)^2}{38} + \frac{(2·7)^2}{28}} = \sqrt{\frac{7·3}{38} + \frac{7·3}{28}}$$

$$= \sqrt{0·19 + 0·26} = \sqrt{0·45}$$

$$= 0·67 \qquad (2)$$

$$\text{Ratio } (1) : (2) = \frac{1·54}{0·67} = 2·3$$

This ratio is well above the level of significance, suggesting that the observed difference of means might occur by chance once in 50 tests.

Test Village

The village headman was very co-operative and called all the people together. Each person's name, age, years of residence on the island, and physical complaints were recorded under the direction of the medical assistant. It was not possible to examine specimens of urine as there was insufficient time. Nevertheless, on the evidence available, it appeared

Table 3

1 White blood cells (×1,000)	2 Frequency	3 Difference in units	4 2×3	3×4

11–	1	+3	+3	9
12–	0	+4	0	0
13–	0	+5	0	0
14–	1	+6	+6	36
	28		−15	133/28=4·75

$$\text{Mean} = 8{\cdot}5 - \frac{15}{28} = 7{\cdot}96$$

$$S.D. = \sqrt{4{\cdot}75 - (0{\cdot}53)^2} = \sqrt{4{\cdot}47} = 2{\cdot}11$$

that many of the inhabitants suffered from bilharziasis.

The women were questioned about the number of pregnancies, abortions, still-births and neonatal deaths among them. It is difficult to decide from such a brief survey whether the abortion and still-birth-rates were higher on the island than on the mainland.

From 14 women of child-bearing age there was a history of 12 abortions, 3 still-births, 16 neonatal deaths and 41 living children. Out of a total of 72 pregnancies only a little more than half of them resulted in a living child who had survived for one year. Only one case of twins was reported. There were no cases of maternal death due to confinement.

There were three interesting cases of skin disease of an unusual type. The three young men were about twenty-one years old. The skin showed large watery blisters which, according to the patients, "had appeared quite suddenly" and for no apparent reason. The word "suddenly" as used by Africans in this context really means spontaneously. Itchiness was complained of in each case. The skin lesion resembled very closely the skin reactions following intensive deep X-ray therapy. No cases of this condition occurred in villagers living outside the arena. The blood pictures of these young men were also of interest. All three had white blood cell counts between 2,000 and 3,000 per mm.^{3}.

The polymorph count in each case was markedly decreased whereas the lymphocyte count was increased. The hæmoglobin estimations averaged 80 per cent Sahli.

No cases of tropical ulcers were seen or reported for the previous fifteen years. There was one epileptic and one mentally defective youth in the village. The village headman could not recall any cases of murder or suicide in his village. There was an unusually high number of graves in the area of the arena.

Control Village

Co-operation was not good here mainly because Chief Nkumbira's religious principles were in conflict with anything to do with medical science. This resulted in many of the women refusing to be examined. Only six women could be induced to give a history of their pregnancies. The figures given were 8 living children, 5 neonatal deaths, 1 still-birth and 1 abortion. These totals, although small, give practically the same proportion of living children surviving to one year as in the test village. No cases of twins could be recalled. There had been one maternal death due to confinement in the last 15 years.

Again no cases of tropical ulcers were seen or recalled over the past fifteen years. There were no epileptics or mental defectives in this village. There had been one case of suicide many years ago. No murders had been committed in living memory. There were no cases of low white cell counts or unusual skin lesions among the inhabitants.

Discussion

On the whole the health of the people in both villages was very good and above the average as compared with the mainland. The complete absence of cases of tropical ulcers is very striking. This was also noted by the Government medical officer who carried out the smallpox vaccination campaign in 1951.

As the people were not desirous of being examined for venereal disease no importance can be attached to the high rate of unsuccessful pregnancies until the women can be properly examined, especially for syphilis. All that can be said is that difficulties during labour must be very uncommon since only one maternal death occurred as the result of a confinement within the past fifteen years, which is in sharp contrast to obstetrical experience on the mainland.

The average white cell counts obtained from the two villages in the survey differ by a figure much larger than that to be expected from chance. This difference may be due to one of two causes. Either the average white blood cell count for the control group is unduly high or the average count for the test group is low. An examination of the figures suggests the latter. Factors reducing the white cell count are relatively uncommon. With the high incidence of parasitic infection one would expect the white blood cell counts to be raised in both the test village and the control villages. As no selection, based on clinical features, was used in the samples the conclusion was that the cases of leucopænia in the test village could be due to exposure to radiation. No other obvious clinical cause for the leucopenia was found.

Recommendation

It is felt that the results of this brief survey merit a fuller investigation by a team qualified to undertake such a task. One suggestion is that the islanders be persuaded to wear photographic film badges which would give an accurate assessment of the degree of exposure. This is a cheap and simple method of investigation. Bone from the bodies in the numerous graves in the area of the arena could be examined for radioactive isotopes.

The effects of radiation on vegetation and wild life require to be investigated. One geologist considers that he has seen a mutant of the plant *Euphorbia candelabrae* in the radioactive arena.

The amount of radioactive material absorbed into the lake water and hence into the fish might provide useful results. The island probably presents a unique field for the investigation of the long-term biological effects of radiation.

Acknowledgments

I wish to express my thanks to the director of medical services, Nyasaland, Dr. P. R. Stephens, for permission to publish this article. I am also indebted to the following for their kind help: Dr. M. S. Garson for geological data and Mr. R. A. Clift for the tables of white cell counts and other useful data obtained during our survey of Chilwa Island.

LETTERS TO THE EDITOR

PHYSICS

Water Waves and Hamilton's Method

OCEAN waves approaching a beach may be discussed by the method of geometrical optics; the frequency having been assigned, the phase velocity is determined by the depth; the rays are determined by Fermat's principle, and the wave crests are the orthogonal trajectories of the system of rays[1]. But it may not be generally realized that Hamilton's optical method, suitably generalized, can be used to treat a much wider class of problems of water waves. The method is essentially Huygens' construction put into mathematical form.

We start with an equation connecting phase velocity W and wave-length λ:

$$W^2 = \frac{\lambda}{2\pi} \tanh \frac{2\pi h}{\lambda} \left[1 + \frac{T}{g\rho}\left(\frac{2\pi}{\lambda}\right)^2 \right]$$

where h is depth, ρ density, and T surface tension. Let y_1, y_2 be wave-numbers so that $(2\pi/\lambda)^2 = y_1^2 + y_2^2$ ($= y^2$, say), and y_3 circular frequency $(2\pi W/\lambda)$; then we have the equation:

$$\Omega \equiv y_3^2 - \tanh hy \ (gy + y^3 T/\rho) = 0 \qquad (1)$$

This we may call the 'Hamilton equation'; regarded as a surface in y-space, it is the analogue of what Hamilton called the "surface of components of normal slowness". Let x_1, x_2 be space co-ordinates, x_3 the time and ψ the phase. Replacing y_r by $\partial\psi/\partial x_r$ in equation (1) ($r = 1, 2, 3$), we get for ψ a partial differential equation which is the analogue of the so-called Hamilton–Jacobi equation. The solution of wave-problems is merely a matter of solving it. This is done by first finding the rays[2] which satisfy the canonical equations $\mathrm{d}x_r/\mathrm{d}w = \partial\Omega/\partial y_r$, $\mathrm{d}y_r/\mathrm{d}w = -\partial\Omega/\partial x_r$, w being a parameter. Then:

$$\psi(x) - \psi(x') = \int_{x'}^{x} y_r \, \mathrm{d}x_r$$

the integral being taken along the ray joining the events x'_r and x_r, with the summation convention. This phase difference is essentially Hamilton's principal function.

As a simple example take $h = \infty$, $T = 0$; the Hamilton equation is then $y_3^2 - gy = 0$, and the rays are $x_1 - x'_1 = -wgy_1/y$, $x_2 - x'_2 = -wgy_2/y$, $x_3 - x'_3 = 2wy_3$, $y_r =$ constant. The phase difference is $\psi(x) - \psi(x') = g(x_3 - x'_3)^2/4\xi$, where $\xi^2 = (x_1 - x'_1)^2 + (x_2 - x'_2)^2$. From this we obtain by simple algebra the familiar Kelvin ship-wave pattern, putting $\psi = 0$ at the prow, for which $x'_1 = Ux'_3$, $x'_2 = 0$, and eliminating x'_r by a condition of stationary phase.

Just as the ordinary method of geometrical optics permits approximate solution of a class of problems far wider than those for which Maxwell's equations can be solved, so the above Hamiltonian method can be used to discuss a very wide range of hydrodynamical problems including those for which h and T vary with position, and even with time. The Hamilton equation can be modified to deal with tidal currents. The most fundamental results in geometrical optics occur in reflexion or refraction at a surface of discontinuity; analogues arise in hydrodynamics at a sharp change in depth, or surface tension (for example, at the edge of an oil-slick), or tidal current. The method deals only with phase; conclusions about amplitude can only be inferred indirectly.

Note added in proof. It may be useful to have a word, analogous to 'photon', 'phonon' and 'graviton', for a fictitious particle which travels with the ray (or group) velocity and carries energy: we suggest the name 'hydron'.

A New Method for the Determination of Plasma Electron Temperature and Density from Thomson Scattering of an Optical Maser Beam

THE Thomson scattering of light by free electrons has not yet been observed in a laboratory plasma—the cross-section for the process is small and until recently no suitable source of light has been available. The advent of a very bright monochromatic light source in the form of the optical maser has markedly changed the situation, however, and in this communication a method is proposed for measuring the temperature and the relative density of electrons in a plasma from the Doppler broadening and the intensity of light scattered from an optical maser beam.

Ruby optical masers already constructed have delivered pulses of 10^4 W. of parallel monochromatic light at 6943 Å. lasting 200 μsec.[1]. Multiple reflexions of such a beam between a mirror placed at the far side of a plasma and the highly reflecting front surface of the optical maser crystal could enhance the beam power by a factor of ten or more, because attenuation by the plasma is slight. Despite the very small cross-section for Thomson scattering ($6{\cdot}65 \times 10^{-25}$ cm.^{2} per electron), with an effective beam-power of 10^5 W. it becomes feasible to detect light scattered from a moderate number of electrons. For example, even at the rather low plasma electron density of 10^{10} cm.$^{-3}$, in 200 μsec. about $4{\cdot}7 \times 10^5$ photons would be scattered from 1-cm. length of beam, and if 1/20 of these were received by a photomultiplier of 4 per cent quantum efficiency a signal-to-noise ratio of more than 30 would be obtained, provided contributions from particles other than electrons may be neglected. The scattering cross-sections at 6943 Å. for most other particles are even smaller, though for neutral atoms of the alkali metals they are comparable.

It will be possible to distinguish between the scattered light and the self-luminosity of the plasma, provided the latter is not overwhelmingly bright, because light scattered through 90° is fully plane-polarized perpendicular to the scattering plane, whereas the self-luminosity of the plasma will generally be unpolarized, or nearly so. Thus the difference in power between components of the light reaching the detector polarized perpendicular to and parallel to the scattering plane will be due to the Thomson scattered light. A polarizing beam splitter and matched photomultiplier channels could conveniently be used for the analysis. To conserve light it would probably be advantageous to use an optical maser crystal cut so as to produce a plane polarized output beam, and orientated so that the plane of polarization is perpendicular to the scattering plane.

The double Doppler effect due to thermal motion of the electrons will give the scattered light a Gaussian wave-length distribution the half-intensity breadth $\delta\lambda_e$ of which depends on the temperature of the electrons T_e, the primary wave-length λ and the scattering angle[2]. If multiple reflexions are used to enhance the optical maser beam-power a scattering angle of 90° is desirable, in which case $\delta\lambda_e = 4{\cdot}32 \times 10^{-5}\lambda T_e^{\frac{1}{2}}$. Thus, for example, when $T_e = 2{\cdot}5 \times 10^5$ ° K., if $\lambda = 6943$ Å. then $\delta\lambda_e = 150$ Å. The electron temperature can be determined from measurements of the relative intensity of the scattered light at different wave-lengths. The Doppler broadening of light scattered by all other particles will be very much smaller, being inversely proportional to the square root of the mass, so if a narrow central region of the wave-length distribution is excluded their contribution to the scattered light will be eliminated.

An electron drift velocity in the scattering plane may be detected because in general it will produce a displacement of the maximum in the intensity distribution away from the optical maser wave-length. The magnitude of the displacement will depend on the drift direction.

Absolute measurements of the electron density, from the ratio between the effective beam-power and the scattered light intensity, would be very difficult. Variations in the relative density could be observed, however, and if a plasma of known density was available a direct calibration could be obtained.

It would be necessary to take great care to keep to a minimum the amount of stray light entering the detecting system from the primary beam. A little could be tolerated, because unlike the light scattered by the electrons it would lie entirely within the narrow wave-length region containing the primary beam—a region which need not be used in determining the wave-length distribution of the Thomson scattered light. Its polarization would be uncertain.

A lower limit to the useful temperature-range is set at about 10^4 ° K. by the breadth of the ruby optical maser output line (~ 1 Å.) and its displacement as a result of crystal heating during optical pumping ($\sim 0{\cdot}05$ Å. ° C.$^{-1}$) (ref. 3), which also make the smallest detectable drift velocity in the scattering plane about 2×10^7 cm. sec.$^{-1}$. Because symmetrical observations of the wave-length distribution of scattered light are desirable, the highest temperature measurable in a hydrogen plasma will be about 10^7 ° K., owing to the almost inevitable presence of strong H_α light at 6563 Å. from the cool outer regions of the plasma.

The density-range over which the method can be used will depend on many factors. Assuming (*inter alia*) that the optical maser beam has an effective power of 10^5 W. and a cross-section of 10^{-2} cm.^{2}, and that the light scattered from 1-cm. length of the beam in a plasma 30 cm. deep is examined with a resolving time of 10^{-4} sec., a lower density limit of about 5×10^{11} cm.$^{-3}$ (due to photomultiplier noise) has been estimated and an upper limit, for a hydrogen plasma, the self-luminous radiation of which in the region of 7000 Å. consists mainly of bremsstrahlung, of about 10^{14} cm.$^{-3}$. Both these limits will be pushed back proportionally if the optical maser power is increased, provided the output pulse length is not shortened unduly.

The method proposed here will not disturb the plasma, and as it will be suitable for pure hydrogen or deuterium plasmas it should be valuable in thermonuclear research. It will provide better space resolution than any existing optical method. The time and space resolution attainable, and the working density-range, are limited only by the optical maser beam power and energy available, which may be expected to be improved in future.

I thank Dr. A. A. Ware and Dr. J. Dyson for advice and encouragement, and Dr. T. E. Allibone, director of this laboratory, for permission to publish this communication.

A Fast Response Total-Radiation Detector

A PYROELECTRIC thermal detector having a high-frequency response of 5 μsec. has been made and has been used to measure the total-radiation loss from a high-temperature gas discharge. This device, which can easily be improved to give a time-constant of better than 1 μsec., should be compared with the more conventional bolometer types having, at best, a response of about 50 μsec.[1]. It consists of a piece of spontaneously polarized ferroelectric material (in this case barium titanate), having electrodes on opposite faces (Fig. 1). The electrode on one face of the ferroelectric is a film of conducting black used to absorb the pulse of incident radiation (and hence the device has a wide spectral response).

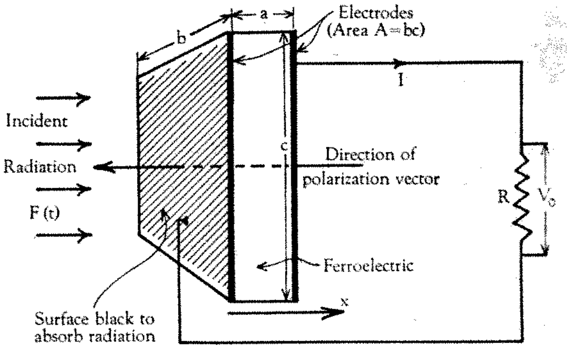

Fig. 1. Pyroelectric unit with electrodes on faces

Solution of the heat conduction equations by the method of Laplace transforms for such an arrangement shows that if a radiation flux $F(t)$ is absorbed at the surface electrode, then:

$$F(t) = \rho S \frac{d}{dt}(a\bar{\theta}) \tag{1}$$

where ρ = density of ferroelectric, S = specific heat, a = thickness of ferroelectric and $a\bar{\theta} = \int_0^a \theta(x)\,dx$, where $\theta(x)$ is the rise in temperature at a thickness x.

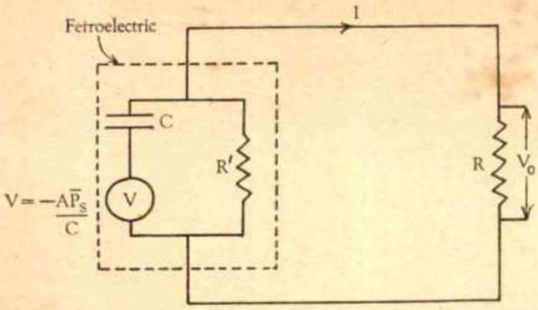

Fig. 2. Equivalent circuit of pyroelectric unit. C, Bulk capacitance of ferroelectric; R^1, leakage resistance of ferroelectric; $\bar{P}_s$, average polarization in the X direction

Equation (1) holds provided that no heat is lost from the ferroelectric. This implies that: (1) The thermal mass per unit area of the electrode M_T should be negligible with respect to the ferroelectric being heated or $M_T < \rho S(\varkappa\tau_1)^{\frac{1}{2}}$, where τ_1 is the minimum resolution time and $\varkappa$ is the thermal diffusivity of the material. (In general, τ_1 can be made less than the other time constants involved.) (2) There should be negligible heat loss from the rear surface of the ferroelectric or $a \gg (\varkappa\tau_2)^{\frac{1}{2}}$, where τ_2 is the maximum length of the radiation pulse.

For short radiation pulses, if the device is mounted in vacuum re-radiation is small, as is any heat loss down the leads due to conduction, if their cross-sections are small.

When the radiation flux is incident, it causes a change in temperature of the barium titanate and hence a change in spontaneous polarization[2]. (This process can be very rapid since dielectric relaxation, associated with the polarization, does not set in until frequencies in excess of 100 Mc./s.) If the absorbing black is efficient, any photo-induced processes will be small. The unit is polarized in the direction between the electrodes, and if the electrodes are connected to a resistance, R, the change in spontaneous polarization P_s manifests itself as a voltage developed across the electrodes. It can be shown[3] that the equivalent circuit is given as in Fig. 2. Now, if $\lambda = (\partial P_s/\partial\theta)$ is the rate of change of spontaneous polarization with temperature at constant stress (almost a constant in the temperature-range of 20°–100° C.), then $\bar{P}_s = \lambda\bar{\theta} = \frac{\int_0^t F(\tau)\mathrm{d}\tau}{a\rho S}$, so that the output for a radiation flux $F(t)$ is given by:

$$V_0(t) = \frac{4\pi\lambda}{\rho S\varepsilon}\exp\left\{-t\left(\frac{1}{R}+\frac{1}{R^1}\right)\Big/C\right\}\int_0^t \exp\left\{\tau\left(\frac{1}{R}+\frac{1}{R^1}\right)\Big/C\right\} F(\tau)\mathrm{d}\tau \quad (2)$$

where ε = dielectric constant of barium titanate; $C = \varepsilon A/4\pi a$ is the bulk capacitance of the barium titanate with electrodes of area A: R^1 = leakage resistance of the barium titanate.

Since the ferroelectric is also piezoelectric, there will be thermal stresses set up due to non-uniform heating, and so in order for equation (2) to apply it is necessary that the ferroelectric is in mechanical equilibrium, with no net resultant body forces on it (in fact supported from rear so that it is free to expand). This is only true when the frequencies associated with the radiation pulse are less than the mechanical resonant frequencies of the ferroelectric, for when they are comparable, the thermal expansion of the ferroelectric excites a mechanical resonance (and hence there is no longer mechanical equilibrium), so that an oscillatory output is superimposed on that of equation (2)—the mean of these oscillations over the frequency of the resonance in fact gives equation (2), but, by the averaging process, the frequency response is effectively limited to $1/f_r$, where f_r is the frequency of the lowest excited resonance.

Since λ changes rapidly close to the Curie temperature at about 110° C., where the spontaneous polarization disappears, the surface temperature should not exceed this value. This places a restriction on the maximum input energy. From the solution of the conduction equation (3) this implies that:

$$F(t) < \theta_{\text{max.}}\left(\frac{\pi\varkappa}{4}\right)^{\frac{1}{2}}\rho S t^{-\frac{1}{2}} \quad (3)$$

but for $t = 1$ msec., this gives $F(t) < 3$ kW. cm.$^{-2}$, so that the fluxes involved by this limitation are very high.

For RC large compared with τ_2, $V_0(t)$ is proportional to $\int^t F(\tau)\mathrm{d}\tau$ and is independent of the dimensions of the ferroelectric. For R large, the device is essentially capacitive, and the random noise associated with it is small. In order to obtain an output proportional to the incident flux the output proportional to $\int^t F(\tau)\mathrm{d}\tau$ is differentiated electronically with a time constant τ (so that the flux $F(t)$ is average of the energy arriving during time τ).

In fact, for a single crystal of barium titanate:

$$V_0 \simeq 980\int^t F(\tau)\mathrm{d}\tau.\text{V. (for } F(t) \text{ in W. cm.}^{-2})$$

For a time constant of 5 µsec., taking typical electronic noise the minimum detectable flux is about 100 µW. cm.$^{-2}$, but with longer time constants the pyroelectric detector can be very sensitive, especially when operated close to the Curie point[4].

Experimental work carried out confirms equation (2) and indicates that reproducible results may be obtained if sufficient time (~20 sec.) is allowed for the temperature of the detector to return to ambient between radiation pulses. It also shows that the upper frequency response is limited by the excitation of mechanical resonances by thermal expansion, rather than by any thermal time constant. Fig. 3 shows the radiation flux obtained with a 5 µsec. time constant from a high-temperature gas discharge[5]. When an equivalent spectral region was used identical results for the flux profile were obtained with photomultipliers; however, since a standard source was not available, the device has not been directly calibrated. The dimensions of the ferroelectric (which in this case

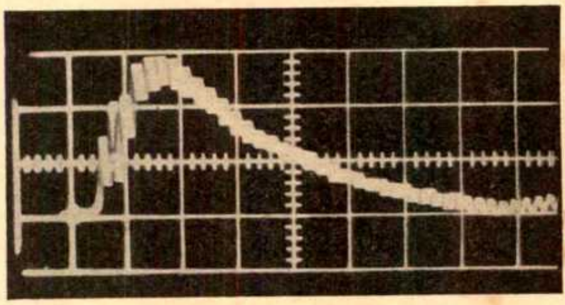

Fig. 3. Radiation flux $F(t)$ from a pinched discharge. Time base, 20 µsec./large division, and time constant, 5 µsec. (Note the superimposed oscillations at 230 kc./s. due to a mechanical resonance)

was a block of ceramic) were 1·0 cm. × 0·5 cm. × 0·125 cm. with radiation falling on the 1·0 cm. × 0·5 cm. face, and a resistance of R = 100 MΩ gave an RC time constant of 0·5 sec. (that is, $\gg\tau_2$). The oscillation at 230 kc./s. seen in Fig. 3 corresponds to a resonant mode of the 1 cm. length of the ferroelectric and, in this case, limits the high-frequency time constant to about 5 μsec. Since equation (2) is independent of the dimensions of the unit provided that the conditions on equation (1) hold, the size of the ferroelectric may be reduced so that resonant frequencies may be increased to give time constants of better than 1 μsec. When ceramic barium titanate is used, other electrode arrangements are possible, for example, electrodes on the edges hold some advantages[3]. These results will be published in detail elsewhere.

This type of detector, besides having a fast response, is very simple to use and manufacture, since it requires no complicated current supply and there is negligible Joule heating. Outputs proportional to both $F(t)$ and $\int^{t} F(\tau)d\tau$ can be obtained. Since the ferroelectric is also piezoelectric, care has to be taken to avoid acoustic pick-up (by placing in vacuum), but it should be a useful instrument where large, short-duration energy fluxes are available, in particular, since (due to the surface black) it has a uniform spectral response, for measurement of radiation losses in controlled thermonuclear research, or in measurement of radiation from explosions, etc.

An Anisotropy Effect in Diffusion under Electric Field

TRACER and self-diffusion investigations under electric field of Li⁺, Na⁺, K⁺, Rb⁺ and Cs⁺ ions in fused alkali nitrates[1], as also in aqueous-agar gel media[2], revealed an asymmetry in their spatial distribution following migration: corresponding data for diffusion in the absence of field showed no asymmetry. Present initially as a narrow zone, 2–5 mm. wide, at the origin, the band migrates 30–50 cm. in the field direction, depending on the intensity and the duration of the applied field; the actual displacement of the centre is a measure of the ionic mobility. A plot of the ion concentration as a function of the distance from origin is sensibly Gaussian with a pronounced skew, the arm in the field direction being more precipitous (Fig. 1).

The asymmetric spread implies an anisotropy effect in the Brownian displacements, and hence, unequal diffusion-rates D_1 and D_2 in and against the field direction, the values being in order of magnitude:

$$D_2 > D_1 > D_0$$

where D_0 corresponds to symmetric diffusion in the absence of field. The relative difference in the diffusion coefficients $(D_2 - D_1)/D_0$ depends on the nature of the ion and its atmosphere. This increases with the intensity and the duration of the field applied and decreases with rise of temperature.

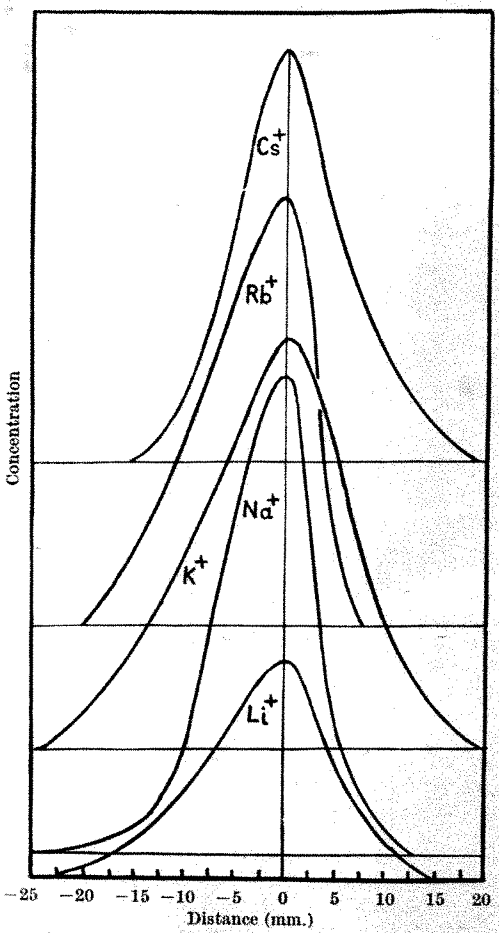

Fig. 1. Concentration distribution of alkali ions following diffusion in fused sodium nitrate at 350° under electric field of 7–10 V./cm., replotted with the zero of the concentration axis displaced to avoid overlapping

The theory of electrodiffusion due to Simnad[3], Lamm[4], Mysels[5,6] and Kauman[7] anticipates an accelerated diffusion, given by:

$$D_e = D_0 + U^2E^2/2k$$

where U is the product of ionic mobility and charge, E the intensity of the field and k a rate constant. The finding that D_0 the diffusion coefficient in the absence of field is invariably less than either D_1 or D_2 is in agreement with this deduction. The theory, however, applies mainly to electrodiffusion of a 'front' of a column of uniform initial concentration where Brownian displacements in a direction reverse to the field are indistinguishable, being behind the 'front'. This is unlike the present work, where the spread of the initial 'zone' is measured in both directions and found to be unequal. This necessitates a further correction, ± δ to the electrodiffusion term D_e, operative in the two directions, namely:

$$D_1 = D_e - \delta$$
$$D_2 = D_e + \delta$$

Though Mysels has considered the case of diffusion from a plane surface[6], the treatment does not include the asymmetry effect reported here.

A simple interpretation of the correction ± δ suggests unequal relaxation times for the completion of the atmosphere around the ion, diffusing in and against the field direction, out of the ionic residua, and that the proportion of these residua is different for ions of same sign but diffusing in opposite directions with respect to the field. It is significant that the asymmetry is reversible with the field direction, and is absent under alternating fields[2]. The idea of unequal time-lags for an ion of a given sign in occupying 'holes' available in and against the field direction is distinct from the difference in the 'free-state' average lives of ions of opposite signs implied in earlier theory.

Yield Stress exerted on a Body immersed in a Bingham Fluid

Boardman and Whitmore[1] have described experiments in which the yield stress in a suspension is measured from the force exerted on a rectangular body which is immersed in the suspension and which has come to rest. They find that the force on the body due to the yield stress depends on the orientation of the body, which it should not, and that this dependence can be expressed by assuming a horizontal-face yield stress about five times the vertical-face yield stress.

From my experience of the flow of suspensions[2,3] I would assume that the boundary over which the yield stress acts is not the surface of the body, but that there is a large quantity of 'solid' suspension above and below the rectangular body acting as part of the body, and that the yield stress is operative over the surface of this much greater area. The reason that this extra 'solid' part of the immersed body exists is probably because the suspension has both a dynamic and a static yield value[2,3]. If the static yield value exceeds the dynamic yield value (with my suspensions of titanium oxide in paraffin it was about 50 per cent greater) and as some of the suspension above and below the rectangular body could be imagined to be brought into action only by shear forces exerted by flowing suspension, then it is clear that a certain amount of the suspension will remain 'solid' in contact with the body.

From the results of Boardman and Whitmore it is apparent that the effective area of the 'solid' suspension above the immersed body is about five times the area in which it is in contact. It can also be assumed that the dynamic yield value is about 29 dynes cm.$^{-2}$, the value found for vertical faces. This can be expected to be less than the value found by assuming a Bingham relationship, owing to the curvature of the shearing-stress/rate of shear curve near the rate of shear axis[3].

LIKE Dr. Rae we too thought that the shear was probably taking place over an envelope of fluid surrounding the immersed body and we carried out some simple visualization experiments in order to detect the shell[1]. The indications were that although an appreciable decay in the rate of shearing occurred near the body there was no sharp envelope. This may have been because our static yield stresses were always less than the dynamic values, even when allowance had been made for curvature of the shearing stress/rate of shear curve near the rate of shear axis[2].

METALLURGY

Growth of Aluminium Whiskers by Vapour Condensation

WHISKERS of volatile metals such as zinc[1,2] and cadmium[2,3] have been grown by vapour condensation methods; but whiskers of other metals have mostly been produced by chemical reduction[4,5]. Aluminium presents particular problems because its compounds are resistant to reduction and because the vapour pressure at its melting point is very small (by extrapolation $1{\cdot}0 \times 10^{-43}$ mm. mercury). At higher temperatures where there is an appreciable vapour pressure the metal is extremely reactive, and even contact with alumina leads to the formation of a sub-oxide. The work reported here shows that it is nevertheless possible to produce aluminium whiskers by a vapour condensation method using high supersaturations.

A growth-chamber of recrystallized alumina, consisting of a 2-c.c. cylindrical crucible inverted on a dish, was contained in a graphite susceptor and supported inside a demountable silica envelope. In the chamber was placed a 0·3-gm. pellet of zone-refined aluminium (resistivity ratio $R_{293^\circ\text{K.}}/R_{4{\cdot}2^\circ\text{K.}} > 11{,}000$); the envelope was evacuated and pumped continuously. High-frequency heating was applied to the susceptor from a work-coil outside the envelope, thus maintaining the lower part of the growth chamber at a temperature of about 1,250° C. for 1 hr. At equilibrium there was a vertical temperature gradient of about 600° C./cm. in the chamber. Although whiskers have been grown at argon pres-

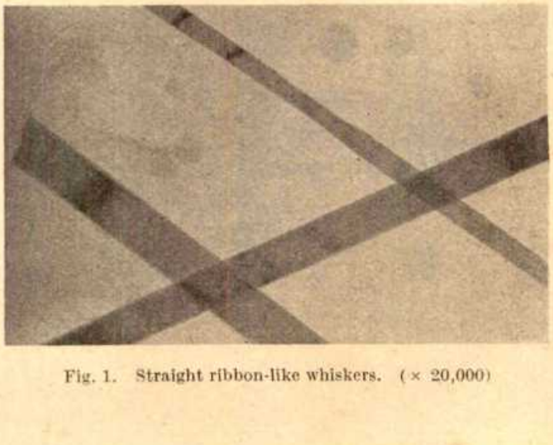

Fig. 1. Straight ribbon-like whiskers. (× 20,000)

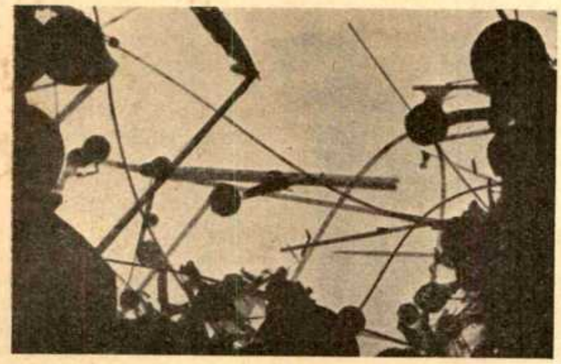

Fig. 2. Coagulated group of whiskers, many with attached balls. (× 4,000)

sures of about 10^{-1} mm. mercury, uncontaminated whiskers have so far been grown only when an evacuated sealed growth-chamber was used. This result led to the particular design of chamber adopted. When molten, the aluminium itself acts as a liquid seal between the crucible rim and dish; it seems likely that the first material evaporated getters any residual gases in the chamber.

At a position where the temperature was favourable, whiskers and ferns grew on the wall of the crucible. Whiskers 300μ in length and up to 20μ in diameter have been found, but many are sufficiently thin to be transparent in the electron microscope (Fig. 1); electron diffraction has shown that they are single crystals.

Each whisker grows with a ball at its tip (Fig. 2), and these balls are believed to be an essential feature of the growth process. Branched whiskers with many balls are quite common, but these tend to be brittle; straight whiskers are very elastic. The whiskers necessarily grow under conditions of extreme supersaturation; the growth mechanism and their properties are being studied and detailed results will be reported later.

I thank J. H. Burrow of the University of Bristol for constructing the silica-ware, and G. Blankenburgs for operating the electron microscope.

Note added in proof. It has just been found that other workers[6] have mentioned the growth of aluminium whiskers by vapour condensation at low pressures in a field emission tube.

CRYSTALLOGRAPHY

Epitaxial Growth of Condensed Aromatic Polycyclic Compounds

The epitaxial growth of thin crystalline films vacuum evaporated on a surface of single crystal is a very common phenomenon nowadays. However, the materials used so far have been mostly restricted only to metals or inorganic compounds. Recently, being concerned with the semiconductor behaviour, vacuum-evaporated films of various kinds of condensed aromatic polycyclic compounds have been often dealt with by many investigators[1]. In the course of electron microscopy and diffraction study of vacuum-evaporated films of those organic materials including metal phthalocyanine, anthanthrone, indanthrone, flavanthrone, pyranthrone, violanthrone and iso-violanthrone, we have found that the epitaxial growth also preferably occurred when those materials were condensed on to a cleavage surface of muscovite crystal, the temperature of which had been raised to an appropriate extent.

In the work reported here, about 2 mgm. of each dye-stuff, which had been originally very fine powder, was evaporated vertically on to a fresh cleavage surface of muscovite (1 in.^{2}) very slowly from a small crucible of fused quartz heated by an electrical furnace in an evaporator, the vacuum of which was about 7×10^{-5} mm. mercury. The substrate crystal had been preheated up to the temperature just below the sublimation point of each compound, which was mostly in a range of 300–400° C. At much lower temperature, the epitaxial growth seemed not to be preferred and the films were composed of small particles, the size of which was about 300 Å. or much less in diameter, quite similar to that condensed on a glass surface. The film thus prepared could be easily detached from the substrate crystal and floated on a clean surface of pure water without any apparent destruction of the film structure as a whole. The specimen for electron microscopy and diffraction study was prepared by placing the floating film on a specimen grid covered with a supporting film of vacuum-evaporated carbon in the ordinary way.

Figs. 1 and 2 show the electron micrographs of condensed films of platinum phthalocyanine and copper phthalocyanine, respectively, together with the corresponding electron diffraction patterns. The film structure of both compounds is not uniform

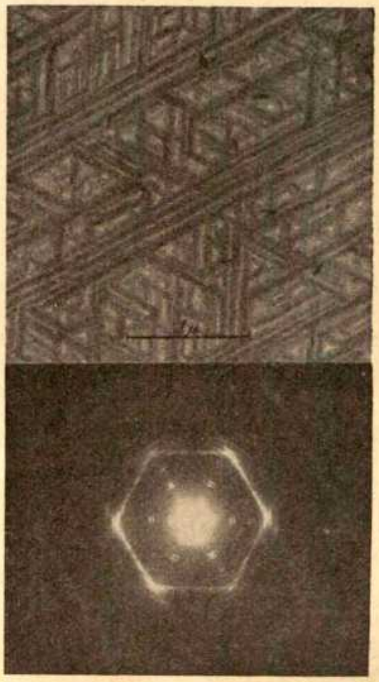

Fig. 1. Vacuum-evaporated film of platinum phthalocyanine on muscovite

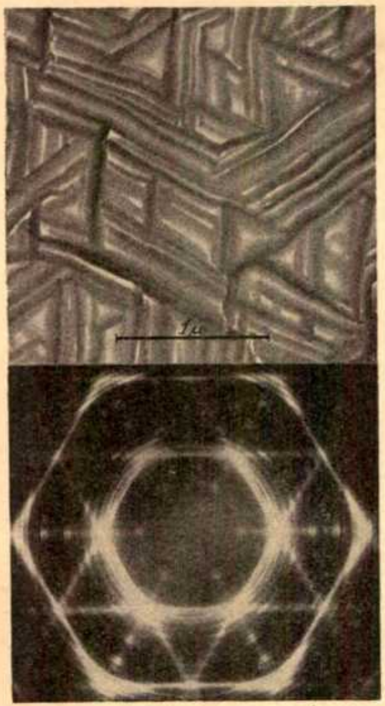

Fig. 2. Vacuum-evaporated film of copper phthalocyanine on muscovite

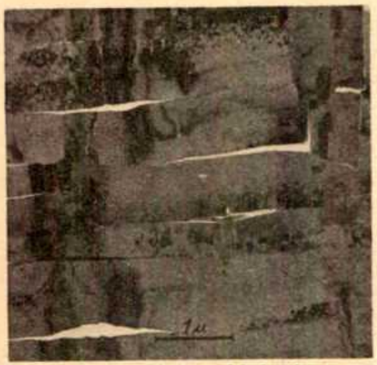

Fig. 3. Vacuum-evaporated film of indanthrone on muscovite

but takes the form of labyrinthine networks composed of long and narrow crystal lamellæ of varying lengths and widths. In the case of platinum phthalocyanine, the elemental crystal strip is rather straight, and at several places very slender ones run parallel in the same direction, while in the case of copper phthalocyanine, it is somewhat twisted. The crossing angle of the elemental crystal strip is mainly 120° in both cases; but in some cases it is locally about 75° for the film of copper phthalocyanine. This can be also confirmed by each electron diffraction pattern, which also evidently indicates the existence of preferred orientation of these organic crystal films.

The diffraction patterns are quite similar to each other, being composed of the three superimposed identical fibre patterns, the meridians of which meet one another at an angle of 120°. The fibre periods along the meridian are 3·77 Å. and 3·79 Å. for copper and platinum phthalocyanines respectively. Furthermore, two series of diffraction spots co-exist on each equator, suggesting that the original films both contain two sorts of lamellæ which differ in crystal habit though their longer axes run in parallel. This is similar to that of the stable β-phase of copper phthalocyanine assuming the 'raft structure' as has been reported in previous papers[2]. These series of reflexions on the equator correspond to the interplanar spacings of 12·99 Å. and 12·09 Å. for copper phthalocyanine and 13·13 Å. and 11·97 Å. for platinum phthalocyanine. Analysis of overall diffraction spots for copper phthalocyanine has revealed that the crystal film assumes the unstable α-phase of its polymorphic modifications. The resemblance of the diffraction pattern to platinum phthalocyanine suggests the similar phase, the existence of which has not so far been reported.

So far as the relative lattice orientation of both films to the substrate crystal is concerned, the equator of one of the elemental fibre patterns is fixed to be in parallel to the *b*-axis of muscovite.

Other condensed aromatic polycyclic compounds also assume preferred orientation on the surface of muscovite when prepared by the same method. Most of them assume one-directional orientation, except zinc phthalocyanine, which shows two-directional orientation. As for the shape of elemental crystal composing the film, pyranthrone, flavanthrone and indanthrone give rise to straight, long and narrow crystals, whereas violanthrone and iso-violanthrone make somewhat wavily twisted ones. Nickel, tin and zinc phthalocyanines contain very small crystal flakes having varying contrasts and indeterminate forms. Particularly in the case of indanthrone, elemental long and narrow crystals become very large and closely contact continuously to each other, showing a tendency to make up a thin single crystalline film as a whole, the electron micrograph of which is reproduced in Fig. 3.

GEOLOGY

Recent Dolomite in the Persian Gulf

A STUDY of recent carbonates in the Qatar area, Persian Gulf, is at present being made by the Koninklijke/Shell Exploratie en Produktie Laboratorium in the Netherlands, in association with V. C. Illing and Partners of London. This work has the work of Houbolt[1] as a background, and is concentrating particularly on the near-shore and intertidal sediments.

In lagoons around the Qatar Peninsula, which are especially numerous on the west side, salinities rise to 45–55 parts per thousand even when the tidal range is 3 ft. or more. On the lower parts of the tidal flats, carbonate sediment generally consists of about 80 per cent aragonite. The proportion of aragonite rises to 95 per cent or more on some of the algal flats just below the level of diurnal high-tide, where salinities of nearly 100 parts per thousand were recorded. This high concentration of aragonite, evidently the product of calcium carbonate precipitation out of

sea-water left in and on the tidal flat between tides, marks the beginning of the evaporitic environment.

Sediment on the upper parts of the broad tidal flats, between diurnal and spring or storm high tides, has been found to consist largely of dolomite and gypsum. In the lowest part of this zone, aragonite in the carbonate fraction progressively decreases landwards and dolomite appears and proportionately increases to about 60 per cent, when the sediment may contain several per cent of gypsum. Higher up, aragonite and calcite decrease sharply, to such an extent that the sediment may consist virtually of dolomite and gypsum. Salinity of the water in this sediment is of the order of 275 parts per thousand. In the highest part of the intertidal zone dolomite becomes subordinate and the sediment consists very largely of gypsum. All these tidal flat sediments contain, in addition, a variable proportion of wind-blown material (largely quartz silt) and halite (almost certainly dissolved again with each high tide).

It is apparent that the dolomite and gypsum have both been derived from sea-water left behind in the sediment on the upper part of the tidal flats and concentrated by evaporation during the time between spring or storm high tides, although it has not yet been established to what extent the dolomite is primary and to what extent it is a penecontemporaneous replacement of pre-existing carbonate. Laboratory experiments over many years have consistently failed to produce true dolomite by evaporation of sea-water at atmospheric pressure, so that any occurrence of recent dolomite is of considerable interest. What is of particular importance in this case is not only that it is found associated with evaporitic minerals at the end of a normal and apparently often-repeated marine carbonate cycle, but also that the scale on which it occurs is obviously of geological significance.

Origin of Ignimbrites

F. J. FITCH[1] has criticized a new hypothesis proposed by me[2] on the origin of ignimbrites of Pliocene to Pleistocene Age, from the North Island of New Zealand. The new petrogenetic concept is based on the presence of two contrasting glasses and their textural relationship, which suggest liquid immiscibility. It is emphasized that the presence of the two glasses can be observed in fresh ignimbrites only because both glasses undergo early selective crystallization. It is because of this crystallization of the glassy constituents that liquid immiscibility has not been recognized earlier. When both glasses have crystallized the ignimbrite contains no glass at all, although two glasses were present immediately on solidification of the rock. Many ignimbrites, particularly ancient ones, therefore, do not afford any evidence concerning the presence of two contrasting glasses and their textural relationship.

Fitch[1] argues the problem of two contrasting glasses on the evidence he obtained in studying Ordovician ignimbrites from North Wales, though he discusses also ignimbrites from New Zealand. His arguments to a great extent appear to be based on insufficient petrographic evidence. This is clearly demonstrated by his statement " . . . only rare quartz phenocrysts preserved within xenolithic obsidian lumps show that intricate resorption outline regarded by Steiner as evidence for gentle flow . . .". The fact is that in New Zealand ignimbrites quartz phenocrysts are commonly abundant, and that in some ignimbrites they are absent. In numerous ignimbrite sheets they occur in the groundmass made up entirely of glass shards and mesostasis. No obsidian xenoliths are present in these rocks. It is these quartz phenocrysts occurring in the groundmass that have been taken by me as supporting evidence of emplacement by flow.

In fresh pulverulites the groundmass consists of glass shards or stream-lined shreds and the intervening glassy mesostasis of different refractive index and colour. One should not confuse these two contrasting glassy phases with the multi-coloured shards and shreds which are present in many ignimbrites and have the same refractive index. If angular or rounded xenoliths of various volcanic and sedimentary rocks are present they show invariably sharp boundaries, and no re-melting or resorption is noticeable. Occasionally, pumiceous xenoliths, always well rounded and more or less flattened, can be observed. These pumiceous xenoliths also show no re-melting or resorption, but they are usually partly or completely crystallized. Thus, so far as the pulverulites are concerned, there is obviously no need for invoking xenolithic origin for any of the two contrasting glasses.

So far as fresh lenticulites are concerned, it is important to distinguish between the rounded pumiceous xenoliths and the common lenticles and shreds, both having characteristically ramifying ends. These ramifying lenticles and shreds are not accidental but primary constituents of these rocks. The lenticles, shreds and the shards, all made up of the same glass, are enclosed by a second glassy phase, that is, the mesostasis. They make up the bulk of the rock. The ramifying lenticles and the larger shreds show gradational separation into glass shards and mesostasis, and a chilled globular emulsion can commonly be seen in the lenticles. The emulsion consists of small immiscible globules of one glass suspended in a glassy base of different refractive index and colour, and should not be confused with the granular mesostasis. The globular emulsion forms also inclusions in plagioclase phenocrysts, and evidently indicates that the magmatic liquid, caught up by the growing crystal, separated, like the bulk of the residual liquid, into two immiscible liquids.

The occurrence of immiscible globules is considered to be a significant evidence of liquid immiscibility. The occurrence of such a chilled emulsion has been recently described by Hjelmquist[3].

No xenoliths identical with or even slightly resembling the mesostasis have been noticed in any of the ignimbrites from New Zealand studied by me, although I examined several hundred ignimbrite samples from numerous localities covering the whole Taupo volcanic zone. There is no evidence that the ignimbrite magma resorbed xenoliths of older ignimbrites and tuffs. Thus, Fitch's criticism opposing the operation of liquid immiscibility is in disagreement with the petrographic evidence afforded by fresh lenticulites and ignimbrites in general. Moreover, to ascribe the origin of a common volcanic rock type, such as ignimbrite, to decomposition of accidental xenoliths, which of necessity would be required to form the bulk of the rock, appears to be highly improbable, if not impossible.

It is significant that none of the countless witnessed nuée ardente eruptions has ever produced an ignimbrite and that the deposits produced by witnessed nuée ardente eruptions differ essentially from fresh ignimbrites. The inconsistencies of the nuée ardente hypothesis[2] suggest that the mode of emplacement of ignimbrites is of fundamentally different type from that of the nuée ardente. On the other hand, the operation of liquid immiscibility explains satisfactorily the textural features of the ignimbrites, and their mode and mechanism of emplacement.

A. STEINER

New Zealand Geological Survey,
Lower Hutt, New Zealand.

[1] Fitch, F. J., *Nature*, **190**, 995 (1961).

[2] Steiner, A., *N.Z. Geol. Surv. Bull.*, n.s., 68 (1960).

[3] Hjelmquist, S., *Geologiska Föreningens Förhandlingar*, **83** (2), 198 (1961).

THE hypothesis that ignimbrite sheets are formed as a result of the eruption of a special kind of acid magma, which develops two immiscible liquid fractions on eruption, is strongly defended by Steiner. He rejects the objections raised in my criticism of his work[1], and repeats much of his original argument[2]. Steiner's hypothesis rests on a fundamentally different interpretation of the textural relationships seen in ignimbrites from that made by the majority of petrologists. Having proved that two contrasting glasses are present as recognizable phases in one ignimbrite, Steiner then assumes that the detailed textural pattern of all ignimbrites can be explained on the basis of this observation. Statistically convincing proof of the assertion that two contrasting phases are present in all ignimbrites is not given, and the volume difficulties inherent in his hypothesis are not considered.

The vast majority of the phenocrysts seen in ignimbrites are broken and abraded, whatever their composition, and Steiner's denial of this fact must throw doubt on his whole philosophy of petrographic interpretation. Without pursuing these differences, however, it is obvious that valid petrological hypothesis cannot be based on petrographic evidence alone, and, if they are to be accepted, Steiner's views on the origin of ignimbrites must withstand a field examination of the rocks. Again we find that the majority of field geologists have arrived at conclusions, regarding the origin of ignimbrites, fundamentally different from those suggested by Steiner's petrographic interpretation. The ash-flow hypothesis is now almost universally accepted on the basis of overwhelming field evidence, amply catalogued by such workers as Enlows[3], Martin[4], Ross and Smith[5], and many others.

One fact alone will illustrate the difference between Steiner's interpretation and those of other petrologists. He asserts that the lenticles and shreds having characteristically ramifying ends, common in many ignimbrite specimens, have a different origin from the rounded pumiceous inclusions seen in other examples. Though this may be so in some rare instances, field evidence indicates that in the vast majority of cases the lenticles are undoubtedly flattened and welded pumice lumps identical in origin to the rounded unwelded pumice lumps present in the unwelded parts of the same ignimbrite sheet. The transition from rounded to flattened pumice lumps in the same sheet can be observed in the field, and to deny it must only reveal a failure to make a thorough field examination of the rocks investigated.

The field evidence undoubtedly supports the hypothesis of collapse and welding for the production of the internal structures and textures of ignimbrites (see the references quoted by Ross and Smith[5]). In the face of the field evidence it is just not possible to accept Steiner's interpretation of the evidence available. The possible alternative origins for the contrasting glass phases seen in some ignimbrites, put forward in my criticism of Steiner, may not be applicable to all cases, but they suggest a more likely explanation of the facts than does his hypothesis. In this connexion, work on the presence of contrasting glass fractions in ignimbrites by Williams[6] is of interest.

Relationships of Fauna and Substratum in the Palæoecology of the Chalk and the Chalk Rock

AN investigation of the palæoecology of the Chalk Rock of south-central England (Oxfordshire–Hertfordshire) has led me to believe that the most important difference between the Chalk Rock and normal Chalk environments was in the nature of the substratum.

The normal Chalk environment was presumably of soft-bottom type, with the bottom consisting of unlithified chalk-mud. The Chalk Rock, in contrast, marks hard-bottom conditions. Its general lithological features in the area examined, where a single main rock band is typical, are related to three occurrences: (*a*) penecontemporaneous lithification of chalk sediment; (*b*) erosion, with production of irregular surfaces and of pebbles of lithified sediment (so-called 'nodules'); (*c*) phosphatic and glauconitic impregnation of exposed erosion surfaces and pebbles, presumably hardening them further. Lithification of sediment before erosion is implied by its ability to form pebbles, and by the occurrence of reworked fossils of which, for example, molluscan examples include sharp internal moulds with the shell lost. An encrusting fauna (for example, serpulid and spirorbid worms, cyclostome and cheilostome Bryozoa, *Spondylus latus* (J. Sowerby), *Ostrea* sp.) found on erosional surfaces and pebbles proves their status as actual features of the bottom. At maximum departure from normal Chalk conditions, the bottom was a hard current-scoured surface, with vertical relief of up to 15 cm. or more due to small-scale erosional pocketing. Later, erosional hollows were filled with new sediment, resulting in close association of both hard and soft sub-strata.

The effect of a change to hard-bottom conditions on members of the normal Chalk benthos will have varied according to their habits in relation to substratum Chalk benthos generally comprises forms adapted to two distinct types of sub-stratum, in summary as follows:

Group A. Soft-substratum elements, living on or in the general chalk sediment: (*a*) surface group: (i) active, including asteroids, some echinoids (for example, *Cidaris*), some lamellibranchs (for example, *Plagiostoma, Syncyclonema*), most gastropods, most non-planktonic foraminifera, plus (ii) sedentary: rhizophytous or lophophytous sponges (for example, *Leptophragma, Guettardiscyphia, Porochonia, Oncolpia, Ventriculites; Rossella*), some other forms, for example, *Spondylus spinosus* (J. Sowerby); (*b*) sub-surface group: burrowing echinoids (for example, *Micraster, Holaster*), some lamellibranchs (for example, *Nucula, Nuculana*), *Dentalium*, some gastropods (‘*Natica*’, *Aporrhais*).

Group B. Hard-substratum elements, cemented or attached in other ways to hard skeletal bodies (for example, echinoid tests, brachiopod or lamellibranch valves, calcareous or siliceous sponge frameworks): (i) cemented: adherent Foraminifera (for example, *Bullopora*), basiphytous sponges (for example, *Farrea, Eurete*), corals (for example, *Parasmilia*), encrusting Bryozoa (for example, *Berenicea*), serpulid and spirorbid Annelida, *Crania*, cemented lamellibranchs (for example, *Ostrea, Dimyodon, Spondylus latus*); and (ii) attached organically: articulate brachiopods (for example, *Cretirhynchia, Gibbithyris*), byssally attached lamellibranchs (for example, *Arca, Septifer*).

Benthos from the normal Chalk consists typically of members of both main faunal facies. Replacement of the normal soft bottom by an altogether hard one will presumably have led to disappearance of most of the soft-bottom benthos, and certainly of sedentary and burrowing forms which could only inhabit soft sediment. But hard-substratum elements, in contrast, could have spread to the bottom itself; in practice, its colonization by cementing forms at least is confirmed by their occurrence on erosional surfaces and pebbles. Abundance of soft-bottom elements in the nodular top of the rock is likely to mark their reappearance during filling of erosional hollows by new sediment. Rhizophytous sponges, the scaphopod *Dentalium*, and probably the echinoid *Micraster*, are examples which can only have lived when such sediment was available.

This communication is an outline of part of the results of an investigation carried out at University College, London, during 1951–54, when I held a research studentship from the Nature Conservancy, under supervision by Dr. T. Barnard. I thank Prof. S. E. Hollingworth for providing facilities.

RADIATION CHEMISTRY

Polymer Production in the Radiolysis of Liquid Cyclohexane

THE radiolysis of cyclohexane gives cyclohexene and bicyclohexyl as the major liquid products[1], the G values of which decrease with dose at low dose-rates or high doses[2]. The formation of a ‘polymer’ (defined here as a substance containing three or more cyclohexane units) has been reported at a low dose-rate and high dose[3], but several other investigations, carried out over a wide range of dose-rate and dose conditions, indicate that no products above C_{12} hydrocarbons are formed[1,3–5].

We have irradiated liquid cyclohexane at ambient temperature (about 20° C.) with cobalt-60γ at a dose-rate of $1{\cdot}2 \times 10^{17}$ eV./min./gm. After being analysed for cyclohexene and bicyclohexyl (by gas liquid chromatography), samples were evaporated to constant weight in a vacuum desiccator using a water pump. This procedure removed cyclohexane and the more volatile products and the residue contained less than 2 per cent by weight of bicyclohexyl. The yields of the products together with the sum of the three yields (total) are plotted against absorbed dose in Fig. 1. The experimental points are omitted for the sake of clarity. The variation of the overall $G(C_6H_{12} \longrightarrow \text{polymer})$ with dose is shown in Fig. 2.

The samples of polymer (usually 50–100 mgm.) were redissolved in 1 ml. cyclohexane and analysed on a 1 m. silicone grease column at 200° C.: these gave two major peaks and at least five minor ones which, from their elution times, were assumed to be

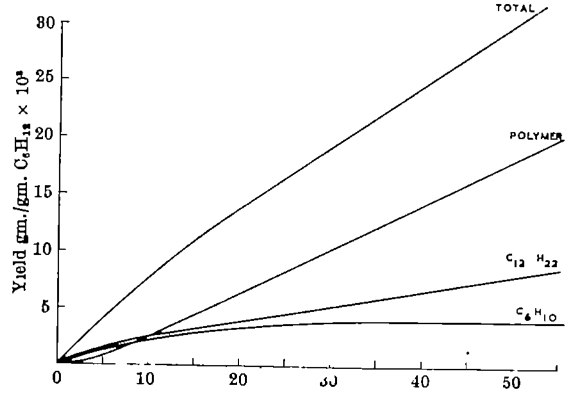

Fig. 1. Product yields versus dose

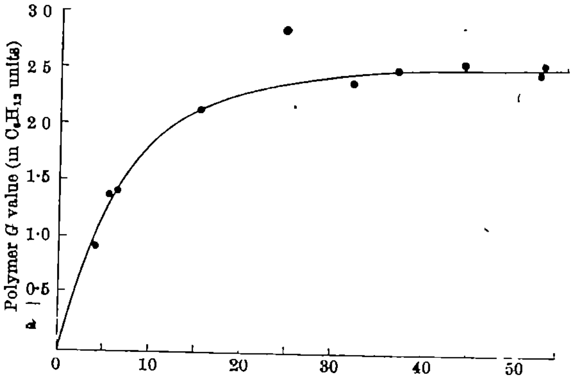

Fig. 2. Polymer G value versus dose

C_{18} hydrocarbons. The variation with dose of the percentage by weight of the C_{18} fraction in the polymer is shown in Table 1. Analysis on the same column at 324° C. gave a diffuse shoulder where C_{24} hydrocarbons eluted. A mass spectrum of the polymer formed at the highest dose indicated the presence of hydrocarbons up to C_{30} (the maximum of the mass range scanned) and the cracking pattern was characteristic of cyclohexyl ring compounds. Although the polymer seemed quite stable in cyclohexane solution, if left exposed to the air for several days, it did not completely redissolve in cyclohexane, giving a white precipitate (cf. ref. 3). These observations indicate that the polymer formed on radiolysis of liquid cyclohexane is a secondary product consisting of a complex mixture of six membered ring hydrocarbons, the molecular weight of which increases with dose.

Table 1. FRACTION OF C_{18} IN POLYMER

Dose eV./gm. × 10^{-20}	Percentage by weight of C_{18} in polymer
5·4	23·7
32·1	14·2
44·4	9·5
52·7	10·8

The following conclusions can be drawn from Fig. 1. The G values of cyclohexene and bicyclohexyl decrease with dose up to an 'equilibrium' dose beyond which the net $G(C_6H_{10}) = 0$ and $G(C_{12}H_{22})$ maintains a constant value. G(polymer) increases from zero at zero dose (Fig. 2) to a constant value. These facts can be explained by the reaction scheme

$$C_6H_{11} + C_6H_{11} \longrightarrow C_6H_{10} + C_6H_{12} \quad (1)$$

$$C_6H_{11} + C_6H_{11} \longrightarrow C_{12}H_{22} \quad (2)$$

$$C_6H_{11} + C_6H_{12} \longrightarrow C_6H_{12} + C_6H_{11} \quad (3)$$

$$C_6H_{11} + C_6H_{10} \longrightarrow R_1 \quad (4)$$

$$R_1 \quad + C_6H_{10} \longrightarrow R_2 \quad (5)$$

Reactions (1) and (2) have been postulated by Dewhurst[1], reaction (3) should be important at this dose-rate from the work of Schuler and Muccini[6], and reaction (4) has been suggested by Dyne[2]. Further addition of radical R_1 to a cyclohexene molecule has been postulated to account for the C_{30} hydrocarbons found in the polymer. It is envisaged that the polymer is formed by ultimate disproportionation and combination of radicals such as R_1 and R_2. These radicals may also react in a manner analogous to reaction (3), but not exclusively so, since this would form a fully saturated polymer, which does not seem to be the case. It should be noted that reactions of radicals such as R_1 and R_2 may give rise to all secondary products, not just those found in the polymer. Thus cyclohexyl cyclohexene, characterized as a secondary product by Dyne[7], could arise from disproportionation of two R_1 radicals.

Irradiations with a pulsed X-ray beam of instantaneous dose-rate = 4·2 × 10^{20} eV./min./gm. gave $G(C_6H_{10})$ and $G(C_{12}H_{22})$ both independent of dose over the limited range studied (up to 5 × 10^{20} eV./gm.) and no polymer formation. It can be shown kinetically that this is due to the preponderance of reactions (1) and (2) over reactions (3) and (4), in contrast to the low dose-rate irradiation. This is in agreement with the dose-rate effect noted in refs. 2 and 6.

Initial values of $G(C_6H_{10})$ and $G(C_{12}H_{22})$[7] give a composite value of G = 7·2 expressed in cyclohexane units, whereas the straight-line portion of the total yield plot in Fig. 1 gives G = 3·9. Thus there is a decrease of about a half in the total decomposition of cyclohexane (based on the yields of these three products) on going from zero dose to about 1·5 × 10^{21} eV./gm. From the shapes of the curves in Fig. 1 it seems likely that cyclohexene is the product responsible for this decrease. It cannot be attributed to a scavenging effect of cyclohexene since we have already taken account of this in the polymer yield. It could be explained as a quenching of excited cyclohexane molecules by cyclohexene, with very little chemical decomposition of the resulting cyclohexene molecule.

Effect of γ-rays on Thymine in De-aerated Aqueous Solutions

IT is well known that X-irradiation of the pyrimidine bases in aqueous solutions in the presence of oxygen causes peroxidation at the position of the 4–5 double bond[1,2]. It has been established, however, that in the absence of oxygen this reaction does not take place, and that the destruction of the bases is considerably reduced. This communication is concerned with the identification of the products formed under these latter conditions. γ-Irradiated de-aerated solutions of thymine subjected to ion exchange column chromatography ('Dowex 50 H^+') showed two peaks, the second of which has been identified as unreacted thymine (Fig. 1*B*) and the first presumed to contain the products of radiolysis (Fig. 1*A*).

The fractions in section *A* were collected, lyophilized and subjected to descending paper chromatography. The solvent system consisted of propanol/water (10 : 3). Subsequent detection with ultraviolet light (2537 Å.) showed a single spot I (R_F = 0·46) which on elution had an ultra-violet absorption spectrum (at different *p*H's) identical with that of hydroxymethyluracil (HMU)[3] (Table 1). When mixed with an authentic sample of HMU the product is inseparable by paper chromatography in several solvents or by ion exchange column chromatography. It is therefore suggested that one of the products resulting from γ-irradiation of thymine in de-aerated aqueous solution is hydroxymethyluracil (I) G = 0·1 (Table 2).

Since addition of radicals to the 4–5 double bond would render the compounds non-ultra-violet absorbing, Fink's technique[4] was used to identify such products. The paper chromatogram was sprayed with 0·5 *N* sodium hydroxide, then with a solution of paradimethylaminobenzaldehyde, which reacts to form a coloured complex with dihydropyrimidine compounds. Four coloured spots were thus obtained on the chromatogram of which three have been

Table 1. ULTRA-VIOLET ABSORPTION RESULTS

I	261	233	286	247

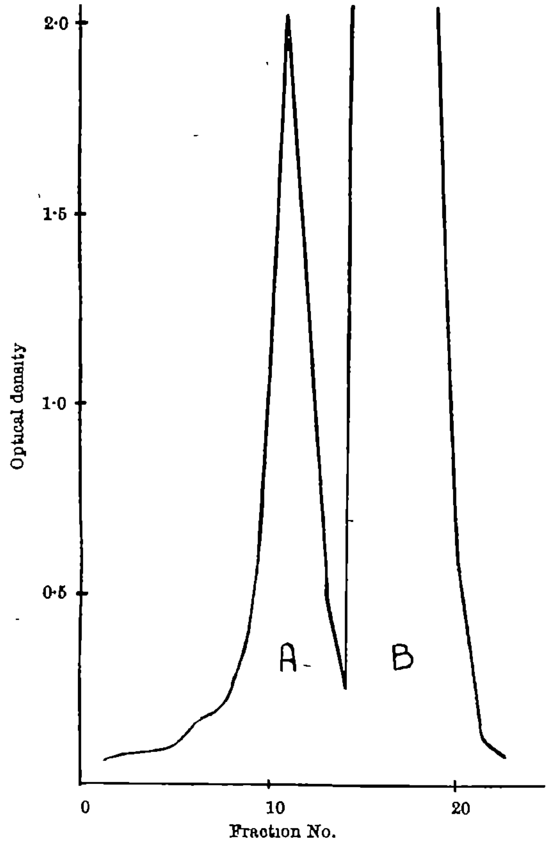

Fig. 1. Ion exchange chromatography of irradiated thymine solution 10^{-3} *M*, in water, 100 ml., irradiated in absence of oxygen at room temperature. Dose 250 kr. Chromatography on 'Dowex $50H^+$', 65 cm., elution with 0 5 *N* hydrochloric acid, at room temperature, fraction volume 3 5 ml./11 min., optical density at 260 mμ

positively identified as *cis* and *trans* thymine glycol (II and III) and dihydrothymine (IV) respectively.

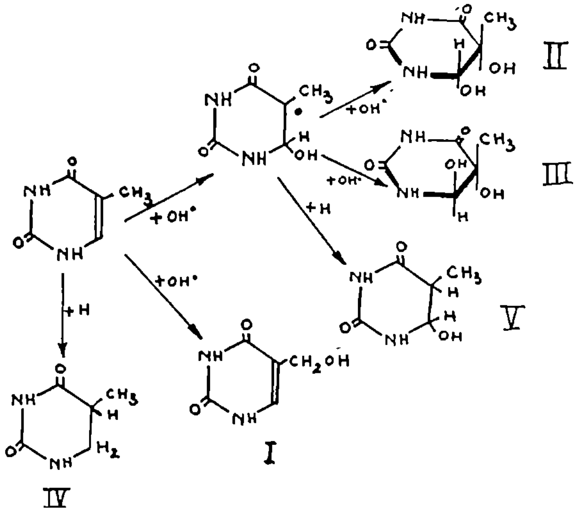
It is interesting to note that the spots of the two glycols showed a particular characteristic coloration which changes rapidly from yellow to pink and finally becomes blue. In general, most compounds of this type produce yellow spots. The chromatographic behaviour of II and III were identical with that of authentic *cis* and *trans* thymine glycol respectively (Table 2). (*Cis* thymine glycol was prepared by isomerization of the *trans* compound by heating at 100° C. for 4 hr.[5].)

Of the other two spots, which were of much weaker intensity, one was identified chromatographically with dihydrothymine. Under the conditions of this column separation this product was not completely separated from the unreacted thymine. This also occurred in control experiments on ion exchange separation of thymine and dihydrothymine.

Table 2. R_F Compounds on Paper Chromatograms

	n-Propanol/ water, 10 : 3	*n*-Butanol/ water, 86 : 13	Isopropanol/ water/conc. HCl, 65 : 18·3 : 16·7	Isobutyric acid/conc. NH_4OH/ water, 100 : 1·12 : 52	*n*-Butanol/ acetic acid/ water, 2 : 1 : 1
HMU	0 46	0·23	—	0·46	—
I	0 46	0·22	—	0·45	—
Glycol (*cis*)	0 44	0·20	0·72	—	0·45
Glycol (*trans*)	0 54	0·28	0 73	—	0·45
II	0·42	0·19	0·72	—	0 44
III	0·53	0·27	0·72	—	0 46
Dihydrothymine	0 68	—	—	—	0·67
IV	0 67	—	—	—	0·66
V	0 58	—	—	—	—
Thymine	0 70	0 47	—	0 73	—

The observed products can be explained by the following degradation of the thymine in de-aerated aqueous solutions (G = 0·65).



From the chromatographic behaviour (R_F = 0·58) it is suggested that the fourth non-ultra-violet absorbing product is V, but it has not yet been possible to synthesize this compound for actual comparison.

I thank Miss J. Conlay and Dr. R. Latarjet for their interest throughout this work, which has been supported by Euratom and by the Commissariat à l'Energie Atomique.

CHEMISTRY

Determination of Stability Constants in Molten Alkali Metal Nitrate Solvents

Most determinations of stability constants in alkali metal nitrate solvents have concerned the halide complexes of silver[1]. Recently the cryoscopic[2], solubility[3], polarographic[4], galvanostatic[5], spectroscopic[6] and e.m.f.[7] techniques have been used for investigating the formation of the halide complexes of various metals (for example, cadmium) in these solvents. A silver–silver bromide electrode has been used to study the bromo-complexes of cadmium and lead[7]. An attempt[8] to use the silver–silver chloride electrode in a similar way to study chloro-complexes was not successful.

The measurement of e.m.f.'s of suitable electrochemical cells should be the most precise and widely applicable technique for the determination of stability constants in these systems. In many cases it is necessary and desirable to determine free metal ion concentrations. Pure metal electrodes cannot be used because of the strong oxidizing properties of the solvents, except in the cases of the noble metals. The high temperatures involved (usually > ~ 200° C.) restrict the use of amalgam electrodes to the low-melting point solvents[9].

Various possible metal-ion sensitive electrodes have been tested in this work. That, finally, found to be satisfactory was an electrode of the third kind, involving palladium metal (which was not oxidized by the solvent) and a melt saturated with the stable sparingly soluble palladium monoxide and the oxide of the metal ion to be studied (for example, CdO). The experimental details of the electrode will appear elsewhere.

In the dilute solutions investigated in this work changes of e.m.f. of the cell:

$$\text{Pd} \mid \text{PdO, CdO, Cd}^{2+} - \text{NaNO}_3 - \text{KNO}_3 \mid$$
$$\text{NaNO}_3 - \text{KNO}_3 - \text{Ag}^+ \mid \text{Ag}$$

when the concentration of Cd^{2+} is varied, will be given by:

$$\Delta E = \frac{RT}{2F}\,\Delta \ln\,[\text{Cd}^{2+}]$$

$$\text{because } [\text{Cd}^{2+}] = k[\text{Pd}^{2+}]$$

where $[Cd^{2+}]$ and $[Pd^{2+}]$ are concentrations, k is the ratio of the oxide solubility products and the dotted line represents a thin 'Pyrex' glass diaphragm. Plots of e.m.f. versus $\log_{10}[Cd^{2+}]$ in the $NaNO_3$–KNO_3 (1 mole : 1 mole) solvent at 254° C. are shown in Fig. 1. The electrode satisfied the usual criteria of reversibility. Although the plots of e.m.f. versus $\log_{10}[Cd^{2+}]$ were always straight lines the slopes varied from ~ 54 to ~ 71 mV. This variation was probably due to the conjugate equilibrium $2O^{2-}-4e_0 \rightleftharpoons O_2$, involving traces of adsorbed oxygen on the palladium electrode. In practice it was more convenient to do a three-point metal ion calibration before each titration than rigorously to exclude oxygen from the system. The validity of this procedure is evidenced by the reproducibility of $\log_{10}\alpha_0/\log_{10}[X]$ plots (see later) obtained by using electrodes with different metal ion concentration responses.

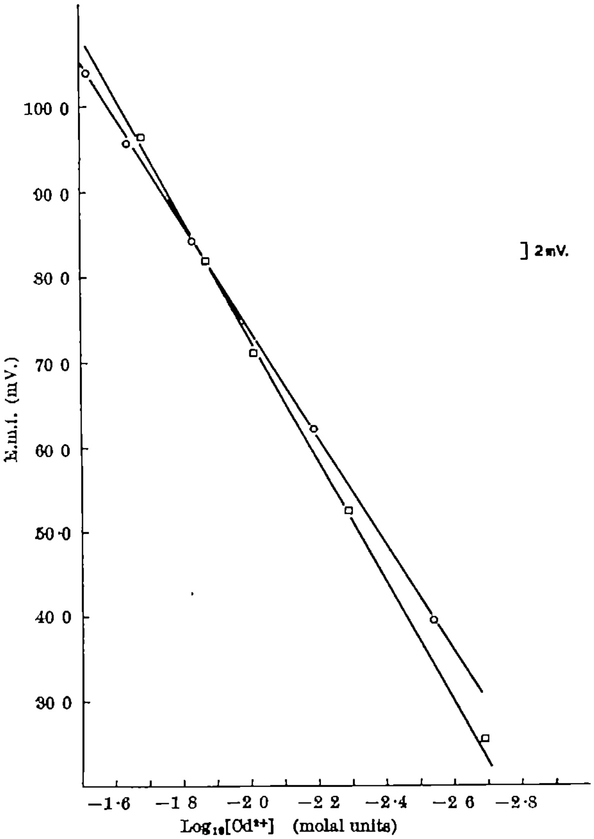

Fig. 1. E.m.f. versus $\log_{10}[Cd^{2+}]$. $NaNO_3$—KNO_3 (1 mole : 1 mole) solvent. T = 254° C. Run 37 ○; slope = 63·0 mV.; run 39 □; slope = 71·2 mV. (2·303 $RT/2F$ = 52·4 mV. at 254° C.)

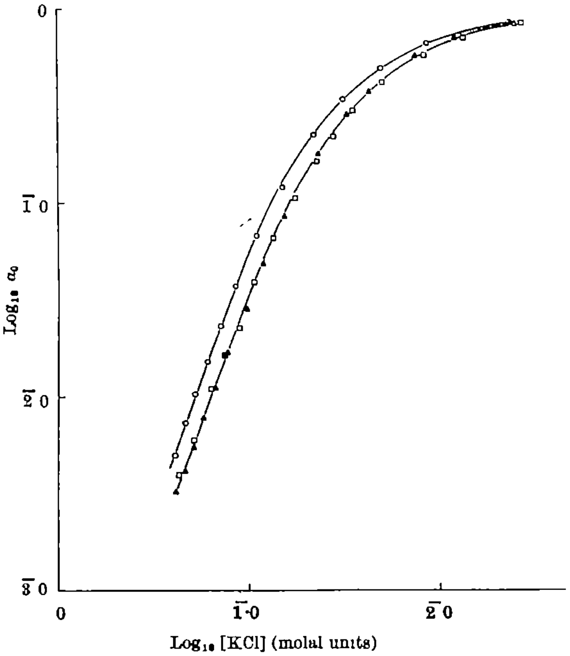

Fig. 2. $\log_{10}\alpha_0$ versus $\log_{10}$[KCl]. $NaNO_3$—KNO_3 (1 mole : 1 mole) solvent. T = 254° C. Run 49 ⊡, $[Cd(NO_3)_2]$ = 0·9892 × 10^{-2} mole kgm.$^{-1}$ ($\Delta E/\Delta \log_{10}[Cd^{2+}]$ = 58·0 mV.). Run 52 △, $[Cd(NO_3)_2]$ = 0 9896 × 10^{-2} mole kgm.$^{-1}$ ($\Delta E/\Delta \log_{10}[Cd^{2+}]$ = 54·8 mV.). Run 54 ○, $[Cd(NO_3)_2]$ = 1·961 × 10^{-2} mole kgm.$^{-1}$ ($\Delta E/\Delta \log_{10}[Cd^{2+}]$ = 57·8 mV.)

The data which are required to determine the stability constants of the chloro-complexes of cadmium in molten $NaNO_3$–KNO_3 at 254° C. have been obtained by measuring the variations of e.m.f. (to 0·1 mV.) during the titration of Cd^{2+} with Cl^- ions. Typical plots of $\log_{10}\alpha_0$ (where $\alpha_0 = [Cd^{2+}]/[Cd(NO_3)_2]$) versus $\log_{10}$[KCl] are shown in Fig. 2. A preliminary analysis by Leden's method[10] indicated that the stability constants were in agreement with the previously published data[5], which because of the limitations of the technique were necessarily less precise. These data will be further analysed using an electronic computer.

When the metal ion concentration was > ~ 2 × 10^{-3} mole kgm.$^{-1}$ the concentrations of free chloride ions were determined experimentally by using a silver–silver chloride electrode in the form of a coiled silver wire and a melt saturated with silver chloride. The high exchange current density of the silver–silver ion system in molten nitrate solvents[11] ensures the reversibility of the electrode down to low silver ion concentrations. The difficulties associated with the silver–silver electrode in the form of a coated wire[8] were not encountered. The rather large solubility product of silver chloride[12], however, restricts the applicability of this electrode.

Various complex forming mixtures are being studied and further details will be published later. I thank Dr. J. E. Prue for useful discussion and the

Isotope Separation by Electrodiffusion

AN enhanced diffusion process occurs when an electric field is superimposed on a diffusion experiment which is being carried out with a system composed of chemically interacting electrolyte species[1,2]. This phenomenon, known as electrodiffusion, resembles ordinary diffusion in its phenomenological manifestations. The process can be described mathematically by a differential equation entirely similar to Fick's second law:

$$\frac{\partial c}{\partial t} = \text{div}, (D_e \text{ grad}, c) \qquad (1)$$

where c, t and D_e represent respectively the concentration, time and the electrodiffusion coefficient, the characteristic parameter of the process.

In general D_e can be expressed as a function of the electrophoretic migration velocities, the concentrations of the various ions, the frequency of the electric field, ν, and the rate constants of the chemical reactions which occur between the various ions. In the particular case where the chemical reaction is a monomolecular interconversion of one ionic species only ($A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B$), the value of D_e is given by[3]:

$$D_e = \frac{E^2(u_A - u_B)^2 k_1 k_2}{2(k_1 + k_2)[\omega^2 + (k_1 + k_2{}^2)]} \qquad (2a)$$

or, introducing the relaxation time of the chemical reaction, [4]$\tau = 1/(k_1 + k_2)$,

$$D_e = \frac{E^2(u_A - u_B)^2 k_1 k_2 \tau^2}{2(1 + \omega^2\tau^2)} \qquad (2b)$$

where $\omega = 2\pi\nu$, and the symbols A, B, u_A, u_B, k_1, k_2, E represent the two forms of the ionic species, their electrophoretic mobilities, the rate constants of the forward and backward reactions and the average potential gradient, respectively.

The purpose of the present communication is to suggest that, in principle, electrodiffusion can be used to achieve separation of isotopes by exploitation of the kinetic isotope effect.

Thus, let A and A' represent two isotopic ions, and let us assume that A and A' react with the functional groups of an ion-exchange or ion-chelating resin forming the immobile complexes B and B':

$$A \underset{k_2}{\overset{k_1}{\rightleftharpoons}} B \qquad (3a)$$

and:

$$A' \underset{k_2'}{\overset{k_1'}{\rightleftharpoons}} B' \qquad (3b)$$

It is obvious then that if any one of the two following inequalities holds:

$$k_1 \neq k_1' \qquad (4a)$$

or

$$k_2 \neq k_2' \qquad (4b)$$

the values of the electrodiffusion coefficients calculated for reactions (3a) and (3b) will not be equal:

$$D_e \neq D_e' \qquad (5)$$

If an electrodiffusion experiment, therefore, is carried out on an ion-exchange or ion-chelating column, one half of which is saturated initially with a mixture of A and A', a separation of the two isotopes will occur. If the degree of separation α is given by:

$$\alpha = \frac{[A'][A_0]}{[A_0'][A]} \qquad (6)$$

(where $[A_0]$, $[A_0']$, $[A]$ and $[A']$ denote the initial concentrations of A and A' at points $x = 0$ and the concentrations after the elapse of time t, at points $x = x'$, respectively) its value can be calculated by solving equation (1) using the suitable boundary conditions. The solutions of equation (1) for the above experimental arrangements are:

$$[A] = \frac{[A_0]}{2}\left(1 - erf\,\frac{x'}{2(D_e t)^{1/2}}\right) \qquad (7a)$$

and

$$[A'] = \frac{[A_0']}{2}\left(1 - erf\,\frac{x'}{2(D_e' t)^{1/2}}\right) \qquad (7b)$$

By means of equations (2a), (2b), (6) and (7) the optimum separation conditions can be calculated for known values of k_1/k_1', and k_2/k_2'; in practice, however, the best conditions for separation will depend on additional factors as well (for example, ordinary diffusion, heat convection, etc.). The influence of ordinary diffusion can be easily taken into account by substituting in equations (7a) and (7b) D_e and D_e' by $(D_e + D_1)$ and $(D_e' + D_2)$ respectively, where D_1 and D_2 denote the respective diffusion coefficients of A and A'.

In Fig. 1 the value of α is plotted as a function of E for various frequencies assuming that $k_1 = k_2 = 1$ sec.$^{-1}$, $k_1' = k_2' = 1{\cdot}1$ sec.$^{-1}$, $\tau = 0{\cdot}5$ sec., $\tau' = 0{\cdot}45$ sec., $u_A = u_B' = 10^{-4}$ cm.^{2}/sec./V., $u_B = u_B' = 0$, $t = 1{,}000$ sec., $x' = 1$ cm., $D_1 = D_2 = 10^{-5}$ cm.^{2}/sec.

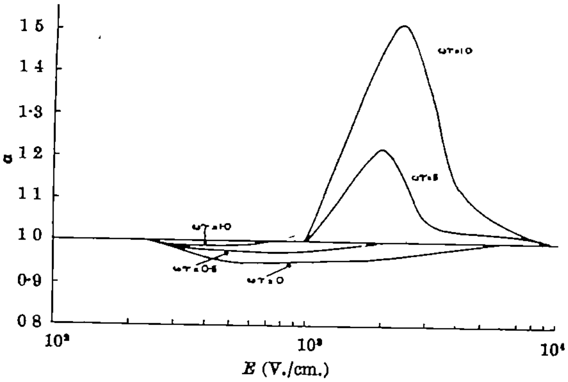

Fig. 1

The results of the computations for this particular case indicate that the separation is enhanced by the use of alternating currents, particularly at high applied voltage, and with frequencies higher than the reciprocals of the relaxation times of the reactions. Direct current also achieves separation; however, experimental considerations (for example, the necessity of using very long columns and the probable blurring effect of electrophoretic anomalies due to conductivity and pH changes in the boundary region[5]) weigh against its use.

I thank Dr. A. D. Jenkins for his help in the preparation of the manuscript and the management of Gillette Industries, Ltd., for the permission to publish this communication.

Existence of Gaseous Sulphides of the Transition Elements: Dissociation Energy of Gaseous MnS

It is of interest to obtain data on the lattice energy, ΔH_0^0[at.], of solids, and dissociation energies, D_0^0, of gaseous molecules of whole groups of compounds, such as homonuclear molecules[1], oxides[2], sulphides[3], etc., and to study the variation of these properties, or the ratio of these magnitudes, $\Delta H_0^0[\text{at.}]/D_0^0 = \alpha$, as a function of the electronic structure of the constituting atoms. An interesting case is that of the sulphides of transition elements.

The simplest discussion of the mechanism of vaporization of solid sulphides [MeS] can be based on three processes:

$$[\text{MeS}] \rightleftharpoons \text{Me} + 1/2\ \text{S}_2 \qquad (1)$$

$$[\text{MeS}] \rightleftharpoons [\text{Me}] + 1/2\ \text{S}_2 \qquad (2)$$

$$[\text{MeS}] \rightleftharpoons \text{MeS} \qquad (3)$$

(Condensed phases, solid and liquid, are marked by square brackets, gases without brackets.) Complications that occur when instead of reaction (2) stoichiometric compounds such as $[\text{Me}_2\text{S}]$ or non-stoichiometric solids $[\text{Me}_x\text{S}_y]$ are formed are not discussed here in detail. Though association of S_2 is not discussed, dissociation is considered.

Which of the processes (1) or (2) predominates is seen immediately by considering the equilibrium:

$$\text{S}_2 + 3[\text{Me}] \rightleftharpoons 2[\text{MeS}] + \text{Me} \qquad (4)$$

and the magnitude

$$A = 3\Delta H_0^0[\text{vap.Me}] + D_0^0(\text{S}_2) - 4\Delta H_0^0[\text{at.MeS}] + T\Delta fef\{2[\text{MeS}] + \text{Me} - \text{S}_2 - 3[\text{Me}]\} \qquad (5)$$

where ΔH_0^0[vap.Me] is the heat of vaporization of one atom-gm. [Me], ΔH_0^0[at.MeS] the heat necessary to transform one half molecule-gm. [MeS] in the constituting gaseous atoms, $D_0^0(\text{S}_2) = 100$ kcal. (ref. 3) the dissociation energy of S_2 and Δfef the difference in free energy functions of the substances given in the braces {}.

If $A > 0$ process (2) predominates:

$$-RT\ln p(\text{Me})/p(\text{S}_2) = A = \Delta H_0^0 + T\Delta fef \qquad (6)$$

For the first row of transition element sulphides[4,5] $\Delta fef \approx -5$ e.u.; the dominant term is the enthalpy difference which from FeS to CuS lies in the narrow limits $\Delta H_0^0(6) \approx +24 \pm 3$ kcal. (well within error limits), that is, $p(\text{Me})/p(\text{S}_2) \approx 10^{-4}$ at 1,000° K. and 10^{-2} at 2,000° K. In this case the relation

$$-RT\ln p(\text{S}_2)/p(\text{MeS}) = D_0^0(\text{MeS}) + 2\Delta H_0^0[\text{at.MeS}] - D_0^0(\text{S}_2) - 2\ \Delta H_0^0[\text{vap.Me}] + T\ \Delta fef\{2[\text{Me}] + \text{S}_2 - \text{MeS} - [\text{MeS}]\} \qquad (7)$$

is obtained from the equilbrium:

$$\text{MeS} + [\text{MeS}] \rightleftharpoons \text{S}_2 + 2\ [\text{Me}] \qquad (8)$$

Δfef is again small, about + 3 e.u.; from a comparison of oxides and sulphides one obtains $D_0^0(\text{MeS}) \approx$ 60–70 kcal. and $\Delta H_0^0(7) \approx -40$ to -50 kcal. for FeS, CoS, NiS, CuS. Thus $p(\text{MeS})/p(\text{S}_2)$ increases with increasing temperature but even at 2,000° K. reaches only 10^{-3}–10^{-4}. This is not easily reconciled with Hsiao and Schlechten's[6] results indicating 20–54 per cent Fe and Co transfer in the vaporization of FeS and CoS; these results would mean that $D_0^0(\text{MeS}) \approx$ 100 kcal. An explanation might be given in the terms of more complicated gaseous sulphides such as Fe_2S, Fe_2S_3 or gaseous polymers. Finally $-RT\ln p(\text{S})/p(\text{S}_2) \approx D_0^0(\text{S}_2) + \Delta H_0^0[\text{vap.Me}] - 2\Delta H_0^0[\text{at.MeS}]$ leads to $p(\text{S}_2) \approx 10$ to $100\ p(\text{S})$. If [Me] reacts with [MeS] to give stoichiometric or non-stoichiometric compounds $p(\text{S}_2)/p(\text{Me})$ is even larger.

In the first row of transition elements MnS is the only clear case of $A < 0$ (Equation 5), with $\Delta H_0^0 = -64$; at the end of this row for ZnS and GaS $\Delta H_0^0 = -99$ and -59 kcal. respectively. For the oxides ΔH_0^0 is strongly negative with the exception of CuO (+6 kcal.), where, however, probably the actual process is $[\text{CuO}] \rightleftharpoons 1/2\ [\text{Cu}_2\text{O}] + 1/2\ \text{O}_2$. For negative ΔH_0^0, that is, process (1), the ratio $p(\text{S}_2)/p(\text{MeS})$ is obtained from the equilibrium:

$$\text{MeS} \rightleftharpoons 1/3\ [\text{MeS}] + 1/3\ \text{S}_2 + 2/3\ \text{Me} \qquad (9)$$

and

$$-RT\ln p(\text{S}_2)/p(\text{MeS}) = D_0^0(\text{MeS}) - 2/3\ \Delta H_0^0[\text{at.MeS}] - 1/3\ D_0^0(\text{S}_2) + 2/3RT\ln 2 + T\Delta fef\{1/3[\text{MeS}] + 1/3\ \text{S}_2 + 2/3\ \text{Me} - \text{MeS}\} \qquad (10)$$

For MnS an estimate similar to that above gives $-\log p(\text{S}_2)/p(\text{MeS}) \approx -6{,}500/T + 1{\cdot}5$. Using the mass spectrometric vaporization technique described previously[7] experiments were carried out with MnS between 1,800° and 1,900° K.: at 1,850° K. $\log p(\text{S}_2)/\log p(\text{MnS}) = 2{\cdot}1$. From equation (10) $D_0^0(\text{MnS}) = 65 \pm 5$ kcal. was obtained. For this third law method free-energy functions were calculated from $r_e = 2{\cdot}1\ A$ and $\omega_e = 540$ cm.$^{-1}$; the data from ref. 5 were taken for Mn and S_2. Further $\Delta H_{298}^0[\text{MnS}] = 49{\cdot}0 \pm 0{\cdot}5$ kcal.[8,9,4] $S_{298}^0[\text{MnS}] = 18{\cdot}7 \pm 0{\cdot}3$ e.u. (ref. 10) and $C_p[\text{MnS}] = 11{\cdot}4 + 1{\cdot}8 \times 10^{-3}T$ (ref. 11) yield $\log p(\text{Mn}) = -3{\cdot}00 \pm 0{\cdot}35$; pressure calibrations by complete evaporation of weighed samples yield $-3{\cdot}44$. Also $-RT\ \ln p(\text{S})/p(\text{S}_2) \approx 2/3\{D(\text{S}_2) - \Delta H_0^0[\text{at.MnS}]\}$ is in agreement with experiment.

For VS, TiS, CrS there are no data: however, $\Delta H_0^0[\text{at.MeO}] - \Delta H_0^0[\text{at. MeS}] = 16{\cdot}5 \pm 2$ kcal. for Ca, Mn, Co, Ni; assuming this difference to be constant ΔH_0^0 of equation (6) is for these three sulphides -70 ± 10 kcal. Assuming $D_0^0(\text{MeO}) - D_0^0(\text{MeS}) \approx 30$ kcal. as for oxides and sulphides of groups II^A, IV^B and Mn one obtains: $\log p(\text{S}_2)/$

$p(\text{MeS}) \approx -3{,}300/T + 1 \cdot 5$ and $p(\text{S}) \approx 10p(\text{S}_2)$: a favourable situation for observing gaseous sulphides.

For the two other rows of transition elements it seems difficult to make predictions; for the rare earths, however, one would expect to find gaseous sulphides since ΔH°_{0}[vap.Me] is relatively low and D°_{0}(MeO) high[12].

Reactions of Gaseous Hydroxyl Radicals

Very little is known of the rates of reaction of hydroxyl radicals. The most extensive work is that of Avramenko and Lorentso[1], but that has been critically reviewed by Steacie[2]. In the present work the homogeneous decomposition of hydrogen peroxide was used as a source of hydroxyl radicals[3], and the relative rates at which hydroxyl radicals react with methane, formaldehyde and carbon monoxide were estimated. The method was checked by independent experiments wherein methane was oxidized thermally at 500° C. to formaldehyde, carbon monoxide and carbon dioxide.

When, using helium as a carrier gas, hydrogen peroxide was decomposed in the presence of methane and carbon monoxide, the competing reactions were:

$$\text{CH}_4 + \text{OH} = \text{CH}_3 + \text{H}_2\text{O} \tag{1}$$

and

$$\text{CO} + \text{OH} = \text{CO}_2 + \text{H} \tag{2}$$

In the presence of small amounts of oxygen, hydrogen atoms were removed by the chain ending reaction

$$\text{H} + \text{O}_2 + \text{M} = \text{HO}_2 + \text{M} \tag{3}$$

whereas methyl-radicals were converted to ethane and a little formaldehyde. Under these conditions:

$$\frac{k_1}{k_2} = \frac{2\text{C}_2\text{H}_6 + \text{CH}_2\text{O}}{\text{CO}_2} \times \frac{\text{CO}}{\text{CH}_4}$$

The CO/CH$_4$ ratio was varied by a factor of 50 yet the values of k_1/k_2 remained constant. Even at temperatures as low as 400° C. where heterogeneous decomposition of hydrogen peroxide predominates, it was found that carbon monoxide and methane were homogeneously oxidized according to reactions 1 and 2.

When methane and oxygen were added to the gas stream most of the methyl radicals formed reacted with oxygen to give formaldehyde, which reacted further according to the reactions:

$$\text{OH} + \text{CH}_2\text{O} = \text{HCO} + \text{H}_2\text{O} \tag{4}$$

$$\text{HCO} + \text{O}_2 = \text{CO} + \text{HO}_2 \tag{5}$$

The results are detailed below.

	400° C.	450° C.	525° C.	600° C.	650° C.
k_1/k_2	0·83	1·10	2 1	2·7	8·4
k_4/k_1	—	—	33	27	22

In the oxidation of methane it was found that the relative rates of oxidation of methane and formaldehyde were proportional to their relative concentrations when surface oxidations were eliminated. Under these conditions, throughout reactions involving a considerable range of mixture strengths, reactions 4 and 1 seemed to predominate in the oxidation. A value of 35 ± 10 was obtained for k_4/k_1 at 500° C.

The variation of k_1/k_2 with temperature gives 7 kcal./mole for $E_1 - E_2$, which is consistent with the value of 10–30 for k_1/k_2 determined at about 1,800° K. by Westenberg and Fristrom[4]. It explains why less carbon dioxide is formed in the oxidation of rich methane/oxygen mixtures at higher temperatures.

The ratio of the steric factors P_1/P_2 must be about 100. This can be understood if the hydroxyl radical has to approach along the axis of the carbon monoxide molecule to give the linear carbon dioxide molecule.

Acknowledgments are due to the Royal Society and Nuffield Foundation for a Commonwealth Bursary and to the National Research Council at Ottawa for research facilities.

Synthesis of a Protected Octapeptide Analogue of Hypertensin II

In order to investigate whether the basicity of the amino-acid residue at position 2 in hypertensin II has any strong bearing on its biological activity or affects the balance of oxytocic and pressor properties of this hormone, the histidine^{1}–hypertensin analogue[2] was synthesized in this laboratory. I used the procedure for histidyl peptides[1], which also leads to the synthesis of the im. benzyl analogue. The latter might spread light on the biological significance of the imidazole ring of histidine.

In an earlier communication[2] the synthesis of a protected heptapeptide, carbobenzoxy-im. benzyl-L-histidyl-L-valyl-L-tyrosyl-L-iso-leucyl-im. benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester, and its corresponding benzyl ester was reported. I now wish to record the synthesis of a protected octapeptide with the amino-acid sequence asp.his.val.tyr.ileu.his.pro.phe.

In view of the sensitivity of the aspartyl bond[3] and in order also to diminish the danger of racemization, I found it safer to increase the peptide chain of the heptapeptide by *N*-terminal addition of the aspartyl residue. Therefore, the heptapeptide methyl ester was prepared again by coupling carbobenzoxy-L-proline with L-phenylalanine methyl ester by means of the ethylene phosphorochloridate method to give an oily dipeptide ester, which failed to crystallize. The oily product was converted into L-prolyl-L-phenylalanine methyl ester, m.p. 158°–159°, and used for the preparation of L-isoleucyl-im. benzyl-L-histidyl-L-prolyl-L-phenylalanine methyl ester dihydrobromide[1]. The tetrapeptide, on condensation with the tripeptide, carbobenzoxy-im. benzyl-L-histidyl-L-valyl-L-tyrosine[1], via the carbodi-imide method, afforded the heptapeptide methyl ester, which finally converted into the octapeptide by two methods. At first, the heptapeptide methyl ester was decarbobenzoxylated with hydrogen bromide in acetic acid and then precipitated by ether product, which is very hygroscopic, coupled with β-benzyl carbobenzoxy-L-aspartate[4] by the mixed-anhydride procedure[5]. Since the coupling of β-benzyl carbobenzoxy-L-aspartate with amino-acids and peptides via the mixed-anhydride procedure proceeds with low yield, the aspartate derivative was used in 100 per cent excess. After coupling, the solvent (tetrahydrofuran) was evaporated to dryness and on adding ether the residue solidified (amorphous). The octapeptide methyl ester obtained (60 per cent yield) was saponified with the equivalent amount of sodium hydroxide, diluted with water and acidified with acetic acid. The octapeptide acid was obtained in solid form and after two purifications from ethanol-ether showed $[\alpha]_D^{22}$ + 38° (*c*, 0·5 in methanol) (calculated for $C_{72}H_{84}N_{12}O_{14}$: C, 64·4; H, 6·3; N, 12·5; found: C, 63·8; H, 6·5; N, 12·1). Paper chromatography of a hydrolysed sample revealed the presence of aspartic acid, valine, tyrosine, isoleucine, proline, phenylalanine and im. benzyl-histidine.

Alternatively, the heptapeptide methyl ester was selectively decarbobenzoxylated by catalytic hydrogenation in dimethylformamide[1] and the product, without isolation, coupled with β-benzyl carbobenzoxy-L-aspartate by the carbodi-imide method. The octapeptide ester was obtained in 50 per cent yield and converted to the acid by saponification. The solid product showed identical optical rotation to that prepared by the mixed-anhydride method. Enzymic experiments are in progress to establish the optical purity of the obtained octapeptide acid. In this connexion it might be of interest to note that carbobenzoxy-L-isoleucyl-im.benzyl-L-histidyl-L-prolyl-L-phenylalanine, incubated with chymotrypsin for 24 hr., failed to give a ninhydrin-positive compound, when the incubation mixture was checked by paper chromatography.

BIOCHEMISTRY

Effect of Tobacco Smoke Condensate on the Aerial Oxidation of Cysteine

THE recent publication by Lange[1] on the inhibition of certain enzymes by tobacco smoke condensate has prompted the publication of an examination of the catalysed aerial oxidation of cysteine.

The oxidation of thiols to disulphides is known to be catalysed by free radicals[2]. A detailed mechanism for the catalysed aerial oxidation of cysteine has been proposed by Rydon[3], who showed that the intermediate thioperoxy radicals would afterwards react at an unionized thiol group:

$$\alpha\text{–S}^- + X\cdot \longrightarrow X^- + \alpha\text{–S}\cdot$$
$$\alpha\text{–S}\cdot + O_2 \longrightarrow \alpha\text{–S—}O_2\cdot$$
$$\alpha\text{–S—}O_2\cdot + \text{HS–}w \longrightarrow \alpha\text{–S—S–}w + HO_2\cdot$$
$$\alpha\text{–S}^- + HO_2\cdot \longrightarrow \alpha\text{–S}\cdot + HO_2^-$$

The presence of free radicals in tobacco smoke has been reported[4] and is thought to cause the rapid darkening of tobacco smoke condensate on prolonged standing at room temperature, even in the absence of oxygen.

Little direct chemical evidence is available for the presence of peroxides in fresh tobacco smoke condensate[1], although the autoxidation of long chain dienes, for example, neophytadiene, has been observed in neutral extracts from fresh tobacco smoke condensate[5].

The rate of oxidation of cysteine to cystine at *p*H 8·5 has been examined in the presence of varying amounts of tobacco smoke condensate. A constant diffused air flow was maintained into the aqueous solution of cysteine while cigarettes were smoked directly into the solution (Fig. 1, curves 1 and 2). Curves 3 and 4 show the effect of pre-condensing the smoke and allowing an ageing period before adding the tar to the cysteine solution and commencing aeration.

Curve 5 shows the negligible effect of pre-inhaled tobacco smoke on the oxidation time, supporting Lange's observations that, in this context, the active principle of the tobacco smoke was readily adsorbed on the surface of the lung. Little immediate loss of cysteine occurred when excess tobacco smoke condensate was added to the cysteine solution in absence of air. This evidence indicates that the oxidation mechanism occurs predominantly through the form-

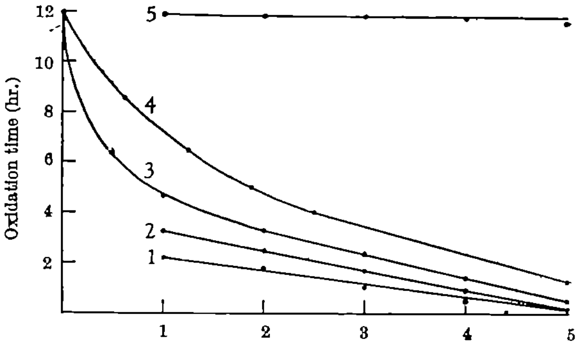

Fig. 1. Effect of tobacco smoke and condensate on the aerial oxidation of cysteine. Curves: 1, Dark-coloured tobacco smoked directly into cysteine solution; 2, light-coloured tobacco smoked into cysteine solution; 3, pre-formed condensate aged 1 month; 4, pre-formed condensate aged 12 hr.; 5, pre-inhaled smoke from light coloured tobacco blown into cysteine solution

ation of thioperoxy radicals. Substantial inhibition of the free radical catalysed oxidation was achieved by the addition of alkyl substituted phenols, for example, thymol, to the reaction mixture.

The proposed mechanism involving thioperoxy radicals does not preclude an *in vivo* mechanism via the unstable mercapturic acid derivatives of the higher polycyclic hydrocarbons[6] formed from the free radicals of the tobacco smoke and cysteine.

The supposition that smokers of dark, well-fermented varieties of tobacco, such as the Eastern European peoples, are less likely to contract forms of lung cancer has been largely disproved[7]. In the present experiments the oxidation time using well-fermented tobacco having an alkaline mainstream smoke was significantly smaller than that of lighter coloured tobacco having an acid mainstream smoke (curves 1 and 2).

The results of this work provide evidence in support of the presence of trapped free radicals in tobacco smoke and of their ability to participate as radical chain propagators in biochemical systems.

An Improved Method for the Separation and Purification of Chlorophyll a

THE procedure[1,2] which has been used for the separation of chlorophyll *a* has involved two awkward steps: (1) the transfer of the chlorophylls from the acetone extract of the plant to a hydrocarbon phase; (2) the adsorption of chlorophylls on talc-like materials prior to the sugar chromatography. The chlorophyll *a* band on the sugar column invariably has a xanthophyll on its leading edge due to the failure of step (1) to complete the xanthophyll separation and a fair amount of pheophytin introduced by step (2). The xanthophyll contaminant causes an enhanced apparent intensity value of the blue band of the chlorophyll *a* spectrum previously reported. Heretofore it has been very difficult to obtain crystalline chlorophyll using these procedures.

In our procedure the initial acetone extract from the plant material is passed through a column containing polyethylene powder where the chlorophylls are completely separated from the xanthophylls, carotenes, pheophytins and lipids. The chlorophylls are then transferred to iso-octane and chromatographed on sugar. The chlorophyll *a* is eluted with 0·5 per cent *n*-propanol in iso-octane and allowed to crystallize out in a refrigerator. The microcrystals have a well-defined powder X-ray pattern and decreased intensity of the blue band. The ratio of the blue band to the red band in our preparation is 1·19 compared with 1·31 of Benitez and Smith[3]. The spectrum of the chlorophyll *a* crystals (using the method of Shibata *et al.*[4]) has a maximum at 740 mμ compared with 735 mμ reported[4].

The procedure for separating chlorophyll *a* is as follows: 200 gm. of spinach is washed and dried on blotting paper, then extracted with 500 ml. of absolute reagent grade acetone. The acetone is diluted with water to give an 80 per cent water–acetone solution. The aqueous extract is applied to a glass column of 5 cm. diameter dry packed with 1,000 ml. of powdered polyethylene ('Dow', melt index (*MI*) < 2) which has been washed with 70 per cent aqueous acetone. After the pigments are adsorbed the column is developed with 70 per cent aqueous acetone with the complete elution of the xanthophylls. The order of the pigments from the bottom of the column is xanthophylls, chlorophyll *b*, chlorophyll *a*, pheophytins and carotenes. The chlorophylls are eluted with 85 per cent aqueous acetone. The chlorophylls can be separated into chlorophyll *a* and chlorophyll *b* at this stage by using polyethylene of low melt index (*MI* 0·044)[6]. However, the separation of the chlorophylls at this point is not essential, as they are readily separated by sugar chromatography, which reverses the order of adsorption of chlorophylls, the sugar chromatography bringing about a further improvement in purity. To the acetone–water solu-

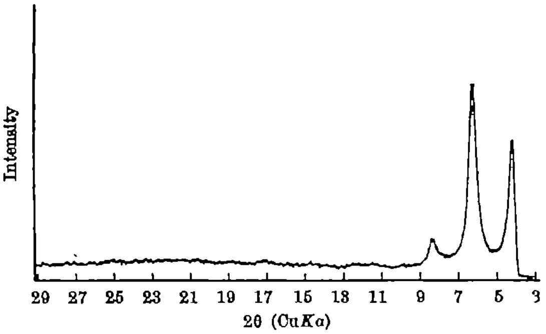

Fig. 1. X-ray pattern of chlorophyll *a* crystals

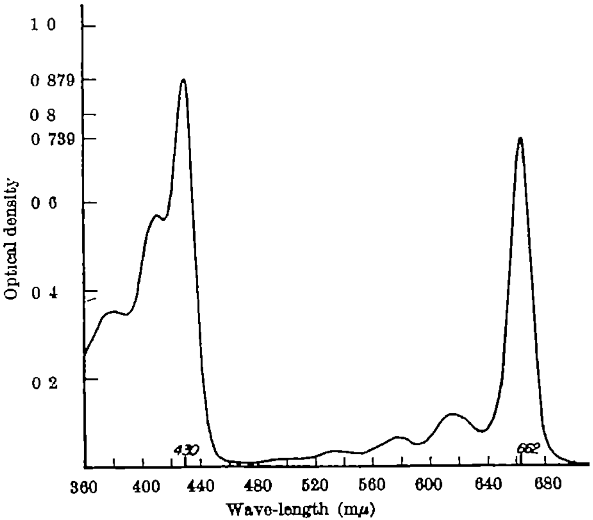

Fig. 2. Absorption spectrum of chlorophyll *a*. Solvent: diethyl ether

tion of the chlorophylls is added 200 ml. of iso-octane (Phillips pure grade) in a separatory funnel and the acetone carefully washed out with water. The iso-octane is dried with anhydrous sodium sulphate and applied to a glass column of 5 cm. diameter dry packed with 1,000 c.c. of powdered confectioners' sugar which has been washed with 250 ml. of iso-octane. The column is developed with 0·5 per cent *n*-propanol in iso-octane and the chlorophyll *a* eluted. The chlorophyll *a* eluate is allowed to remain in a refrigerator overnight when microcrystalline chlorophyll *a* can be collected by filtration or centrifugation.

The yield of chlorophyll *a* is 40 mgm. The X-ray pattern is shown in Fig. 1, and the optical density versus wave-length is shown in Fig. 2.

We are now not only in a position to examine the properties of very pure materials in solution, but also of ordered arrays which previously had been difficult if not impossible to obtain.

5-Hydroxytryptamine in the Sub-cellular Particles of Rabbit Brain

In the course of experiments on the sub-cellular distribution of substance *P* in the rabbit brain[1], we have confirmed Whittaker's finding[2] that the rat fundus stimulating action of his "synaptic vesicle fraction" was higher than that of the mitochondrial or supernatant fraction. As pointed out by him, however, the total amount of brain 5-hydroxytryptamine (5HT) thus estimated was about several times as much as that reported by previous workers[3]. This should be attributable to his omitting extracting 5HT by acetone. Using the acetone extraction[3] and Vane's rat fundus preparation[4], therefore, we attempted to compare the sub-cellular distribution of brain 5HT with and without acetone treatment. Methods of preparation of the rabbit brain homogenates and of sub-cellular fraction were as described previously[1]. As illustrated in Fig. 1, the amount of 5HT estimated is lowest in the vesicle fraction, while that in the mitochondrial fraction is relatively high. It is apparent at a glance that the 5HT distribution obtained by omitting acetone treatment as in Whittaker's experiment is quite similar to that of substance *P*[1,2]. In fact, it was found that the rat's fundus was considerably sensitive to substance *P*, and the 5HT equivalence of acetone-insoluble aliquot of each fraction measured with the fundus preparation ran parallel to their substance *P* content (Fig. 1).

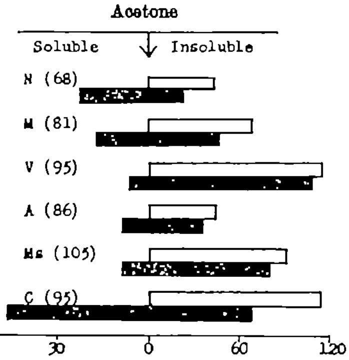

Fig. 1. White, without acetone extraction; black, acetone-soluble (left) and acetone-insoluble (right). Abscissæ: mμgm. 5-HT equivalence; 1 μgm. 5-HT corresponding to about 570 unit substance *P* equivalence. *N*, Nuclear; *M*, mitochondrial; *V*, synaptic vesicular; *A*, amorphous; *Ms*, microsomal, *C*, cytoplasmic supernatant fraction. The values in parentheses represent percentage of recovery of (5-HT substance *P*) activity after acetone treatment with reference to the 5HT equivalence without acetone treatment

Our finding that 5HT of the brain was present rather in the heavier granules than the lighter ones seems to resemble Baker's results on 5HT in the intestinal mucosa[5]. Using the centrifugal fractionation in the density gradient similar to Baker's[5] or Blaschko's[6], therefore, the distribution of 5HT in the combined sub-cellular fraction of mitochondria and microsomes was examined. As shown in Fig. 2, the 5HT of the brain was higher in the heavier particles as in the intestinal mucosa[5], while the fundus-stimulating activity of the acetone-insoluble aliquot, that is, substance *P* activity, was higher in the lighter ones. In view of these findings, it might be said that the 5HT of the brain would play a less significant part in transmission in the central nervous system, if the central chemical transmitter existed in the so-called 'synaptic vesicle fraction'. In connexion with the latter view, however, many questions still remain[7].

We have been able to confirm also that such a particulate 5HT in the brain was liberated (66–99 per cent) by raising the temperature (60° C.), lowering the *p*H (3–4), hypotonicity (0·03 *M* sucrose) and treatment with ether or acetone. Potassium ion (80–160 m*M* potassium chloride) also effected release of 5HT (47–62 per cent at 4° C.), but sodium, calcium or magnesium chloride did not (0–20 per cent). Two hours after adding reserpine (10 ~ 50 μgm./ml.) into the particulate suspension at 4° C., only 20 per cent of 5HT was transferred from the particles into the supernatant. In contrast to the bound acetylcholine, the particulate 5HT was almost completely inactivated on incubation with crude monoamine oxidase prepared from pig serum by Blaschko's method[8].

During these observations, we found that the particulate 5HT was not so unstable as described by

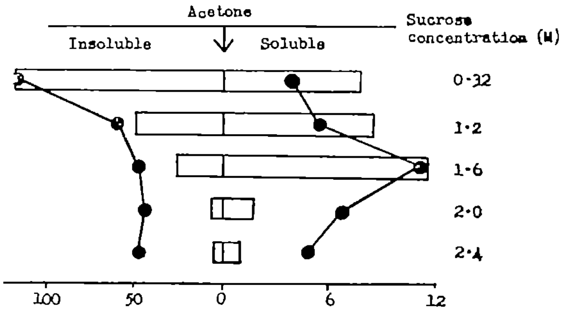

Fig. 2. Solid circles, the activity–protein ratio. Abscissæ: the same as in Fig. 1. The scale for the activity–protein ratio was arbitrarily chosen, readily to compare with the distribution of 5HT activity

Whittaker[2]. Using the 5HT solution (50 ngm./ml. in 0·3 *M* sucrose) as the substrate, therefore, we investigated in which fraction the 5HT-destroying activity was found and confirmed that only the microsomal fraction had such an activity of some significance. But it was not enhanced by ether treatment as suggested by Whittaker, while the substance *P*-destroying activity of this fraction[1] was largely activated by ether[9]. The former activity was inhibited by iproniazid, but the latter was not. This also indicates that the particulate 5HT activity of brain homogenates observed by Whittaker was mainly due to the particulate substance *P*. In the microsomal fraction copper was found, and 5HT inactivation seems to be attributable to contained cæruloplasmin.

Effect of a Concentrate of Rice Polishings on Serum Lipoproteins

Oncley *et al.*[1] have shown that in man about 75 per cent of the plasma cholesterol is associated with the β-lipoprotein, the remaining 25 per cent being associated with the α-lipoprotein. Examination of serum lipoproteins of patients suffering from hypercholesteræmia has revealed a moderate depression of α-lipoprotein and elevation of β-lipoprotein[2]. Bossak *et al.*[3] reported serum lipoproteins in various animal species and showed that, with ingestion of cholesterol, β-lipoprotein increased with a simultaneous depression of α-lipoprotein.

It has recently been shown that a concentrate of rice polishings can prevent the development of fat, fatty liver, and cholesterol fatty liver[4,5]. The lipotropic action of the concentrate has been attributed to choline and other lipotropic substances present in this concentrate. Since a concentrate of rice polishings reduced hepatic lipids[4], it was thought worthwhile to investigate the effect of this concentrate on serum lipoproteins of albino rats kept on cholesterol-supplemented diet. The experiment was performed on 24 albino rats. The animals were divided into four groups of six each. The animals of Group I were kept on a basal diet containing casein 20 per cent, sucrose 65 per cent, groundnut oil 10 per cent, salt mixture 4 per cent and vitaminized sucrose 1 per cent. The animals of Group II were given the above basal diet supplemented with 0·5 per cent cholesterol. The animals of Group III were given the basal diet supplemented with 0·5 per cent cholesterol + 20 c.c. rice polishing concentrate/100 gm. of the diet. The animals of Group IV were given basal diet supplemented with 0·5 per cent cholesterol + 30 c.c. rice polishing concentrate/100 gm. of the diet. The animals were killed after 12 weeks of experiment. The different sera were subjected to paper electrophoretic separation. The technique utilized was essentially similar to that used by Flynn and deMayo[6].

The paper strips were stained with sudan black *B* according to the method of Jencks and Durrum[7], cut uniformly into 5-mm. sections and eluted with chloroform and methanol mixture 2 : 1, and readings were recorded at 590 mμ in a photoelectric colorimeter. Readings obtained were calculated and expressed as percentage of the total α- and β-lipoproteins. The results are shown in Table 1.

Table 1. Average Percentage Distribution of α- and β-Lipoproteins in the Sera of Albino Rats kept on High Cholesterol Diet and treated with Rice Polishing Concentrate (R.P.C.)

Group	No. of animals	Diet	Experimental period in weeks	Average percentage distribution of α- and β-lipoproteins α	β	β/α ratio
I (normal)	6	Basal diet	12	45·0	55·0	1·22
II	6	Basal diet + 0·5 per cent cholesterol	12	16·0	84·0	5·25
III	6	Basal diet + 0·5 per cent cholesterol + 20 c.c. R.P.C./100 gm. diet	12	34·2	65·8	1·92
IV	6	Basal diet + 0·5 per cent cholesterol + 30 c.c. R.P.C./100 gm. diet	12	44·0	56·0	1·27

A concentrate of rice polishings is a very good source of the B vitamins. This concentrate has also been found to contain essential amino-acids[8]. It is likely that B vitamins, especially choline, inositol, nicotinic acid and essential amino-acids, may possibly influence the physiological levels of lipoproteins[9-11].

Origin of the Lactate Dehydrogenase Isoenzyme Pattern found in the Serum of Patients having Primary Muscular Dystrophy

The electrophoretic pattern of lactate dehydrogenase (LDH) isoenzymes has repeatedly been determined in human serum for specific detection of tissue necrosis. Indeed, it is generally accepted that the necrotic tissue impresses its LDH pattern on the basic distribution of LDH isoenzymes as found in the serum. Thus in hepatitis the electrophoretically slowest serum LDH (LDH5) (for nomenclature see ref. 1) markedly increases as it constitutes the dominant fraction of liver LDH. In myocardial infarction especially LDH1 (the most rapid fraction) rises as it corresponds to the dominant LDH isoenzyme of human heart muscle.

This being accepted, the results obtained on the serum of patients having primary muscular dystrophy become rather challenging. On this material total LDH activity is found to be considerably increased[2] although plain necrosis seems absent from the diseased muscle. However, it was demonstrated[3,4] that the release of enzymatic protein from dystrophic muscle is much more intense than from normal controls. If this observation elucidates the high total LDH-level found in the serum of those cases, another difficulty remains. One expects that the serum pattern of LDH isoenzymes should present a shift towards the slowest fractions since in human skeletal muscle LDH5 strongly dominates[5,6]. Richterich *et al.*[7] found the increase concerned mainly with LDH1 and LDH2. Our investigations confirm these observations, but we found that LDH3 also participates in that increase. Different explanations can be proposed: (1) selective release of LDH isoenzymes from diseased muscle; (2) selective elimination of these isoenzymes; (3) changes in the LDH pattern of the affected muscle. We have obtained experimental evidence which strongly supports the third hypothesis.

Using agar-gel electrophoresis for separation of LDH isoenzymes and a histochemical procedure for their subsequent detection, we examined the LDH isoenzyme pattern in biopsy specimens of normal and dystrophic human muscle. Biopsy specimens of about 10 mgm. fresh weight were homogenized in twice their volume of distilled water and centrifuged for 10 min. at 10,000*g*. For the separation we used a small-scale method of agar-gel electrophoresis[8,9] needing sample volumes of only 1·5 μl. Electrophoresis was effected at a field strength of 35 V./cm. and at the constant temperature of + 12° C. The agar concentration was 1 per cent in a barbital buffer of *p*H 8·4 and ionic strength 0·05.

Zones of LDH activity were revealed by a staining reaction based on the reduction of nitro-blue tetrazolium into a purple insoluble formazan. We kept to the original Van der Helm procedure[10]; but the substrates were mixed with an agar solution (final agar concentration 1 per cent), poured on top of the electrophoresis strip and left for setting. This double agar plate was then incubated for 60 min. at 37° C., fixed in 2 per cent acetic acid, dried into a clear film and finally scanned at the wave-length of 546 mμ. Percentages between the zones of LDH activity were then calculated in the conventional way.

We thus analysed muscle extracts from 5 patients having primary muscular dystrophy and compared them with 5 normal controls. Results are presented in Table 1. In all pathological samples LDH5, which constitutes the dominant LDH of normal skeletal muscle, was found to be markedly decreased. It may even become the weakest fraction. Thus in dystrophic muscle the percentage of LDH1, LDH2 and LDH3 increases at the expense of LDH4 and LDH5. This shift is clear-cut and is revealed even by simple visual estimation of the stained zones. These modifications, apart from providing an explanation for the serum LDH pattern, may also constitute an important feature in the biochemical detection of muscular dystrophy.

Table 1. PERCENTAGE BETWEEN LDH ISOENZYMES IN MUSCLE EXTRACTS FROM NORMAL INDIVIDUALS AND FROM PATIENTS HAVING MUSCULAR DYSTROPHY (AGAR-GEL ELECTROPHORESIS)

Normal skeletal muscle		LDH1	LDH2	LDH3	LDH4	LDH5

Proteins of Central Nervous Origin Present in Cerebrospinal Fluid

WHILE the cerebrospinal fluid from healthy persons has a relatively poor protein pattern, the number of demonstrable protein fractions may be high in patients with neurological or some mental diseases. More than 30 different proteins can thus be demonstrated in the cerebrospinal fluid by micro-immuno-electrophoretic technique[1]. All these proteins were identified with anti-human serum during the precipitation phase of the immuno-electrophoresis. These proteins are therefore of plasma origin or at least immunologically identical with plasma proteins.

Formerly the cerebrospinal fluid was regarded as a serum transudate only reproducing the serum protein distribution in a diluted form. This concept has now been revised, especially since electrophoresis has revealed different distributions of the proteins in the cerebrospinal fluid and serum, respectively. Furthermore, an intrathecal production of proteins has been supported by investigations with radioactive proteins[2].

In an attempt to elucidate the problem of an intrathecal production, the cerebrospinal fluid was analysed by micro-immuno-electrophoresis in which anti-human serum was replaced during the precipitation phase by a polyvalent anti-cerebrospinal fluid serum. This was prepared by immunization of rabbits with a pooled concentrate of cerebrospinal fluid proteins mainly from patients with cerebral tumours.

33 samples of cerebrospinal fluid from patients with neurological and mental disorders and from some healthy persons were examined. In addition to the proteins which were demonstrated in the cerebrospinal fluid by means of anti-human serum we were able to identify 3 hitherto unknown fractions with the aid of anti-cerebrospinal fluid serum. All 3 fractions are situated in the β_2- and γ-globulin field. We have given these fractions the preliminary symbols $C\beta_{2\cdot 1}$-, $C\beta_{2\cdot 2}$- and $C\gamma$-globulin (Fig. 1). The fractions could also be demonstrated separately after absorp-

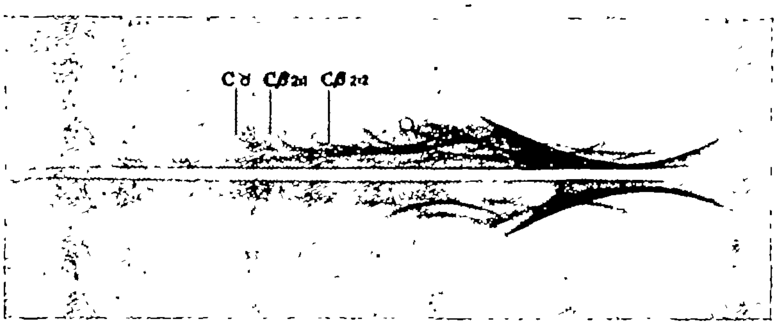

Fig. 1. An original micro-immuno-electrophoretic slide showing all the three specific cerebrospinal fluid proteins, namely, two β_2-globulins ($C\beta$-2 : 1 and $C\beta$-2 . 2) and one γ-globulin fraction ($C\gamma$), precipitated with the aid of anti-cerebrospinal fluid serum in one and the same sample (above). Serum from the same patient studied with anti-cerebrospinal fluid serum. The three above-mentioned fractions cannot be demonstrated (below)

tion of the anti-cerebrospinal fluid serum with normal serum.

The fraction $C\beta_{2\ 1}$ was found in 11 out of 33 samples from patients with multiple sclerosis, polyneuropathy, cerebral or spinal cord tumour, virus meningitis, paranoid psychosis, and severe anxiety state. $C\beta_{2:2}$ was observed in 7 samples from patients with multiple sclerosis, polyneuropathy, cerebral or spinal cord tumour, and virus meningitis. $C\gamma$-globulin was demonstrated in 2 samples from patients with polyneuropathy and cerebral tumour, respectively. These 3 fractions were never seen in the cerebrospinal fluid from patients without neurological or mental disorders. In none of the cases with one or more of these 3 fractions in the cerebrospinal fluid was any corresponding fraction found in the serum from the patients.

It thus appears that proteins of other origin than serum can be found in the cerebrospinal fluid of patients with neurological and mental disorders. As these 3 fractions were not demonstrable in serum, they do not seem to migrate in retrograde direction over to the blood.

Incorporation *in vitro* of Carbon-14 from NaH^{14}CO$_3$ and 2^{14}C-Glycine into DNA of Red Cells of the Duck

The exchange or renewal reactions of deoxyribonucleic acid (DNA) in non-dividing cells have been proved by many investigators[1]. But the DNA does not seem to be in a dynamic state in erythrocytes of birds[2]. Indeed, Allfrey and Mirsky did not find incorporation of nitrogen-15 from ^{15}N-glycine into DNA of chicken red cells *in vitro*. On the contrary, studying the fixation of carbon-14 from NaH^{14}CO$_3$ by duck red cells *in vitro* we found that DNA was radioactive[3]. Both carbon dioxide and glycine are precursors of DNA[1].

Allfrey and Mirsky found that ^{15}N-glycine is taken up into hæmoglobin by reticulocytes, and the nitrogen-15 enrichment of globin was found to be 0·020 after 23 hr. of incubation. The error is ± 0·001. As the nitrogen-15 enrichment of DNA was found to be 0·000, we can deduce that the incorporation of nitrogen is at least 20 times lower in DNA than in hæmoglobin.

In our measurements 50 ml. of duck blood were incubated with 200 μc. of NaH^{14}CO$_3$. We found that the specific activity of globin was 154 dis./min./mgm. of C and that of DNA was 83 (error < 5 per cent). Because the fixation of carbon-14 from NaH^{14}CO$_3$ into globin takes place through the dicarboxylic acid cycle followed by transaminations of ketoacids[4] and the ^{14}CO$_2$ is directly used for purine and pyrimidine synthesis, our results cannot contradict those of Allfrey and Mirsky.

Further work has proved the existence of a dynamic state of DNA in the erythrocytes using both NaH^{14}CO$_3$ and 2^{14}C-glycine.

Samples of 100 ml. of heparinized duck (*Cairina muschata* L.) blood, to which were added 30 mgm. of sodium-benzyl-penicillin and 35 mgm. of dihydrostreptomycin sulphate, were incubated in vessels slowly rotating (25 cycles/min.) for 20 hr. at 38·5° C. in an atmosphere of 95 per cent oxygen and 5 per cent carbon dioxide. 300 mgm. of glucose and 10 μc. of 2^{14}C-glycine (exp. 1) or 0·5 mc. of NaH^{14}CO$_3$ were also added. After the incubation the red cells were collected by centrifugation and washed several times with saline, then hæmolysed by freezing in liquid air bath and thawing twice.

The hæmolysate was then centrifuged at 2,500*g* and hæmoglobin was prepared from supernatant solution. The sediments, ghosts and nuclei were washed four times with saline. They were homogenized and extracted by stirring for 6 hr. with 20 vol. of 10 per cent sodium chloride at 85° C. The suspension was centrifuged at 10,000*g* for 1 hr. and the clear extract was poured into 6 vol. of distilled water. Then the fibrous nucleoprotein precipitated was collected and from that DNA was prepared according to Allfrey and Mirsky[2]. The DNA purity was proved by infra-red absorption spectroscopy. The spectrum obtained is shown in Fig. 1 and is very similar to those reported by Sutherland[5].

The deoxyribose content of DNA was determined by the diphenylamine reaction according to Barton[6], and it was found to correspond to deoxyribose of pure DNA (purchased from the California Corporation for Biochemical Research, Los Angeles, California).

The DNA and globin specific activities were measured by the gas phase counting method[3].

In Table 1 the ratios between DNA and globin ^{14}C specific activities are reported. We can see that this ratio is of the order of 1 per cent using 2^{14}C-glycine and of the order of 40 per cent with ^{14}CO$_2$. These results agree with those found by Allfrey and Mirsky using ^{15}N-glycine and with our previous measurements with NaH^{14}CO$_3$. Indeed, owing to experimental error and low efficiency of their measurements

Table 1

Exp. No.	Labelled precursor	DNA*	Globin*†	DNA/globin
1*a*	2 ^{14}C-glycine	14·2	360	0·04
1*b*		7·2	570	0 01
2*a*	NaH^{14}CO$_3$	13·6	37	0·37
2*b*		83	154	0·54

* ^{14}C specific activity in disintegrations/min./mgm. of C.
† Error, 5 per cent.

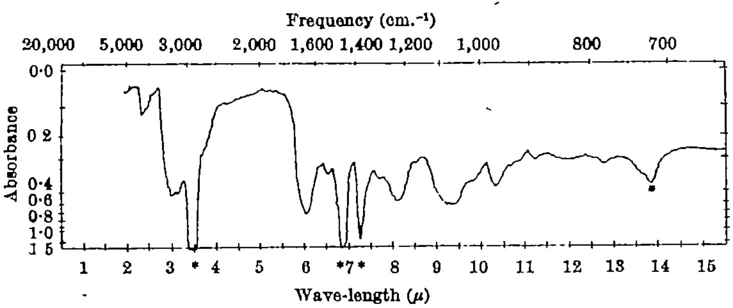

Fig. 1. Infra-red spectrum of DNA in silicon oil, Perkin-Elmer spectrometer model 221 with sodium chloride prism. Picks with asterisks are due to silicon oil

Allfrey and Mirsky could not detect so low a nitrogen-15 incorporation into DNA.

The higher value of ratio between the specific activities of DNA and globin using as labelled precursor $^{14}CO_2$ instead of 2^{14}C-glycine can be explained by the following:

(1) Carbon dioxide is a direct precursor of DNA, but incorporation of carbon-14 from CO_2 into globin takes place indirectly via dicarboxylic acids cycle and keto-acids transaminations.

(2) Glycine is a direct precursor of both DNA and hæmoglobin.

The fixation of carbon-14 into DNA is higher by a factor of 10 using labelled glycine than using labelled carbon dioxide. Probably it could be due to the different amounts of unlabelled carbon dioxide and glycine present in the system.

Finally, in our opinion, it can be concluded that the turnover of exchange or renewal reactions for DNA in duck erythrocytes *in vitro* is much lower than in that for hæmoglobin, but incorporation of carbon-14 represents a test for a dynamic state of DNA also.

Occurrence of Salicyluric Acid in Milk

HIPPURIC acid was isolated from milk by Karabinos and Dittmer nearly twenty years ago[1], but approximately 7 mgm. per cent of the non-protein nitrogen in milk is still unaccounted for[2]. Using ion exchange chromatography, several nitrogenous constituents, other than amino-acids, have been identified in milk very recently by Schwartz and Pallansch[3]. In the present communication evidence that cow's milk contains the glycine conjugate of salicylic acid is presented.

Salicyluric acid was detected during attempts to decrease the development of oxidized flavours in milk by increasing the level of anti-oxidants or sequestrants of dietary origin. Since all rations fed to dairy cattle contain flavonoids, which are non-toxic and possess anti-oxidant properties, a large supplementary dose of quercetin (150 gm) was given in three doses by drenching to a dairy cow. Daily milk and urine samples were collected before and after the quercetin supplement, and examined for the presence of quercetin or its degradation products. The results were negative in that no quercetin metabolites were detected in either the milk or urine. However, a substance now identified as salicyluric acid was detected in both the milk and urine whether quercetin was fed or not.

The paper chromatographic technique applied to the milk was the same as that used earlier to detect the metabolites of quercetin in rat urine[4]. Briefly, this involved extraction of milk with petroleum ether to remove lipids, followed by extraction of aromatic acids from the acidified milk (pH 2–3) with ether. Non-fat milk powders were first extracted in a Soxhlet apparatus, with petroleum ether followed by acetone. Aliquots of the ether or acetone extracts of milk or urine were then migrated in 2 dimensions on 17-in. sheets of Whatman No. 1 filter paper. The chromatograms were developed in the first direction overnight in the bottom phase of a chloroform/acetic acid/water mixture (2 : 1 : 1) and in the second direction by a 3-hr. migration in 20 per cent potassium chloride. The air-dry chromatograms were examined under short-wave ultra-violet light for the presence of fluorescent and absorbing areas. Finally, each chromatogram was sprayed with diazotized sulphanilic acid (DSA) and 20 per cent sodium carbonate in order to produce colours with phenolic substances.

The major aromatic acids detected in cow's urine were salicyluric, hippuric, and salicylic. The chromatographic properties of these acids are shown in Table 1. Three additional observations were confirmatory as to the identity of salicyluric acid. First, the area on the chromatogram suspected of being salicyluric acid was cut out and subjected to hydrolysis for 3 hr. by refluxing with 20 per cent hydrochloric acid. The paper chromatogram of the ether extract of the hydrolysate contained almost all the salicyluric acid unchanged, indicating great stability to acid hydrolysis under these conditions; which is also true of authentic salicyluric acid. Second, an area corresponding to salicylic acid was detected on the same chromatogram, indicating that a small but significant amount of the salicyluric acid was converted to salicylic acid with a different set of R_F values (Table 1). Third, a positive test of the salicyluric acid spot on the paper chromatograms of milk extracts resulted when the procedure described by Gaffney *et al.*[5] for the determination of hippuric acid in urine was applied. This involves a reaction between the glycine moiety of salicyluric acid with p-dimethylaminobenzaldehyde to produce a yellow colour (azlactone).

Both hippuric acid and salicyluric acid, but not salicylic acid, were detected in fresh milk, evaporated milk, and non-fat powdered milk. These results are confirmatory of hippuric acid in milk[1]; but salicyluric acid has not to our knowledge been reported previously.

Table 1. CHROMATOGRAPHIC BEHAVIOUR OF AROMATIC ACIDS

Compound	R_F values $CHCl_3$	 KCl	Behaviour under ultra-violet	Colour with $DSA\text{-}Na_2CO_3$
Salicyluric acid	0·40	0·72	blue fluorescence	yellow
Salicylic acid	0·90	0·65	blue fluorescence	yellow
Hippuric acid	0·58	0 93	absorbs	colourless

The amount of salicyluric acid in milk was determined by comparison of the spot size of suitable aliquots of the ether extracts of acidified milk with the spot size of known amounts of salicyluric acid (1–5 µgm.) on two-dimensional chromatograms. A sample of fresh milk from a local store contained approximately 160 µgm. of salicyluric acid per litre, a commercial sample of evaporated milk (about 27 per cent total solids) contained about 400 µgm./l., and two commercial non-fat powdered milk samples contained between 200 and 300 µgm. salicyluric acid per 100 gm. of the dry powder.

The most reasonable explanation for the origin of salicyluric acid in milk is that small amounts are able to pass through the mammary gland from the blood. Most of the salicylic acid ingested in the ration apparently is converted to salicyluric acid by glycine conjugation, followed by excretion in the urine. The possibility that the presence of salicyluric acid in milk indicates contamination by urine can be ruled out because we were able to detect salicyluric acid in milk that was obtained by hand milking and known to be uncontaminated by urine.

Structure of Mucoprotein isolated from Normal and Tumoral Cartilage

CERTAIN experimental evidence has been reported by different authors on the variations existing in some properties of complex polysaccharides isolated from normal tissues and from tumours.

With regard to cartilage it has previously been reported[1] that in the course of experimental carcinogenesis differences can be detected in the composition of mucopolysaccharides. On the other hand we have observed[2] that molecular properties of mucoprotein isolated from normal cartilage and from chondroma are almost similar and the only change of the molecule is restricted to the chemical structure as evidenced by a higher content of the protein component in the chondroma mucoprotein.

Recently results reported by Muir[3] suggest that the mucopolysaccharide isolated from cartilage is a complex consisting largely of chondroitin sulphate cemented by a small amount of peptide or protein. The complex is depolymerized to some extent by proteolytic enzymes, and the kinetics of depolymerization seems to be specific for each complex polysaccharide under digestion.

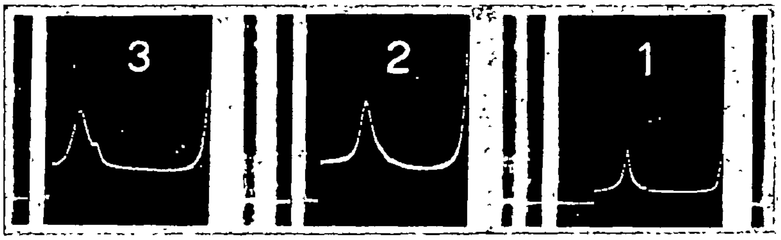

Fig. 1. Ultracentrifuge patterns of cartilage mucoprotein. 1, Undigested mucoprotein, 2, mucoprotein digested with trypsin; 3, mucoprotein digested with papain. Photographs have been taken 120 min. after reaching full speed (47,660 r.p.m.)

In this communication the action of proteolytic enzymes on normal and tumoral cartilage mucoproteins is reported in order to elucidate further the differences existing between the compounds under investigation.

It has been observed that crystalline proteolytic enzymes do not affect the viscosity of mucoprotein solutions (Table 1). Also papain is poorly effective on both compounds, while in Muir's experiments a reduction of 80 per cent in viscosity was observed.

Table 1. PERCENTAGE REDUCTION OF VISCOSITY OF NORMAL (1) AND TUMOUR (2) CARTILAGE MUCOPROTEINS AFTER DIGESTION WITH PROTEOLYTIC ENZYMES

	(1)	(2)
Papain	8	7
Trypsin	6	5
Chymotrypsin	–	–
Carboxypeptidase	3	3

Since it is difficult to believe that the structure of Muir's and my preparations were different, a series of experiments was carried out to find out if differences have occurred in some other molecular properties. In Fig. 1 sedimentation diagrams of mucoprotein isolated from normal cartilage are shown before and after treatment with proteolytic enzymes. It is noteworthy that proteolytic enzymes are able to modify the normal sedimentation coefficient of mucoprotein (Table 2).

Trypsin	4·8 (asymmetric peak)
Chymotrypsin	5·3
Carboxypeptidase	5·2

It was of interest also to note that mucoprotein isolated from chondroma behaved in a similar manner.

The results reported here indicate that the molecular structure of mucoproteins which I have isolated is different from the chondroitin sulphate complex described by Muir, and give stronger support to the hypothesis of the similarity of structure of normal and tumoral mucoproteins.

PHYSIOLOGY

Action of 3-Hydroxytyramine and some Tryptamine Derivatives on Spinal Neurones

PHARMACOLOGICAL studies on the depression of spinal reflexes produced by the topical application of comparatively strong solutions of 3-hydroxytyramine to the exposed spinal cord have led to the conclusion that this catecholamine could be an inhibitory transmitter acting on spinal motoneurones[1]. Recently, it has also been suggested that derivatives of tryptamine may be transmitters within the spinal cord[2]. When applied electrophoretically, adrenaline and nor-adrenaline have no action on spinal neurones[3] although these catecholamines, 3-hydroxytyramine and many derivatives of tryptamine depress the synaptic excitation of lateral geniculate neurones[4]. These agents are not, however, inhibitory transmitters in this portion of the visual pathway.

In the present experiments, 3-hydroxytyramine (Grade *A*, California Corp. Biochemical Research), tryptamine, α-methyl-tryptamine and ergometrine were applied electrophoretically to various types of spinal neurones located in the lumbar segments of cats lightly anæsthetized with pentobarbital sodium. The compounds were passed as cations from the drug-containing barrels of 5-barrel electrodes, the central barrels of which were used for recording extracellular potentials[3]. The neurones were identified by their responses to volleys in dorsal and ventral root fibres[3]. None of these substances affected the responses of spinal interneurones even though they were applied by electrophoretic currents as large as 150–200 × 10^{-9} amp. It is assumed that extracellular concentrations of electrophoretically applied compounds are proportional to the currents which are used, and usually currents of 50–100 × 10^{-9} amp. are sufficient to demonstrate the activity of neuronal excitants and depressants[3–5]. 3-Hydroxytyramine failed to influence the firing of interneurones and Renshaw cells and was without action on motoneurones, even after the commercial product had been recrystallized[6]. In the case of motoneurones the compound was passed into the environment of cells from which extracellular focal potentials, both antidromic and orthodromic, were being recorded. The application of γ-amino-*n*-butyric acid from another barrel of the electrode reduced both types of response[5], yet 3-hydroxytyramine, passed with larger electrophoretic currents, had no effect.

These observations indicate that this catecholamine is unlikely to be an inhibitory transmitter in this region of the central nervous system. The term 'inhibition' was applied to the depression of reflexes produced by topical application of the compound because the depression was prevented by strychnine[1]. When administered intravenously this alkaloid diminished the magnitude of inhibitory postsynaptic potentials[7]; but it is surprising that the doses which were used in the recent investigation[1] were so effective in abolishing the action of topically applied 3-hydroxytyramine. It is conceivable that the catecholamine was converted to an inhibitory transmitter during its diffusion through spinal tissue. Another possibility to be considered is that 3-hydroxytyramine bears some structural similarity to the transmitter. If this be so, the comparatively large amounts of the catecholamine reaching motoneuronal receptor sites after topical application may be sufficient to operate the inhibitory synapses, whereas the concentrations attained electrophoretically may be inadequate.

The tryptamine derivatives and ergometrine, a powerful depressant of lateral geniculate synapses[4], did not affect the responses of interneurones, although L-glutamic acid had its usual excitatory action when passed from other barrels of the electrodes[3]. It is therefore unlikely that tryptamine receptors are of great significance with respect to the operation of synaptic transmitters within the spinal cord.

I wish to acknowledge gifts of recrystallized 3-hydroxytyramine hydrochloride (Dr. H. McLennan, University of British Columbia) and of α-methyl-tryptamine methanesulphonate (Dr. A. Hofmann, Sandoz, Ltd.).

Sodium Chloride Sensitivity and Electrochemical Effects in a Lorenzinian Ampulla

IN the course of experiments on effects of polarizing currents on Lorenzinian ampullæ, in which current pulses were applied to the receptor with electrodes filled with sodium chloride, we found accidentally that the receptor is sensitive to very small amounts of sodium and chlorine ions. This prompted us to examine the chemosensitivity of the ampulla.

Single ampullæ of *Mustelus canis* were set up in a flow chamber as illustrated in the inset of Fig. 1. Large ampullæ, about 1 cm. long and 0·5 mm. in diameter, were chosen for this purpose. The ampulla pore (*P*), which *in situ* opens into the sea-water, was superfused at constant flow-rate with sea-waters of different composition. A selector device allowed switching from one sea-water type to another with no appreciable change in flow-rate. The ampulla bulb (*B*), which contains the receptor nerve ending (*R*), and the emerging axon were in mineral oil. Generator and action potentials were led off single dissected axons (*A*) near the point of their emergence from the bulb.

At constant temperature[1,2], pressure[3,4], and flow-rate, the receptor produces a background discharge of impulses of fairly constant frequency. This frequency is altered when the sodium chloride content of the perfusing sea-water is changed. An increase in concentration of sodium chloride above that of normal sea-water causes an increase in frequency; a decrease in sodium chloride causes the opposite effect (Fig. 1*a*).

The effect is not caused by an unspecific osmotic pressure change: an equivalent increase in osmotic pressure of the sea-water by addition of sucrose causes no appreciable change in impulse frequency. Even a 100 per cent rise in osmotic pressure with sucrose, one that corresponds to more than 200 times the change in threshold required for sodium chloride, is without effect (Fig. 1*b*).

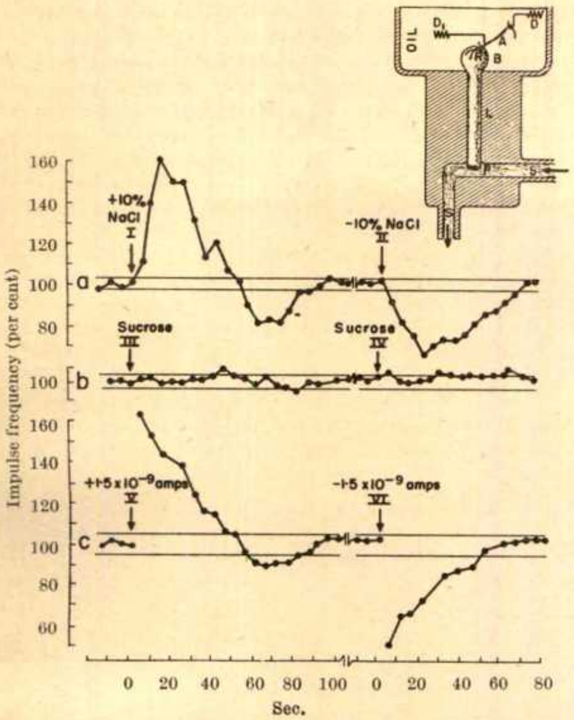

Fig. 1. *a*, Effects of concentration of sodium chloride on impulse discharge of the receptor. The ampulla pore is bathed with normal sea-water; the corresponding mean impulse frequency (100 per cent) and its standard error are delimited by the horizontal lines. The pore is bathed with sea-water the sodium chloride content of which is at I, raised 10 per cent by addition of sodium chloride to normal sea-water; and at II, lowered 10 per cent by dilution. *b*, Effects of increases in osmotic pressure equal to and 10 times that of I by addition of sucrose to normal sea-water. *c*, Effects of a current of $1 \cdot 5 \times 10^{-9}$ amp. through the interior of the ampulla in the direction V, bulb-to-pore; VI, pore-to-bulb

The threshold of the effect is remarkably low. Most ampullæ show a change in impulse frequency with a 5 per cent change in concentration of sodium chloride in the sea-water bathing the pore. The most sensitive ampullæ have thresholds around 0·5 per cent (2 m*M* differential). The sensitivity of the receptor to sodium chloride is several orders of magnitude greater than that of its afferent axon. It is similar to that of some taste[5–9] and hypothalamic 'osmoreceptors'[10–13].

Another striking feature of the effect is the shortness of its latency. The exact value of the latency could not be assessed, because it is shorter than the time resolution of our perfusion system (0·8 sec.). From the considerations which follow, the latency is likely to be of the order of msec. In any event, it is certain to be shorter than 0·8 sec.

This raises the question of how the receptor element located in the bulb can sense with so short a latency an ionic change occurring at the distant pore. In general, one thinks of chemoreceptor excitation as the result of a direct reaction between the chemical agent and the receptor element. Such a mechanism cannot apply here. The receptor element proper is located within the bulb (no nervous structures are found in the rest of the ampulla; in fact, the entire tubule and the peripheral parts of the bulb and jelly can be cut away without the receptor losing its ability to produce rhythmic nerve impulses[4] or to sense ionic changes). The stimulus, namely, the change in concentration of sodium chloride, occurs at the pore of the ampulla, 1–2 cm. away from the receptor element. The entire ampulla up to its pore is filled with a viscous jelly. We have measured the diffusion constant of sodium-24 in the jelly and found it to be $0 \cdot 85 \times 10^{-5}$ cm.²/sec. This is close to the constant of a sodium chloride solution of about equal concentration to that in sea-water (0·5 *M*)[14]. Under the conditions of the experiment of Fig. 1*a*, it would thus take more than 2 hr. to produce a 1 per cent change in sodium concentration at the level of the receptor element by diffusion. Even a change in concentration at the receptor by a factor of 10^{-12}, which would call for a remarkable receptor sensitivity indeed, would require 17 min.—far longer than the observed latent period. A mechanism involving a chemical action of a diffusing agent on the receptor is thus clearly excluded.

An electrochemical mechanism seems more plausible. Murray[15] has already shown that ampullæ *in situ* are sensitive to small voltage gradients in the water around the fish. We have passed electrical currents through the isolated receptor between an electrode fitted to the pore and a micro-electrode placed on the bulb near the terminal portion of an axon. Current through the interior of the ampulla in the direction bulb-to-pore is found to add, at the site of impulse initiation, with the background generator current and, thereby, to enhance the frequency of background impulses. Inverse effects are produced with current in the opposite direction (Figs. 1*c* and 2). The threshold is of the order of 10^{-9} amp. and the latency of the order of msec.

When the concentration of sodium chloride at the ampulla pore is changed by, say, 10 per cent, as in the example of Fig. 1*a*, a potential change is measured at the sea-water-pore junction. The current through the interior of the ampulla resulting from this junction potential is in the direction bulb-to-pore after an increase in sodium chloride, and in the opposite direction after a decrease. (The circuit is closed in most experiments through non-polarizable ground

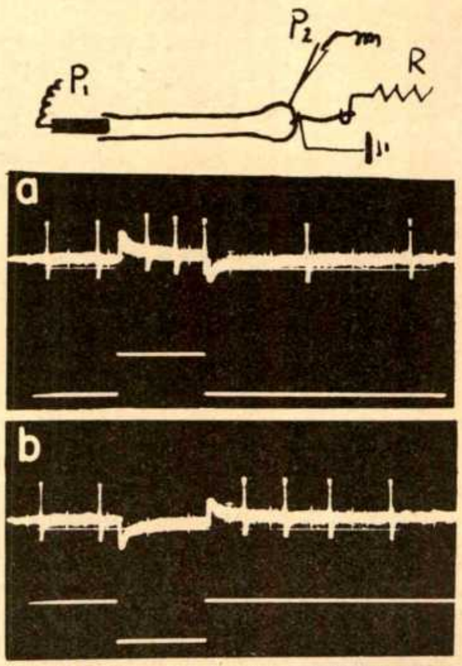

Fig. 2. Enhancement and depression of background receptor discharge by electrical current. Current pulses of 110 msec. duration are passed between electrode P_1 and microelectrode P_2: *a*, in the direction bulb-to-pore; *b*, pore-to-bulb. Time marker, 50 msec.

electrodes in contact with the sea-water and axon.) The current is of the right order of magnitude and in the right direction to account for the observed changes in impulse frequency.

The present results give evidence for a 'chemo'-receptor process of high sensitivity mediated through an electrical mechanism. They do not resolve, however, the question of the physiological role of the ampulla; whether the animal utilizes the ampulla as a sodium chloride receptor, or whether purely electrical[15], pressure[3,4] or other changes are the physiological stimuli, remains to be shown through behaviour studies.

We thank Mr. M. Mendelson for making part of the diffusion constant determinations. The work was supported by the U.S. National Science Foundation and National Institutes of Health.

Injury-induced Synthesis of Deoxyribonucleic Acid in the Lens of the Sea Bass

PREVIOUS work has shown that small mechanical injuries to the epithelium of the rabbit lens can initiate a wave of stimulation to synthesis of DNA and mitosis. The number of cells stimulated to divide is relatively large compared with the size of the injury itself. This reaction is being examined in order to gain a better understanding of the relationship between injury and the induction of cell division.

Examination in cold-blooded animals would offer the advantage of a considerably wider physiological range of temperatures within which the reaction could be studied. Also, the possibility of obtaining this reaction in an *in vitro* system may be greater with the lens of a cold-blooded animal.

The present work demonstrates that small mechanical injuries to the lens epithelium of the bass (*Centropristes striatus*) induces synthesis of DNA in a large number of the surrounding cells. The lenses were injured by insertion of a fine steel needle through the cornea, and into the lens in a manner similar to that previously described[1]. The fish were maintained in tanks of circulating sea water, at approximately 22° C. for 48 hr. At the end of this time the lenses were removed and incubated for 5 hr. in 16 ml. of the following solution at 12° C.: Eagle's basal medium[2] to which was added 0·35 gm. sodium chloride/100 ml., plus tritium-labelled thymidine (sp. act., 3·0 c./mM), at a concentration of 5 μc./ml. The lenses were then fixed in Carnoy's fluid and afterwards prepared for autoradiography[3]. The slides were covered with

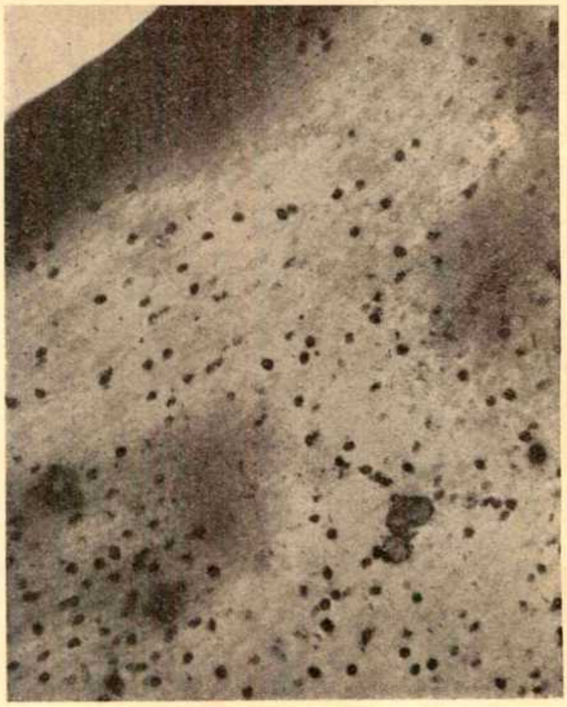

Fig. 1. Autoradiogram of whole-mount of sea bass lens epithelium, fixed 48 hr. after injury. The lens was removed at 46 hr., and immersed in a solution of modified elasmobranch Ringer, containing tritium-labelled thymidine, at 5 μc./ml. Injury site is toward upper left

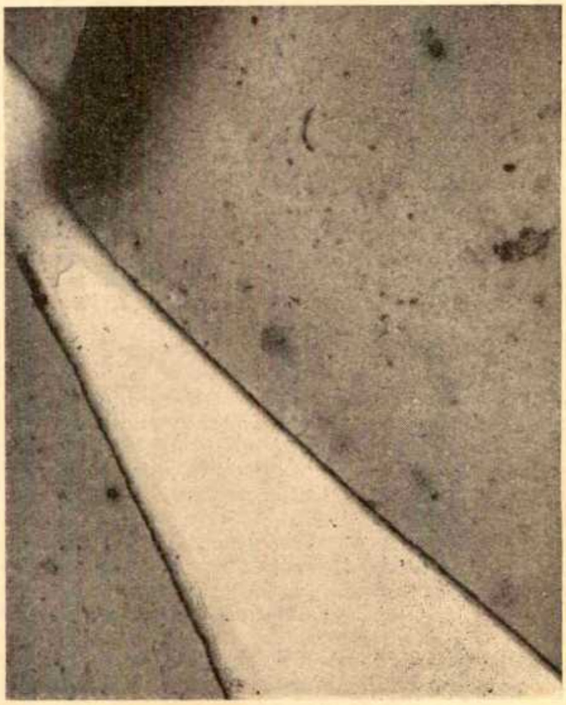

Fig. 2. Autoradiogram of whole-mount of uninjured sea bass lens epithelium. With the exception of the injury, the lens was treated identically to that shown in Fig. 1

Kodak *AR* 10 stripping film, and exposed for 38 days before photographic development. Of the seven experimental preparations obtained, all showed a well-defined injured area. Surrounding this was a large number of cells with radioactive nuclei. Fig. 1 is a photograph of a portion of such a preparation. This large number of reacting cells is comparable with the number seen in the rabbit lens epithelium following injury. Preparations from lenses which had not been injured did not show this number of radioactive nuclei, although a small number of scattered radioactive nuclei were evident in these controls (Fig. 2).

These results indicate that, as in the case of the rabbit lens, a comparatively small mechanical injury can result in the stimulation of synthesis of DNA in a large proportion of the surrounding cells. It is not apparent at the present time whether this stimulation of synthesis of DNA is a propagated response, as has been demonstrated in the rabbit[4]. The number of cells responding, however, is very large compared with the size of the injury itself.

The nature of the stimulus remains obscure. The possibility that the initiation of the cell cycle in these cells is due to the withdrawal of a naturally occurring inhibitor must also be considered. The lens of a cold-blooded animal, such as the bass, may be useful in studying the nature of this reaction under different conditions of temperature, and perhaps in an *in vitro* system.

Influence of Salicylate on Cortisol Secretion in the Dog

SIMILAR antiphlogistic and biochemical effects of salicylate, adrenocorticotropic hormone (ACTH) and cortisol[1] have stimulated interest in establishing a possible influence of salicylate on the secretion of adrenocortical hormones in man and experimental animals. Studies in dogs, guinea pigs and rats have shown a stimulatory effect of salicylate on cortisol secretion[2]. It has been emphasized, however, that these experiments used a dose per unit of body-weight greater than the comparable therapeutic dose in man[3,4]. Furthermore, an anti-rheumatic effect of salicylate has been demonstrated in a patient whose adrenocortical function had been suppressed by 9-α-fluorohydrocortisone[5]. In view of this conflicting evidence, the present work was designed to determine whether or not salicylate has a direct stimulatory effect on the adrenal cortex.

Adult mongrel dogs, anæsthetized by intravenous administration of sodium pentobarbital, were hypophysectomized by a transbuccal approach[6] 1–3 days before examination. All experiments used an isolated perfused dog adrenal preparation[7]. After several control collections of adrenal venous effluent, the agents under examination were administered directly into the arterial circuit of the perfused glands. The plasma concentrations of sodium salicylate (intravenous preparation, Eli Lilly and Co.) and sodium acetyl salicylate (freshly prepared by dissolving equal parts of sodium bicarbonate and acetyl salicylic acid in water) ranged from 7 to 50 mgm./100 ml. and the duration of administration ranged from 15 to 35 min. At the end of each experiment, an injection of ACTH (intravenous preparation, Upjohn Co.) was given at the rate of 1 unit/min. to verify adrenal viability and to compare the cortisol secretion rates under supramaximal stimulation with the previous salicylate periods. Cortisol concentrations in the adrenal venous effluent were determined by the method of Peterson *et al.*[8]. Sodium salicylate added *in vitro* to plasma containing known concentrations of cortisol did not interfere with the spectrophotometric analysis. The arterial and venous plasma-concentrations of salicylate were determined by the method of Brody *et al.*[9].

Table 1. LACK OF EFFECT OF SALICYLATE ON CORTISOL SECRETION FROM PERFUSED DOG ADRENAL GLANDS

Exp.	Control cortisol (μgm./min.)	Salicylate perfusion Salicylate (perfused	Dose mgm./100 ml.)	Cortisol (μgm./min.)	After ACTH Cortisol (μgm./min.)
1	1·6	Sodium	25	0·9	4·2
			50	0·7	
2	5·3	Sodium	25	3·8	9·1
			50	1·9	
3	0·6	Sodium acetyl	7	0·5	2·5
4	3·4	Sodium acetyl	15	1·5	10·0
			25	1·1	
5	10·7	Sodium	25	8·6	16·3

Table 1 summarizes five experiments in which salicylate compounds perfused directly into adrenal glands resulted in no influence upon cortisol secretion either in the presence or absence of ACTH. In Exp. 4 salicylate concentrations in adrenal venous blood were identical to simultaneously measured arterial concentrations, indicating that the adrenals did not accumulate salicylate. In Exps. 1–4 hypophysectomized dogs were used so that little endogenous ACTH was present. Under these conditions control cortisol secretion-rates from the adrenals were variably low, and there was no increase in cortisol secretion following administration of the salicylate compounds. ACTH given at the end of these experiments showed the expected stimulation of cortisol secretion. In Exp. 5 a non-hypophysectomized preparation was used, and the secretion-rate of cortisol was high during the control period. The addition of sodium salicylate to these adrenals stimulated by endogenous ACTH again failed to alter cortisol secretion significantly.

Adrenocortical response to salicylate administration in man is suggested by the appearance of Cushing's syndrome in a patient treated for acute rheumatic fever[10] and by the observed increase in urinary steroids in patients treated for rheumatic diseases[11]. In animal studies salicylate raised dog and rat plasma cortisol concentrations; similar effects in the guinea pig were abolished by hypophysectomy[2].

On the other hand, normal or low plasma and urine 17-hydroxycorticosteroid values were found in normal humans and in patients with rheumatic diseases receiving salicylate[12-15]. While short-term salicylate administration in man resulted in no increase in cortisol synthesis, prolonged administration was associated with a fall in cortisol turnover[5].

The present acute experiments demonstrate no direct stimulatory influence of salicylate on adrenal cortisol secretion in the dog; in fact, the data may be interpreted as showing a modest suppression of cortisol secretion.

Fate of Fructose in the Newly Delivered Fœtal Lamb

IT is well known that the blood of the fœtal lamb contains a high concentration of fructose and that this disappears within a few hours of birth[1-4], yet two recent publications have shown that the perfused liver of the fœtal and new-born lamb is unable to metabolize fructose before the fifth day after birth[5,6], and it is known that fructokinase is absent from the liver of the fœtal lamb[7]. In view of these observations, the results of some preliminary experiments on the urinary excretion of fructose in newly delivered fœtal lambs would appear to be of interest.

Six lambs weighing 3·3–5·4 kgm. were delivered by Cæsarean section under spinal anæsthesia from four cross-bred ewes at 138–141 days gestation age (term is about 147 days). Catheters were inserted under local anæsthesia into a femoral artery and into the bladder (via a small abdominal incision) of the fœtus while it was still attached to the mother by the umbilical cord. Blood samples were taken and the bladder was emptied as completely as possible immediately before dividing the umbilical cord and at intervals during the next 6 hr. Blood and urine fructose was measured as described by Bacon and Bell[1].

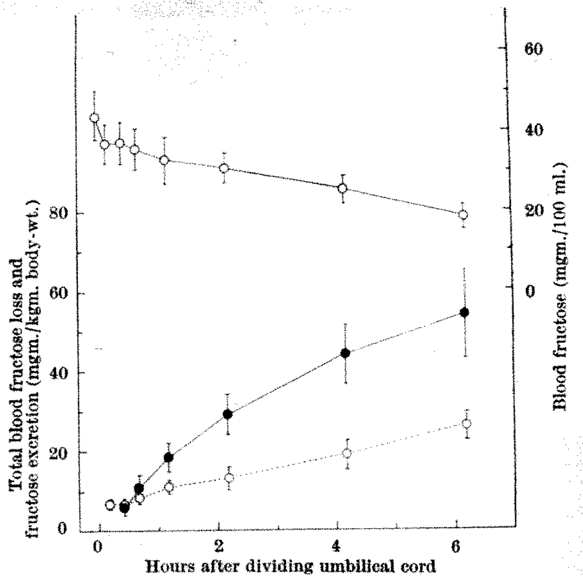

Fig. 1. Blood fructose concentration (○—○), total urinary excretion of fructose (●—●) and apparent total loss of fructose from the blood ○…○) in newly delivered fœtal lambs of 138–141 days gestation age. Means ± standard error, 6 lambs

The results (means ± standard error) are summarized in Fig. 1, which shows the blood fructose concentration, the total amount of fructose excreted in the urine, and the total amount of fructose disappearing from the blood at different time intervals after dividing the cord; this last was calculated on the generous assumption that the blood volume in ml. was equivalent to 10 per cent of the body-weight in gm. There were considerable quantitative differences between individual lambs. Urine was excreted at a mean rate of 5·0 ± 1·56 ml./kgm./hr. over the first 6 hr. and the urinary fructose concentration varied from 42–1,536 mgm./100 ml. Nevertheless the results were wholly consistent. In each experiment, the amount of fructose excreted in the urine was more than sufficient to account for the apparent loss of fructose from the blood; indeed, as shown in Fig. 1, the mean rate of urinary fructose excretion was rather more than twice the apparent rate of fructose loss from the blood. Since the urinary fructose must have been derived mainly from the blood, this difference was presumably due to fructose passing from the tissues and/or extracellular fluid into the blood, so leading to a low estimate of blood fructose loss.

Until some estimate has been made of the total body fructose loss (and of the rate of fructose production), it is not possible to calculate the amount metabolized by the lambs. Nevertheless, as shown in the work on perfused livers[5,6] these experiments suggest that the amount metabolized may be extremely small, and that in the prematurely delivered fœtal lamb the urinary excretion of fructose probably accounts for the greater part, if not all, of the total fructose loss. While it has not yet been shown that this also applies to the fœtal lamb *in utero* and to the new-born lamb delivered naturally, the available information on fœtal urinary fructose excretion and on the rate of fall of blood fructose in normal new-born lambs suggests that they are similar to those observed in the present work. This would seem to suggest that fructose is of little importance as a source of energy to the fœtal and new-born lamb. However, Dickens and Greville[8] have shown that, unlike other fœtal tissues, the fœtal membranes of several species can utilize fructose almost as readily as glucose. Therefore, the possibility remains that the fructose of fœtal ungulates, which have unusually low blood glucose concentrations[4], may provide a source of energy for the amnion and allantois.

PHARMACOLOGY

Effect of Drugs on the Uptake and Release of ^{3}H-Norepinephrine in the Rat Heart

FOLLOWING the administration of a wide variety of drugs such as psychoactive agents (reserpine, chlorpromazine, imipramine), sympathomimetic amines (tyramine, amphetamine), cocaine, adrenergic blocking agents (phenoxybenzamine), and hypotensive drugs (guanethidine) a lower concentration of injected ^{3}H-noradrenaline was found in the heart, spleen and adrenal glands[1-3]. Most of these drugs also increase the rate of metabolism of ^{3}H-noradrenaline in the whole mouse presumably by preventing the protective binding of the hormone and exposing it to enzymatic attack[4,5]. Although these drugs have many actions, they could produce a common-end result by different mechanisms. They might lower the tissue levels of ^{3}H-noradrenaline by blocking the entry of the circulating catecholamine into the storage site, preventing the binding or causing the release of the bound ^{3}H-noradrenaline or by a combination of these.

If a drug prevents the uptake, it should lower the tissue levels of ^{3}H-noradrenaline only when given before the ^{3}H-catecholamine. If it reduces the concentration when given after ^{3}H-noradrenaline when the hormone is bound in tissues, then it releases the catecholamine. To distinguish between these actions rats were given drugs before or after the intravenous injection of ^{3}H-noradrenaline and the amount of the ^{3}H-catecholamine in the heart was measured.

Male rats (Sprague–Dawley), weighing from 160–180 gm., received 10 μc./100 gm. *dl*-7-^{3}H-noradrenaline (20 mc./mgm.) in the tail vein. The rats were killed after 2, 4 or 24 hr., and the hearts were homogenized with 12 ml. of ice-cold 0·4 *N* perchloric acid. After centrifugation the supernatant solution was assayed for ^{3}H-noradrenaline[6]. Drugs were given before or after ^{3}H-noradrenaline as shown in Table 1. Rats were divided at random in groups of 6–12 for each drug treatment.

Reserpine, amphetamine, *d*-adrenaline and phenoxybenzamine reduced the amount of ^{3}H-noradrenaline in the heart when given after as well as before the ^{3}H-catecholamine (Table 1). Tyramine was previously shown to have this action[7]. It is concluded that these drugs release the bound hormone from its storage site. The experimental technique does not distinguish whether or not these drugs may also inhibit the uptake of ^{3}H-noradrenaline.

Table 1. EFFECT OF DRUGS ON THE UPTAKE AND RELEASE OF ^{3}H-NORADRENALINE IN RAT HEART

Drug	Dose (mgm./kgm.)	Time drug given before or after ^{3}H-noradrenaline	Time rats killed after ^{3}H-noradrenaline (hr.)	^{3}H-Noradrenaline in heart (mμc./gm.)
None	—	—	2	300 ± 15
Chlorpromazine	10	30 min. before	2	112 ± 6 *
Chlorpromazine	10	30 min. after	2	271 ± 14
None	—	—	24	58 ± 9
Chlorpromazine	10, 10	30 min. and 12 hr. after	24	49 ± 10
None	—	—	2	276 ± 15
Imipramine	10	30 min. before	2	132 ± 8 *
Imipramine	10	30 min. after	2	269 ± 25
None	—	—	24	91 ± 11
Imipramine	10, 10	30 min and 12 hr. after	24	94 ± 12
None	—	—	4	216 ± 17
Reserpine	1	30 min. before	4	3 ± 0·5 *
Reserpine	1	30 min. after	4	17 ± 2 *
None	—	—	2	240 ± 28
d-Adrenaline	2	10 min. before	2	115 ± 5 †
d-Adrenaline	2	0·5 min. before	2	99 ± 5 *
d-Adrenaline	2	10 min. after	2	159 ± 22 ‡
None	—	—	4	217 ± 15
Phenoxybenzamine	20	30 min. before	4	111 ± 17 *
Phenoxybenzamine	20	30 min. after	4	119 ± 21 †
None	—	—	4	217 ± 15
Dichloriso-proterenol	20	30 min. before	4	148 ± 11 †
Dichloriso-proterenol	20	30 min. after	4	173 ± 19
None	—	—	4	268 ± 7
Amphetamine	5	30 min. before	4	44 ± 10 *
Amphetamine	5	30 min. after	4	164 ± 14 *

All drugs were given intramuscularly except *d*-adrenaline, which was given intravenously. Twelve animals were used for phenoxybenzamine and dichlorisoproterenol and six for all other drugs.
* $P < 0·001$. † $P < 0·01$. ‡ $P < 0·05$.

Treatment with chlorpromazine, imipramine and dichlorisoproterenol produced a lower concentration of ^{3}H-noradrenaline when given before, but not after, the ^{3}H-catecholamine (Table 1). Cocaine was previously shown to have this action[7]. From these observations, it appears that these drugs block the entry of ^{3}H-noradrenaline into storage sites but do not cause its release.

Because chlorpromazine and imipramine blocked the uptake of ^{3}H-noradrenaline, the ability of these drugs to block its release was examined. Previous studies have shown that monoamine oxidase inhibitors produce a higher concentration of ^{3}H-noradrenaline in the rat after 24 hr. by preventing the spontaneous release of the hormone[8]. Chlorpromazine and imipramine did not appear to block the release of ^{3}H-noradrenaline in 24 hr. (Table 1).

Morphological Correlate to a Cholinergic Sympathetic Function

THE sympathetic ganglion cells in the cat are heterogeneous with respect to acetylcholinesterase (AcChE) activity when stained histochemically with the thiocholine method[1,2]. Only a limited number possess high AcChE activity (heavy staining) comparable with that of anterior horn cells and other accepted cholinergic cells. The majority of the sympathetic ganglion cells show very faint or no activity. Some cells are intermediate with respect to staining intensity. There has been recent discussion whether the outstandingly 'AcChE-rich' cells are correlated to a peripheral cholinergic function[1-3]; but definite proof for such a hypothesis has been lacking until now. In an earlier paper[2] it was shown that the stellate ganglion is especially rich in cells with high AcChE-activity compared with the superior cervical ganglion and the prevertebral ganglia. This communication explains that finding.

It is known that sectioning of the post-synaptic fibres of nerve cells results in their becoming tigrolytic, that is, loss of ribonucleic acid (RNA)-staining, and it also results in a reduction of their AcChE-activity[4]. The staining methods for RNA and AcChE[5] were used to associate the AcChE-rich nerve cells in the stellate ganglion with their appropriate post-ganglionic outflow. It was found that sectioning of the cardiac nerves had no influence on the AcChE-rich cells while the opposite type of operation (sectioning of all post-ganglionic fibres except the cardiac nerves) resulted in an almost complete disappearance of AcChE from the majority of these cells. Denervation experiments performed in different combinations showed that practically all AcChE-rich nerve cells in the stellate ganglion give rise to post-ganglionic fibres to the fore leg. The changes in the AcChE-rich ganglion cells could be correlated to different degrees of cholinesterase disappearance from the sweat glands of the fore paw. It was now logical to study histochemically the ganglia which innervate the hind leg. When the ganglia of the sympathetic chain were examined AcChE-rich cells were found in significant amounts in the region of *L*6–*S*2. The well-defined cell-type described is very unusual in other paravertebral ganglia (Fig. 1) and seems to be almost lacking in the prevertebral ganglia. A typical frequency diagram for lumbosacral ganglia is shown in Fig. 2.

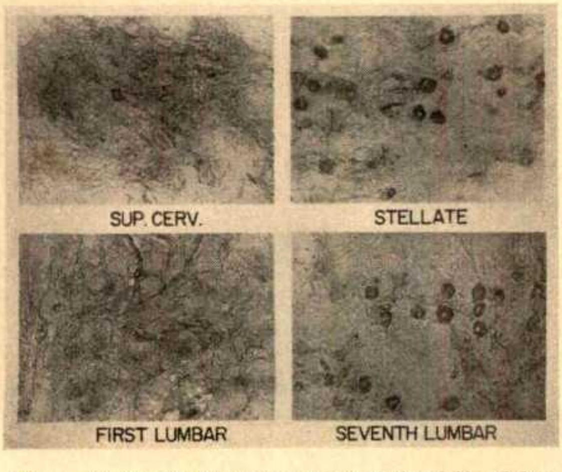

Fig. 1. Photomicrographs from representative fields of four sympathetic ganglia stained for AcChE. Thiocholine method. Incubation time, 30 min. Light microscope. (× *c*. 77)

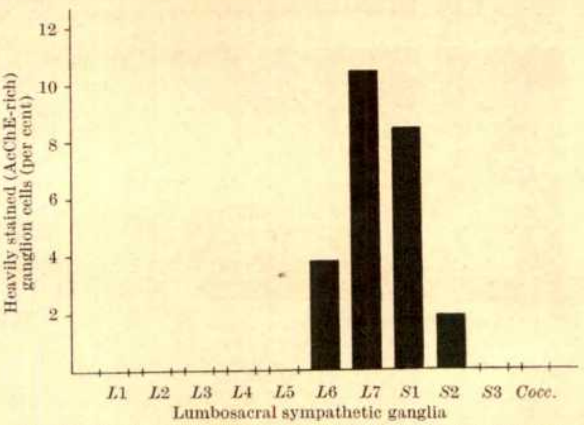

Fig. 2. Frequency diagram showing the number of AcChE-rich ganglion cells in different lumbosacral ganglia after 30 min. incubation

The above-mentioned experiments will be described and discussed in detail in a series of later papers.

It should be pointed out here that the AcChE-rich sympathetic ganglion cells are predominantly localized in those particular ganglia which give rise to post-ganglionic fibres to the cholinergic sweat glands[6], the classical exception in the sympathetic nervous system with respect to neurohumoral transmission[7]. There is a striking similarity between Langley's classical experiments and the findings presented here.

It is evident that the AcChE-rich cells described constitute the morphological correlate to a pharmacologically well-known cholinergic function within the sympathetic nervous system of the cat.

Physiological Disposition and Fate of Nicotine labelled with Carbon-14 in Mice

COMPARATIVELY few investigations have been reported concerning the tissue distribution of nicotine. These previous studies, which were performed using chemical[1-4] and radiometric[5] methods, showed wide discrepancies. In order to try to elucidate the reason for these diverging results and to obtain further information regarding the pharmacological actions of nicotine we have performed whole-body autoradiography using labelled nicotine. Carbon-14 was introduced in the methyl group by methylating nornicotine with formaldehyde-^{14}C (ref. 6).

White mice weighing about 20 gm. were injected intramuscularly with nicotine labelled with carbon-14. The dosage used was 10 μgm./gm. body-weight corresponding to a radioactive dose of approximately 0·1 μc./gm. body-weight. In a few experiments pregnant mice were used to allow a study of the placental passage of nicotine. The mice were killed 1, 2, 5, 7, 10,

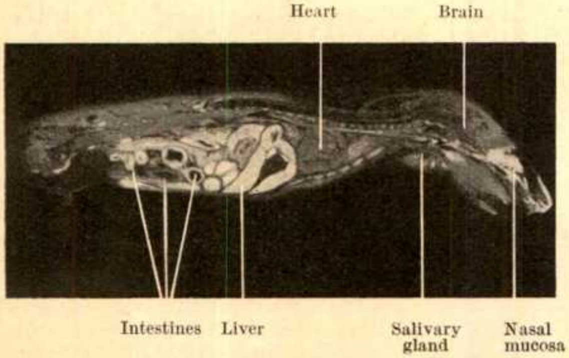

Fig. 1. Autoradiogram showing the distribution of radioactivity in a mouse 15 min. after intramuscular injection of nicotine labelled with carbon-14. White areas correspond to high concentration of radioactivity

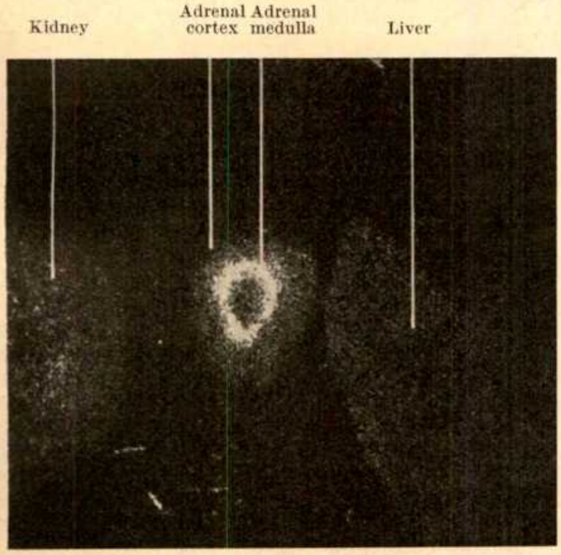

Fig. 2. Enlarged detail of autoradiogram showing the distribution of radioactivity in the adrenal gland 1 hr. after intramuscular injection of labelled nicotine. High activity is observed in the adrenal medulla with the highest concentration in a zone along the border between the medulla and the cortex

30 min. and 1, 2 and 4 hr. after the injection by immersing them into a mixture of acetone and carbon dioxide ice, after which autoradiography was performed[7].

Judging from the whole-body autoradiograms it is obvious that a short time (1–2 min.) after intramuscular injection a considerable part of the radioactive nicotine has been absorbed from the site of injection. The most remarkable finding in these mice is the high brain concentration (Fig. 1). The radioactivity in the brain and spinal cord is considerably higher than in other tissues, and throughout the entire period of examination (up to 4 hr. after injection) the brain shows a high content of radioactivity. 15–30 min. after injection a concentration of radioactivity is noted in the gastric mucosa and radioactivity can also be observed in the lumen of the stomach. The mucous membranes of the nasal cavity show a very high amount of radioactivity. In pregnant mice radioactivity is found in the fœtuses, indicating that nicotine passes the placental barrier.

The main excretory route for nicotine is by the urine. A few minutes after the injection radioactivity can be observed in the renal hilus and in the urinary bladder. Another excretory route for nicotine and its metabolites seems to be the fæces through the bile and the stomach.

Another interesting finding is the high concentration of nicotine in the adrenal medulla. This can be observed a short time after injection, and is persistent during the whole time of observation. In some of the mice a rather sharp zone of radioactivity concentration is observed along the border between medulla and cortex (Fig. 2). Experiments are in progress to localize further nicotine in the adrenal medulla and in ganglion cells by microautoradiographic methods.

Metabolism investigations show that the nicotine is rapidly broken down in the organs. In the liver, the brain and the fœtuses, however, only one metabolite was observed (presumably cotinine). The autoradiographic picture demonstrates thus both nicotine and its metabolites. Experiments are in progress in order to follow the metabolic rate of nicotine in different organs and also to identify the metabolic compounds.

This investigation was supported by a grant from the Swedish Tobacco Co.

HISTOCHEMISTRY

Histochemical Adenosine Triphosphatase Activity in Dark and Light Cells of Collecting Tubules in the Mammalian Kidney

IN the kidneys of various species, the collecting tubules are composed of two types of cells. These were apparently first seen by Heidenhain[1], and described in subsequent years as light and dark (intercalated) cells[2]. The name given to these cells alludes to the fact that the cytoplasm of the dark cells stains with various commonly used dyes more intensely than that of the light cells. The dark (or intercalated) cells reveal also strong metachromasia[3]. Electron micrographs show that the dense cytoplasm of the dark cells contains more RNA granules than the cytoplasm of the light cells. Mitochondria are more numerous in the dark cells and are localized not only in the basal but also in the apical portion of the cytoplasm[4]. In contrast, electron-dense granules are more numerous in the light cells than in the dark cells. These granules are composed of phospholipids and proteins and contain one or several crystals with a hexagonal or square lattice[5].

Histochemical reactions which localize enzymatic activity in these cells show a marked difference in staining pattern. This difference has been described previously for succinic dehydrogenase and tri- and diphosphopyridine nucleotide diaphorase in the rat kidney[6]. In this communication, a similar difference in the staining reaction for mitochondrial adenosine triphosphatase is recorded.

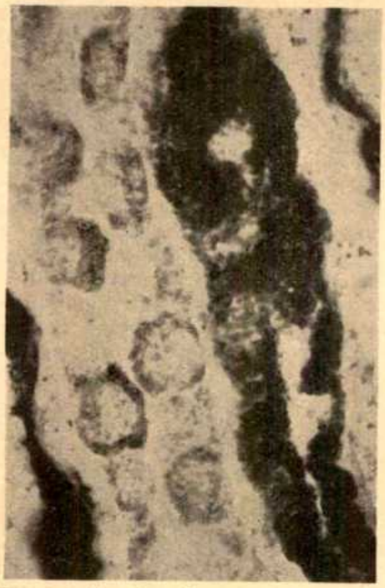

Fig. 1. Frozen section from the outer medulla of the rabbit kidney stained for adenosine triphosphatase activity. To the left a collecting duct is shown. The difference in the granular staining reaction of dark and light cells is striking. To the right an ascending limb of Henle's loop shows intense mitochondrial activity. (× 1,000)

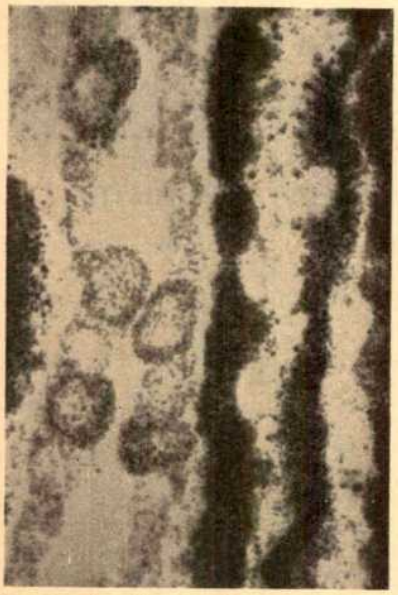

Fig. 2. An adjacent section from the same kidney stained for succinic dehydrogenase (MTT technique of Pearse). A similar enzymatic distribution pattern as that in Fig. 1 is noted. (× 1,000)

Surgically removed human kidneys as well as kidneys of dogs, rabbits, rats and mice were examined. The technique for the demonstration of mitochondrial adenosine triphosphatase has been recently described[7]. Small blocks of tissue are frozen immediately on removal in petroleum-ether or isopentane, cooled to −70° C. Cryostat sections are cut at 5μ and fixed in a neutralized solution of 6 per cent formalin containing 1 per cent calcium chloride, for 5 min. at the freezing point of the mixture (−2 to −3° C.). The slides are then immersed for 15 min. in 0·2 *M tris* maleate buffer *p*H 7·2 at room temperature, and thereafter incubated in the lead-ATP medium of Wachstein and Meisel[8] for 15–30 min. After the usual treatment with ammonium sulphide the sections are mounted in Kaiser's glycerogel. The calcium method for adenosine triphosphatase of Padykula and Herman[9] was also used on cryostat sections that had been fixed for 15 min. in neutral formalin. Results were similar although the method proved to be more capricious.

In all species, the initial portion of the collecting ducts show most of the cells to contain spherical granules corresponding to enzyme-positive mitochondria, while only occasional cells reveal none or only a few of these adenosine triphosphatase positive organelles. The enzyme-rich cells which apparently correspond to the intercalated dark cells decrease in number as the collecting ducts approach the renal pelvis. None is seen in the vicinity of the papilla. At the border of the cortex and medulla the contrast between enzyme-rich and enzyme-poor cells is very striking. This is clearly shown in Fig. 1, which depicts a field from the outer medulla of a rabbit kidney. The neighbouring ascending limbs of Henle's loops are studded with filamentous mitochondria giving a positive reaction for adenosine triphosphatase. Longer fixation of the sections in neutral formalin at 4° C. without the wash in buffer, or fixation of small tissue blocks in cold neutral formalin completely abolishes the mitochondrial staining reaction. This treatment, however, accentuates the staining reaction of vascular capillaries and of some cellular membranes. Fig. 2 shows a fresh-frozen section stained for the demonstration of succinic dehydrogenase for comparison. The similarity between the staining patterns of both methods is obvious. The physiological significance of the marked contrast between the two cell types in the collecting ducts awaits clarification. A marked increase in the number of dark cells in the medullary portions of these tubules occurs in experimentally induced potassium deficiency of the rat, and coincides with the inability to concentrate urine in this experimentally induced renal lesion[10].

Zinc Enzymes and the Hippocampal Mossy Fibre System

IN 1960[1], I pointed out that some simple modifications in the intravital dithizone (diphenyl-thiocarbazone) method used by histochemists[2,3] for the display of zinc show clearly that the site of the specific (pink) staining in the neighbourhood of the hippocampal

'*CA*3' and '*CA*2' pyramidal cells is topologically identical with the zone occupied by the 'mossy fibre system' (the axons of the granule cells of thefascia dentata); while the conspicuous arc of pink staining within the facia dentata is coincident with the '*CA*4' cell-and-fibre zone. I interpreted these concentrations of zinc as histochemical peculiarities of the histoanatomically peculiar 'syncytial periaxoplasm' which the mossy fibre system exhibits, for most of its course, in ammoniacal-silver preparations[1].

A further slight modification of the dithizone method, namely, leaving slabs of tissue 5-mm. thick in the zinc-acetate-enriched formalin fixative for some 8 hr. before counterstaining with methyl green and cutting 80-μ frozen sections for mounting in glycerine jelly, produces semi-permanent-coloured preparations. The precise location of the pink dye, however, for example, as between the mossy fibres and the shafts of apical dendrites of pyramidal cells, still cannot be microscopically distinguished. To surmount this difficulty, I have more recently slightly modified Timm's[4] silver-sulphide method for the histological display of heavy metals, by varying the intervals between death and fixation as well as the development time, diluting the gum-arabic to 5 per cent, and counterstaining with methylene blue or neutral red. This gives permanent, 10μ, contrasting-coloured sections (Fig. 1) in which different elements of the mossy fibre system can be made to stand out conspicuously from all other structures in the forebrain, and which can be studied informatively at various magnifications.

Low powers of the microscope reveal syncytially skeining long homogeneous brown stripes bestrewn with black particles along their margins wherever they cross the pallisade of apical dendrites of pyramidal cells of '*CA*3' or '*CA*2'. Higher magnifications, with certain variations of the method, and notably in the 'end-bulb' region in the guinea pig after prior dithizone treatment, furnish a clear picture of these black particles outlining the shafts of the apical dendrites in '*CA*3' and '*CA*2' (Fig. 2); and with other variations in the time parameters, give visual confirmation, in the form of pools of homogeneous brown precipitate, of the 'confluence of periaxoplasm at the end-bulb', previously deduced from the ammoniacal-silver studies[1].

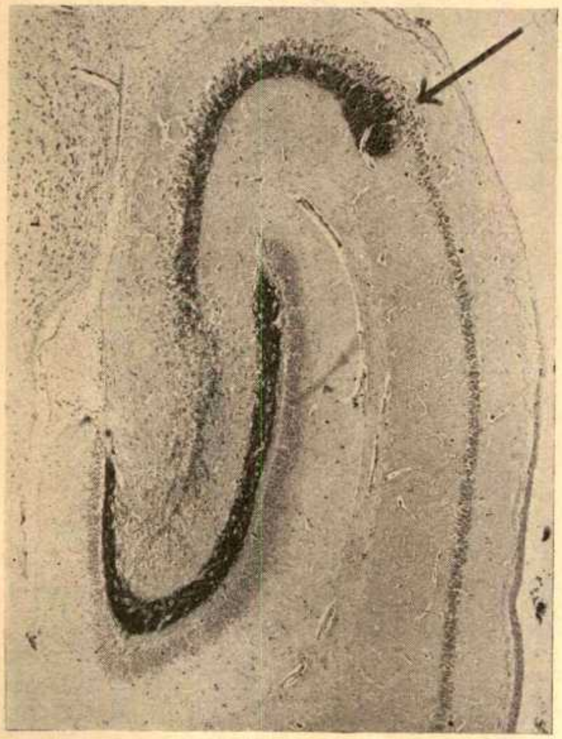

Fig. 1. Transverse section of dorsal hippocampus of guinea pig, showing the mossy fibre system and the '*CA*4 arc' impregnated by silver-sulphide, and the cell-layers counter-stained by methylene blue; 'end-bulb' indicated by arrow. (× 30)

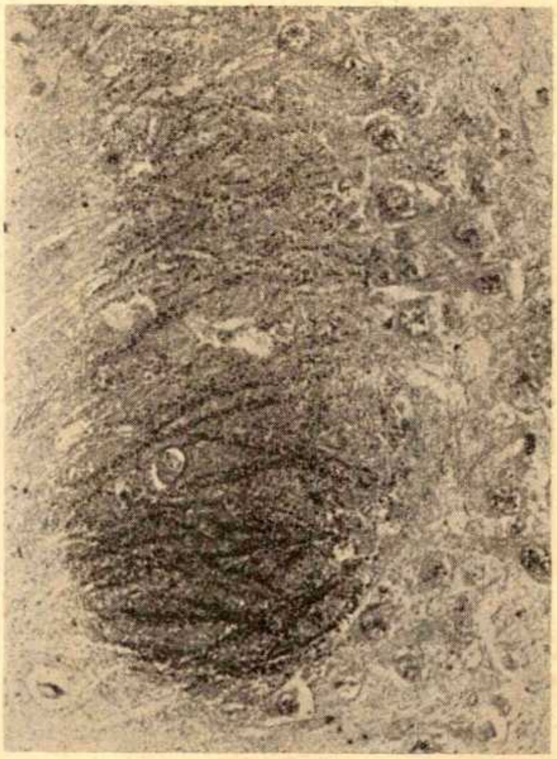

Fig. 2. Enlarged view of the end-bulb region in the guinea pig, prepared as in Fig. 1 after intravital dithizone, showing the 'outlining by black-particles' of the apical dendrites where traversed by mossy fibres. (× 210)

There would seem no reasonable doubt but that the metal responsible for the brown and the black silver-sulphide precipitate is zinc; that this zinc is linked with some diffuse enzymatic protein in the periaxoplasm; and that it is either specially concentrated, or linked with some other enzymatic protein, at the 'mossy' *synapses-de-passage*. My own histo-enzymatic preparations show apparently significant concentrations of acid phosphatase in especially the 'end-bulb': the one part of the mossy fibre system where non-impregnation by ammoniacal-silver had previously given intimation of disappearance of axis-cylinders and a change in the 'chemical specificity'[1]; while succinic dehydrogenase selectively outlines the pallisaded '*CA*3' and '*CA*2' apical dendrites where traversed by the mossy fibres. It is difficult to avoid the working hypothesis (without prejudice to the presence of other enzymes such as acetyl-cholinesterase) that the generality of the periaxoplasm probably contains a zinc-acid-phosphatase, manufactured at '*CA*4' where periaxoplasm first appears[1]; and that each mossy synapse contains an additional zinc-dehydrogenase, presumably elaborated by the mitochondria within each 'presynaptic bag'[5]. Perhaps a third zinc-enzyme must be sought to explain the intensity of the dithizone staining and the diffuse impregnation, by ammoniacal-silver and by silver-sulphide, within the '*CA*4 arc'.

I have elsewhere[6] expounded the thesis that a fibre system possessed of such peculiar morphological and chemical characteristics ought to be investigated intensively for comparably peculiar neurophysiological attributes, having in mind its exploration by pre-modelled sets of pick-up microelectrodes during inputs of species-meaningful, for example, auditory, patterns of stimuli, in non-anæsthetized animals, by people with the facilities for such research.

The silver-sulphide method in the guinea pig also reveals a fine-grain dispersion of zinc-substance between the '*CA*2' somata, as if diffused from the end-bulb. This has interesting possible causal relations with the hippocampal pathology associated with experimental carbon monoxide seizures in the guinea pig, as observed in this laboratory, to be reported on fully elsewhere.

HISTOLOGY

Use of Fluorescein-labelled Rheumatoid Factor for locating Sites of Antibody Fixation in Tissues

RHEUMATOID factor is a macroglobulin component of the serum of patients with rheumatoid arthritis and can be demonstrated in a variety of serological tests by its reactivity with aggregated γ-globulin or with antibody combined with antigen. Exploiting its peculiar affinity for specifically bound antibody, I have used rheumatoid factor labelled with fluorescein in preliminary experiments as an immunohistological reagent for locating sites of antibody fixation in sections of quick frozen tissue by Coons's technique.

The rheumatoid factor reagent was prepared from a euglobulin fraction of pooled, inactivated rheumatoid serum[1]. The euglobulin was conjugated with fluorescein following the method described by Marshall[2]. Unconjugated fluorescein was removed by dialysis against 0·1 *M* disodium phosphate solution (*p*H 8·6), which minimized re-precipitation of euglobulin. Following conjugation, the sensitized sheep cell agglutination titre of the euglobulin solution had fallen from 1/8,000 to 1/1,000, but there was no further loss of hæmagglutinating activity after dialysis or absorption with guinea pig and human tissue powders.

The reactivity of the rheumatoid factor reagent with tissue-bound antibody was demonstrated by the following procedure. Unfixed sections of quick-frozen normal human kidney (test sections) were exposed overnight to the globulin fraction of an antiserum prepared in the rabbit against isolated human glomeruli. This immune serum, absorbed with human serum, was known to contain antibodies reactive with certain tissue elements in human kidney. Adjacent kidney sections were exposed overnight to normal rabbit globulin (control sections). After washing thoroughly in 0·1 *M* disodium phosphate (*p*H 8·6), the test and control sections were exposed to the rheumatoid factor reagent for 1 hr. at room temperature: in parallel experiments, fluorescein-labelled sheep anti-rabbit globulin antiserum was substituted for the rheumatoid factor reagent.

In the test sections the rheumatoid factor reagent reproduced the distribution of 'staining' observed with the conjugated sheep anti-rabbit globulin antiserum, indicating that the rheumatoid factor reagent had located the sites of specific fixation of rabbit antibody. Antibody fixation could still be demonstrated by the rheumatoid factor reagent when the rabbit antiserum was diluted 1 in 32. It was evident, however, from the degrees of fluorescence produced by the two conjugates that the rheumatoid factor reagent reacts less well with antibody bound to the media of arterioles and the basement membrane of the glomerular capillaries than with antibody at other sites—the basement membrane of the tubules, the adventitia of blood-vessels and the interstitium.

The reaction of the rheumatoid factor reagent with bound antibody in the test sections could be inhibited by unlabelled rheumatoid euglobulin (sheep cell agglutinating titre 1/16,000), but not by the euglobulin fraction of a rheumatoid serum with a negative sheep cell agglutination test and positive *F* II-latex

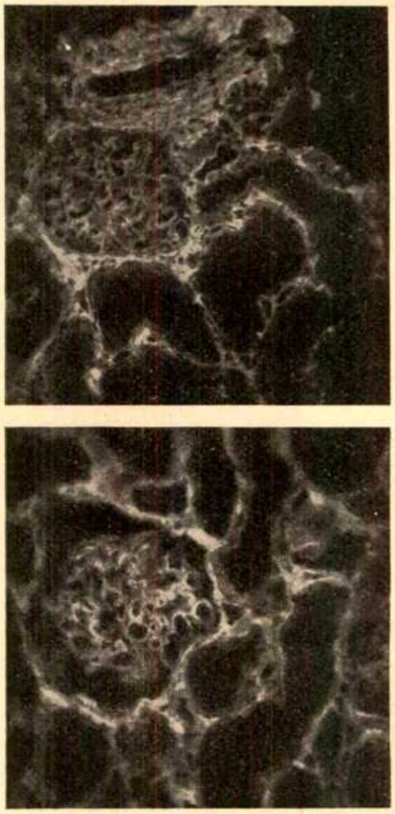

Fig. 1. Fluorescence photomicrographs of human kidney sections. Above, Specifically bound rabbit antibody globulin has been located by fluorescein-labelled sheep anti-rabbit globulin antiserum. The basement membranes of the tubules and glomerular capillaries and the adventitia and media of the artery showed specific green fluorescence. (The internal elastic lamina is visible because of its brilliant white autofluorescence.) Below, The bound rabbit antibody globulin has been located by fluorescein-labelled rheumatoid factor. The basement membranes of the tubules and glomerular capillaries showed specific green fluorescence

fixation test nor by normal human euglobulin or fresh guinea pig serum. After absorption of the rheumatoid factor reagent with insoluble, aggregated human γ-globulin, which reduced the sheep cell agglutinating titre from 1/1,000 to 1/4, there was still a discernible although considerably reduced reaction with bound antibody.

The control sections, treated with normal rabbit globulin instead of the rabbit antiserum, showed no 'staining' with the rheumatoid factor reagent although native human globulin, presumably denatured by freezing, thawing and drying, could be demonstrated by a conjugated specific antiserum. Similarly, there was no reaction with native globulin in sections of normal rabbit tissue.

In this experimental model, rheumatoid serum factor conjugated with fluorescein has proved to be an effective reagent for locating fixed antibody in tissue sections. The possible application of this technique to the problem of detecting specifically bound antibody in other experimental conditions and in spontaneous disease is being explored.

While this work was in progress the Rheumatic Diseases Research Centre was receiving financial support from the Nuffield Foundation and the Empire Rheumatism Council.

I wish to thank Dr. A. G. S. Hill and Dr. D. G. Scott for helpful advice and criticism.

HÆMATOLOGY

Differences in Hæmostatic Behaviour between Arterial and Venous Blood

Previous papers from our laboratory have shown marked differences in the behaviour of arterial and venous blood in hæmostasis. Only citrated arterial blood shows hæmostatic properties when used as a perfusion fluid in the dog's hind leg preparation[1], citrated venous blood being devoid of these properties and, moreover, having a strong inhibitory activity when added to arterial blood[2].

It has been observed that heparin, besides its effects on coagulation, has, at least in some dogs, a marked tendency to prolong determinations of bleeding time. When a standard dose of heparin (300 I.U./kgm.) was injected intravenously into a series of 800 dogs the bleeding time remained normal in 63 per cent (heparin-resistant dogs); 18 per cent showed a moderately prolonged bleeding time; whereas in 19 per cent (heparin-labile dogs) the bleeding time was higher than 30 min.[3]. On the other hand, it has been shown in the dog's hind leg preparation that heparinized arterial blood taken from heparin-resistant or heparin-labile dogs, when in contact with foreign surfaces, changes its hæmostatic behaviour according to the kind of surface[4]. This extreme lability of heparinized blood in respect of its hæmostatic properties makes a sharp contrast with citrated blood, the hæmostatic properties of which remain active for a long time after withdrawal from the animal. Moreover, even in the intact animal it has been observed that rapid contact of heparinized arterial blood flowing through short tubes (placed between the ends of a severed artery) was enough to change its hæmostatic characteristics[5].

The present investigation shows further differences in the hæmostatic behaviour of arterial and venous blood in the intact heparinized animal, these differences being detected when blood is withdrawn and put into contact for some time with a plastic surface and is afterwards re-injected into the circulation of the animal.

The experiments were carried out in two types of dogs previously chosen for their resistance or lability towards a standard dose of heparin. After 10 min. of the intravenous injection of heparin (300 I.U./kgm.) followed by a continuous injection at a rate of 2 I.U./kgm./min., samples of blood were taken from either jugular vein or carotid artery and placed in plastic (cellulose nitrate) tubes, under a layer of mineral oil, at room temperature. The amount of blood taken varied according to the weight of the dog; taking the blood volume as 10 per cent of the body-weight, 2 per cent of the total blood volume was withdrawn for the foreign surface test. After a predetermined time of contact, the blood was re-injected (by the route from which it was withdrawn) and after 3 min. bleeding time determinations were performed by means of skin cuts in the inner aspect of both legs.

When arterial blood from a heparin-resistant dog is placed in contact with a plastic surface and re-injected into the animal, the bleeding time remains normal (5 determinations), but if venous blood is allowed to come into contact with the same surface over the same period of time and then re-injected, hæmostasis is suppressed, as shown by bleeding time values higher than 30 min. (14 determinations).

When arterial blood from heparin-labile dogs is placed into contact with a plastic surface and is again injected into the animal, the bleeding time becomes normal (8 determinations), as would be expected from previous findings on this subject[5]. Venous blood is devoid of these properties, that is, bleeding time remains higher than 30 min. when, after contact with plastic surface, the blood is re-injected into the animal (2 determinations).

In these two sets of experiments the effect on hæmostasis is observed with an amount of venous or arterial blood as small as 2 per cent of the assumed total blood volume and in a period of time higher than 10 min. (10–60 min.). These are critical values, since if smaller quantities are used or the time of contact with the plastic surface is shortened, the phenomenon does not occur (8 determinations). Furthermore, the effect is only observed with heparin administered *in vivo*. The use of heparin *in vitro*, or the application of other anti-coagulants such as sodium citrate (3·8 per cent) and oxalate mixture (1·2 per cent ammonium-oxalate and 0·8 per cent potassium oxalate), are unable to reproduce the phenomenon (11 determinations).

That 2 per cent of the total blood volume, by mere contact with a foreign surface, should acquire the property of changing hæmostasis in the whole animal is rather surprising. Heparin has a broad spectrum of biological activity[6] and seems to sensitize plasma proteins when in contact with foreign surfaces[4,5]. The results given here show that the effect of this sensitization on hæmostasis depends on the source from which the blood is taken, venous blood being active in heparin-resistant dogs, arterial blood in heparin-labile dogs.

As shown previously, the number, agglutinability or clot-retraction activity of platelets do not change after heparin injection[5], their role being, therefore, very questionable in the phenomenon described here. The ability of heparin to make complexes with a variety of plasma proteins is a point that should be stressed, since many observations in our laboratory suggest that the role of plasma proteins is more significant than the participation of blood elements in the control of hæmorrhage in small vessels and capillaries[6]. With the use of heparin, efforts are now being made to isolate and identify the plasma components involved in hæmostasis.

The First Human Blood, ---/---, which Lacks the 'D-like' Antigen

THE 'D-like' antigen has been demonstrated in all Rh positive and Rh negative human bloods including the rare D--/D-- and r^Gr^G (ref. 1), as well as in rhesus and other lower monkey red blood cells, but it was not found in common laboratory animals[2,3]. One of the characteristics of this antigen is its capacity to induce formation of 'anti-D-like' antibodies in guinea pigs. These red cells which possess this antigen after exposure to its antibody yield eluates exhibiting the 'D-like' specificity.

The unique blood of a normal, female Australian aborigine, Mrs. E. N., which is deprived of all known antigens of the Rh–Hr system, was described recently by Vos, Vos, Kirk and Sanger[4]. As this rare blood was neither Rh positive nor Rh negative, an excellent opportunity was provided to determine whether it carried the 'D-like' antigen. If the ---/--- red cells lacked the 'D-like' property, the question arose of the probable theoretical implications of the relationship of the 'D-like' antigen to basic Rh substance.

Joint parallel studies of the ---/--- blood and the 'D-like' antigen were undertaken based on three criteria: (*a*) absorption with ---/--- red blood cells; (*b*) elution of the antibody; and (*c*) antigenicity in guinea pigs. These investigations demonstrate that this exceptional ---/--- blood devoid of Rh–Hr antigens also does not possess the 'D-like' property.

'Anti-D-like' reagents prepared by absorptions with Rh negative or Rh positive red blood cells did not produce potent reagents since all random bloods possess the 'D-like' antigen; however, using ---/--- red blood cells for absorptions, more potent reagents were obtained which would suggest that these red cells did not carry the 'D-like' property (Table 1).

Eluates were prepared according to the technique described previously[3]. In contrast to Rh negative bloods, the red blood cells of E. N. failed to yield eluates with 'D-like' specificity as indicated in Table 2. While we used a guinea pig anti-rhesus reagent, Vos and his co-workers used a reagent prepared from guinea pigs injected with *rr* red blood cells and confirmed the results shown in Table 2.

Frozen glycerinated ---/--- blood on arrival from Australia was maintained at −70° C. As a control a freshly drawn specimen of Rh negative blood was also preserved in glycerine, frozen and maintained at −70° C. To avoid the loss of red cells incidental to deglycerinization, thawed, unwashed samples were used for injections. (Guinea pigs injected with glycerine revealed no toxic effects.) At three-day intervals each of two series of guinea pigs received two injections of 2·0 ml. of the bloods which contained approximately 1·0 ml. of sediment. When tested ten days later by two absorptions at 1 : 5 with *rr* red blood cells, of the 20 guinea pigs inoculated with the control *rr* blood, 12 produced 'anti-D-like' antibodies; however, none of the 20 guinea pigs inoculated with ---/--- blood showed 'anti-D-like' specificity. Four of the 20 guinea pigs inoculated with ---/--- blood produced an antibody exhibiting anti-N specificity which was not observed in the pre-inoculation specimens. Since the ---/--- red blood cells are of genotype *NN*, the source of stimulation is obvious.

The immunization experiments carried out in Australia were made with heat extracts of group O, *rr* red blood cells and ---/--- red blood cells. While the five guinea pigs injected with heat extracts of ---/--- red cells failed to produce 'anti-D-like', two of these five produced an antibody also identified as anti-N. Of the four guinea pigs injected with heat extracts of *rr* red blood cells, three showed very weak 'anti-D-like' specificity when absorbed with *rr* red cells. After absorbing these sera with the ---/--- red blood cells, all four gave 'anti-D-like' specificity

Table 1

Guinea pig serum (351) diluted 1: 10 and absorbed twice with washed red blood cells	Tested with									
	R_2R_2	R_1R_1	R_1r	R_0r	r′r	r′r	r″r	rr	rr	---/---
---/---	+ + +	+ + +	+ + +	+ + +	0	0	0	0	0	0
R_1R_1	+ +	+ +	+	+	0	0	0	0	0	0
rr	$+^s$	$+^s$	$+^s$	+	0	0	0	0	0	0

Guinea pig No. 351 was injected twice with Rh negative red cells. Readings were taken after incubation for 45 min. at room temperature, light centrifugation and resuspension of the sedimented red cells.

Table 2

Pooled guinea pig anti-rhesus serum 1 : 5	Tested with							
	R_2R_2	R_1R_1	R_1r	R_0r	rr	rr	rr	---/---
Absorbed with rr	+ ±	+ ±	+ +	+ +	±	±	0	0
Eluate from red blood cells :								
---/---	0	0	0	0	0	0	0	0
rr	+ + + +	+ + + +	+ + + +	+ + + +	0	0	0	0

Readings were taken after incubation at room temperature for 1 hr., light centrifugation and resuspension of the sedimented red cells.

of stronger activity than that obtained on absorptions with *rr* red blood cells.

The view that the E. N. genotype, ---/---, is the result of suppression or deletion of that part of the chromosome bearing the Rh locus has been considered by Vos *et al.*[4]. Another possibility may be that ---/--- represents basic material remaining after loss of products of the Rh–Hr genes by one or another genetic mechanism, but, on the other hand, it could represent basic material on which the Rh–Hr genes deposit their products.

Based on our previous observations and the results of this joint study, it would appear that when a gene produces an Rh–Hr antigenic determinant, it simultaneously produces a 'D-like' antigen. We would like to offer the hypothesis that the 'D-like' material constitutes unaltered basic Rh substance which, by a series of mutations in man, has evolved into the complex Rh–Hr situation as it exists to-day. Such a theoretical possibility was mentioned as early as 1952 by Murray and Clark[5]. In any event at this stage of investigation one can conclude that the 'D-like' antigen is associated with all random human bloods bearing any one or more of the antigenic determinant groups of the Rh–Hr system.

We thank the King Edward Memorial Hospital for Women, Perth, for financial support, and Dr. G. A. Kelsall for his co-operation. We also thank the Western Australia Department of Native Welfare for facilitating the collection of blood from Mrs. F. N.

PATHOLOGY

Rat Tail Tendon Denaturation and Rheumatic Diseases

DR. B. J. RIGBY and co-workers[1,2] in their studies on mechanical properties of rat tail tendon have extrapolated a possible explanation for the pathological alterations that occur in rheumatic diseases of humans. They consider the damaging effects of rheumatic diseases to be caused in part by a denaturation of collagen which was a function of temperature. It is our contention that the extrapolation cannot be made for several reasons.

There are a number of observations on rat tail collagen that make it distinct from other mammalian collagens in spite of the similarity of rat collagen's chemical composition and shrinkage temperature to that of other mammalian collagens. Rat tail tendon collagen can be partially solubilized with cold distilled water[3] and approximately 90 per cent of the tendon collagen is dissolved in dilute acetic acid[4]. Most mammalian collagens do not exhibit these properties. Neuman[5] showed that rat tail tendon collagen was completely solubilized by heat treatment in water at 60° C. for 20 min.; whereas the other mammalian tail or Achilles tendons were not solubilized or only solubilized to the extent of 20–30 per cent. However, the solubility and thermal characteristics of rat tail tendon are very similar to those seen in fish collagens.

In our investigations on infectious arthritis, we have been interested in comparing the thermal properties of articular cartilage with that of other collagens. Meyer[6] had originally questioned the similarity of the collagens of tendon and cartilage. Recently we have come across an observation[7] that human costal cartilage has a shrinkage temperature of 83°–87° C.

Table 1. COMPARISON OF BOVINE TENDON AND CARTILAGE COLLAGEN

Temperature	Solubilization* (per cent) Tendon†	Articular cartilage†
37° C.	7·6	1·3
45° C.	13·4	3·5
50° C.	28·1	5·3

* Based on the amount of hydroxyproline that appeared in the filtrate.

† Suspensions of bovine Achilles tendon and bovine articular cartilage were incubated for four days in 0·1 *M tris* buffer, *p*H 8·0, containing 1 : 5,000 dilution of merthiolate.

Our approach was to study the effect of temperature on the solubilization of collagen. Solubilization of collagen was used as a measure of the degree of collagen denaturation. Table 1 shows that bovine tendon collagen is four to six times more solubilized by heat than bovine articular cartilage collagen irrespective of the temperature. These data indicate greater thermal stability of bovine articular cartilage collagen as compared to bovine tendon collagen. We interpret these data to be contrary to the denaturation hypothesis put forth by Rigby *et al.*[2].

Denaturation of collagen as a function of temperature is too broad a phenomenon to explain the specific lesions observed in rheumatic diseases and the variations in the clinical course of the disease process. Denaturation of articular cartilage collagen may still occur in rheumatoid arthritis, but this could well originate in as yet unknown mechanisms involved in the pathological process.

In regard to the importance of the time factor[2] in rheumatic disease, it has been observed frequently that the destructive effects seen in these diseases depend more on the intensity of the rheumatic attack than the duration of a milder form.

Tissue-Specificity in the Soluble Antigens in Kidney Microsomes

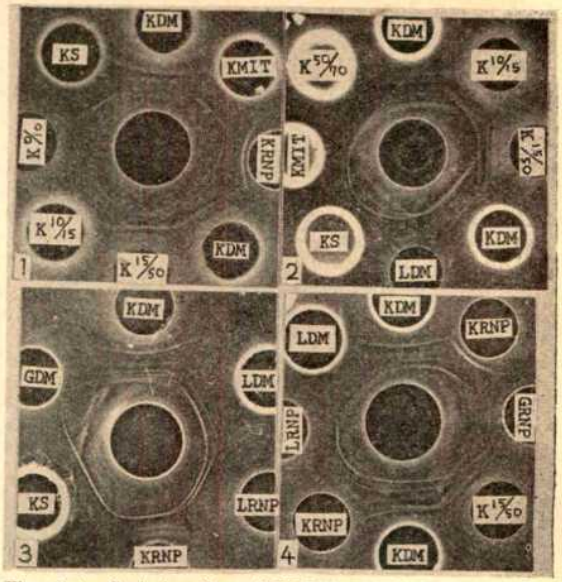
It has been suggested that the membrane of the endoplasmic reticulum contained in the microsomal fraction is the site of the localization of tissue-specific antigens[1]. This structure may, however, be of immunologically complex nature, consisting of a number of antigenically different molecules, only several of which may be tissue-specific. This brief communication is concerned with attempts to identify and partially purify the tissue-specific antigens in the microsomal fraction of chicken kidney. In the immunological test the double diffusion agar technique was adopted, since this method is considered to be most adequate for the analysis of the complex antigen–antibody system and, in fact, it has been successfully used for the immunological characterization of the constituents of the different cell fractions of rat liver[2].

The microsomal fraction was isolated from adult chicken kidneys by a routine method[3], and this was injected into rabbits to prepare the antisera. Sometimes the microsomal pellet was dispersed in a medium composed of 0·14 *M* sodium chloride, 0·1 *M* phosphate buffer and 2 per cent ethylenediamine tetra-acetic acid (EDTA) (*p*H 8·0). The residue obtained by centrifugation after such treatment was also used as antigen for preparation of the antisera. Since preliminary tests revealed that the EDTA-treated microsome, in spite of removal of some soluble proteins together with RNA, produced more potent antisera than untreated microsome without causing any essential difference in the results, the following account concerns results obtained with the anti-EDTA-treated microsomal sera as reagents.

For testing, the homogenates of kidneys, livers and lungs of adult chickens were separately fractionated according to methods described by D'Amelio and Perlmann[2] to prepare the following samples; 0·5 per cent deoxycholate extract of mitochondria, 0·5 per cent deoxycholate extract of microsome (DM-fraction in the following description), EDTA extract of ribosome and cell sap. Double diffusion test in agar was run at 37° C. for 2 days, and then the dishes were kept under 4° C. for 2 further weeks. Concentration of the antigens to be tested had been previously adjusted to contain approximately 1·0–2·0 mgm. protein/ml.

When the antigen–antibody precipitates became stationary, the antisera gave at least 5 major lines and several minor ones in reaction with the DM-fraction of the homologous organ. These lines can be separated into two distinctly different groups. One is a rapidly migrating group containing 2 major lines, and it is common to all the fractions of kidney. In contrast, the other group, which is slowly migrating, is highly specific for DM-fraction (Figs. 1 and 2). Moreover, a heavy precipitin-line appeared closest to the well containing the EDTA extract of ribosome, which may be caused by an antigen specifically predominant in this fraction.

The antigenic components of the slowly migrating group identified in DM-fraction of kidney are not only highly fraction-specific, but some of them display a high degree of tissue-specificity. DM-fraction of lung scarcely gave any visible lines to fuse with the lines belonging to this group, while in the reaction with the same fraction prepared from liver 2–3 faint identical lines became perceptible. But at least 1 major and 1–2 minor antigenic components of the slowly migrating group of kidneys were always left as specific for this tissue (Figs. 3 and 4). The antigens of the rapidly migrating group were shown to be non-specific, being common to DM-fractions prepared from kidney, liver and lung, though the concentration of the last one was very low. Only in the reaction with DM-fraction of lung another rapidly migrating band appeared. This may be caused by antigens of blood cells, which might occur due to the extreme difficulty of complete removal of these cells from the lung.



Figs. 1–4. Central wells, anti-EDTA-treated microsomal sera. Peripheral wells, antigen solutions to be tested: *KDM*, DM-fraction of kidney; *KMIT*, deoxycholate extract of kidney mitochondria; *KRNP*, EDTA extract of kidney ribosome; *K*0/10, precipitate obtained from DM-fraction of kidney at 10 per cent saturation of ammonium sulphate; *K*10/15, *SF*10/15 of DM-fraction of kidney; *K*15/50, *SF*15/50 of DM-fraction of kidney; *K*50/70, *SF*50/70 of DM-fraction of kidney; *KS*, cell sap of kidney; *LDM*, DM-fraction of liver; *LRNP*, EDTA extract of liver ribosome; *GDM*, DM-fraction of lung; *GRNP*, EDTA extract of lung ribosome

Next, efforts were made to separate the tissue-specific components from DM-fraction of kidney by means of the fractional precipitation of ammonium sulphate. Throughout the process *p*H was kept at 7·5 with *tris*-buffer. The precipitate obtained at 10 per cent saturation was found to be insoluble with deoxycholate as well as with saline or EDTA solution at any *p*H between 7·0 and 8·5. The proteins precipitated between 10 per cent and 70 per cent saturation were easily dissolved with water without adding any detergent and were able to be used for immunological test as aqueous solution. The reaction of these water-soluble proteins with the antisera represented a full spectrum of the precipitin-lines recognized between the antisera and DM-fraction of kidney. Further fractional precipitation revealed the following points (Figs. 1 and 2): (1) The proteins precipitated between 10 per cent and 15 per cent saturation (*SF* 10/15) usually gave one or two lines of the slowly migrating group; these were common to DM-fraction of liver. (2) Viscous and yellowish solution obtained from the precipitates between 15 per cent and 50 per cent saturation (*SF* 15/50) contained all the antigenic components which were identified to be kidney-specific; contamination with the components of *SF* 10/15 occurred sometimes, varying from preparation to preparation. (3) The precipitate between 50 per cent and 70 per cent saturation gave a colourless solution and contained all the components of the rapidly migrating group.

Confirmatory results were obtained with the use of the proteins similarly sub-fractionated from DM-fraction of liver or lung. No perceptible lines appeared in the reaction between the antisera and *SF* 15/50 of lung. As expected, *SF* 15/50 of liver was devoid of the kidney-specific components which were contained in the same sub-fraction of kidney.

Preliminary chemical analysis of the separated sub-fractions has indicated that *SF* 15/50 can be characterized by its high lipid content. In fact, the precipitin lines which appeared when this sub-fraction was allowed to react with the antisera were stainable with sudan black and oil red *O*.

Naturally, a considerable number of microsomal antigens which cannot be rendered soluble may be left undetectable in the present test. The results reported briefly here, however, permit us to assume that the water-soluble *SF* 15/50, which is probably extracted from the membrane of the endoplasmic reticulum[4], may contain antigenically different molecules in each tissue.

I thank Mr. A. G. Sato for his collaboration.

IMMUNOLOGY

'Microspot' Test applied to Cellulose Acetate Membranes

WIDE interest has been demonstrated in the antigen–antibody 'microspot' test on agar gel-coated cover-glasses[1]. The technique has now been extended to permit use of cellulose acetate membranes, the advantages of which over agar gel for immuno-precipitation purposes has been pointed out by Kohn[2].

Strips of cellulose acetate membrane (Oxo, Ltd.), 5 cm. × 2 cm., are ruled with a longitudinal line down the middle and five transverse lines 1 cm. apart, the latter starting 0·5 cm. in from one end of the strip. This produces eight ruled squares, 1 cm. × 1 cm., which may be numbered consecutively in one corner. The lines and numbers may be made with pencil; or more vivid marking can be obtained with 'Polynk' (George T. Gurr, Ltd.), applied with a fine pen.

The strips are immersed in a suitable dilution of antiserum in buffered saline (for example, pH 7·6) and lightly blotted to remove excess moisture. A 10 per cent concentration is sufficient for strong antisera, but higher concentrations can be used, if an antiserum is weak. Control strips are prepared by impregnation with a similar concentration of normal serum.

A microdrop of test antigen is spotted on the centre of each of the squares on the serum-impregnated strip. Thus, eight dilutions of a single antigen, or antigenic samples from eight different sources, may be tested on a single strip. Capillary melting point tubes drawn to fine apertures can be used for applying the microdrops; but more uniform results are obtained if they are applied with 1 µl. Drummond microcap disposable micropipettes (Shandon Scientific Co., Ltd.).

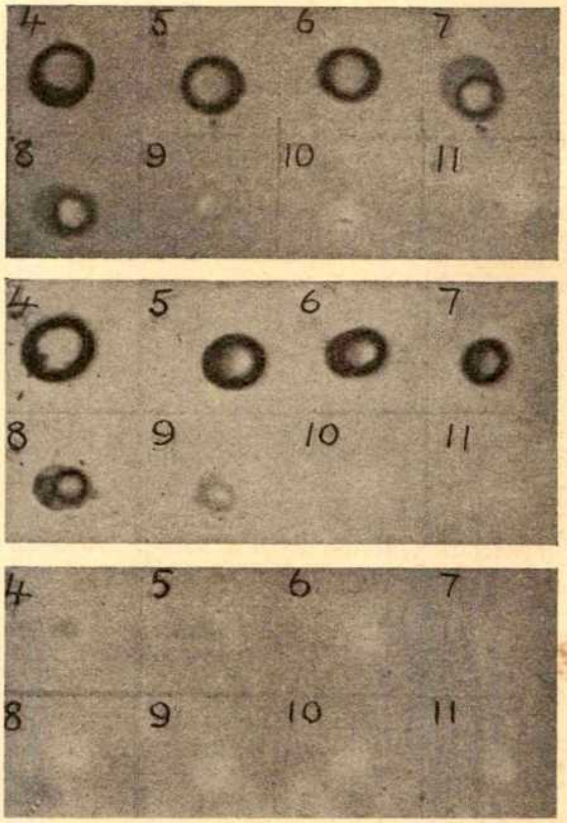

Fig. 1. 'Microspot' test for human γ-globulin on antiserum-impregnated cellulose acetate strips with dilutions 4–11 of five-fold serial dilutions of human serum. Top strip incubated 1 hr.; centre strip, 24 hr.; bottom (control) strip, impregnated with normal rabbit serum, incubated 24 hr. Positive reaction can be seen, even after 1-hr. incubation, with dilution 9 (1 : 390,615). Note halos at unreacted spotting sites

The spotted strips are incubated in a moist chamber, or under a light mineral oil as recommended by Kohn[2]. As little as 1 hr. may be sufficient to allow the antigen–antibody precipitation to go to completion.

The strips are then washed in buffered saline for 1–2 hr. (preceded by a quick rinse in a mild detergent solution, if mineral oil immersion has been used) and stained. I have found Kohn's suggestion of 0·002 per cent nigrosine in 2 per cent acetic acid an excellent dye for 'microspot' strips. Results are readily read on the dye-wetted strips within 1 hr.; but the staining is allowed to continue overnight for possible appearance of exceedingly weak precipitation reactions. Depending on the relative concentrations and purity of the antigen–antibody system, positive reactions appear as stained spots or concentric bands of precipitate against an uncoloured, or lightly coloured, background.

Offsetting the advantage of the direct visibility of the precipitate in the agar-gel 'microspot' test is the much greater sensitivity of the cellulose acetate membrane 'microspot' test. Whereas on the gel[1] I was able to detect the γ-globulin in pooled human serum diluted 1 : 100, using the same reactants on the membrane I have obtained a positive 'microspot' test for γ-globulin with a 1 : 400,000 dilution of the pooled human serum (Fig. 1). This represents a γ-globulin concentration of about 2×10^{-2} μgm./ml., or an absolute equivalent of 2×10^{-5} μgm. of γ-globulin detected on the test strip. This should make the test most suitable for the forensic laboratory for determining the nature and origin of minute quantities of antigenic substances.

Though the use of serum-impregnated membranes is alone described in this communication, I have used a reversed form of the test by impregnating the strip with antigen and using it for the detection of antibody. In either case, speed of reaction and extreme economy of reactants are outstanding properties of the test.

I thank A. W. Wheeler for technical assistance.

Enhancement of the Complement Fixation Reaction with a Soluble Antigen from *Mycoplasma mycoides*

THE soluble polysaccharide (galactan)[1] isolated from *Mycoplasma mycoides* var. *mycoides* (*M. mycoides*) can be used in precipitin or indirect hæmagglutination reactions to detect antibody to *M. mycoides*. When the galactan was used in place of the standard particulate antigen in the complement-fixation test for contagious bovine pleuropneumonia[2] with known positive sera, fixation of complement was usually weak or absent. As unheated normal bovine serum has been shown to potentiate complement-fixation with heated bovine[3,4] and swine[5] antisera, its effect on complement-fixation by the galactan–bovine antibody system was tested.

Normal bovine sera free from demonstrable bactericidal and complement-fixation antibody to *M. mycoides* were obtained from 4–6-month-old calves, and were used when fresh or within 3 weeks when stored at −12° C. Bovine antisera of known titre to the standard complement-fixation test[2] and the hæmolytic system of the standard test were used. Dilutions were made in veronal buffer[6].

Constant antigen and antiserum concentrations were tested with and without added normal bovine serum in the presence of dilutions of complement. To 0·4 ml. of a 1/40 dilution of the test serum was added 0·5 ml. of each complement dilution and 0·2 ml. of a 1/40 dilution of normal bovine serum, then 0·2 ml. galactan solution (6 μgm./ml.) was added and the mixture was allowed to stand at 3–4° C. overnight. In control tubes reagents omitted were replaced by buffer. In the morning the tubes were warmed to 37° C., 0·2 ml. of hæmolytic system was added, and the test was read after incubation at 37° C. for 30 min. Fixation of complement did not occur when galactan and antibody were mixed unless unheated normal bovine serum was present (Table 1).

Table 1. EFFECT OF NORMAL BOVINE SERUM ON COMPLEMENT-FIXATION BY GALACTAN ANTISERUM TO *M. mycoides*

Reagents present (+)			Dilutions of complement (reciprocals) with degree of fixation					
Galactan 6 μgm./ml.	Antiserum No. 24 (1/40)	Normal bovine serum *D*75 (1/40)	12·6	20	32	50	80	100
+		+	–	–	–	–	–	3
+	+		–	–	–	–	–	3
+	+	+	–	3	4	4	4	4
	+	+	–	–	–	–	–	3

4, Complete fixation; –, no fixation.

When either the antigen or antiserum concentration was varied independently in the presence of constant concentrations of complement and normal bovine serum, the optimal concentration of antigen was in the range of 6–12 μgm./ml. Antisera tested with galactan at this concentration gave lower titres than when tested with the standard particulate antigen.

Four of five sera obtained from calves aged between 4 and 6 months potentiated complement-fixation with galactan and antiserum to *M. mycoides*.

The complement-fixation potentiating effect of normal bovine serum was found to be destroyed by heating to 56° C. for 30 min.[3]. Further work on the nature of the serum factor(s) is proceeding.

BIOLOGY

Factors affecting the Human Sex Ratio

WE present here evidence suggesting the existence of at least two kinds of factors affecting the human sex ratio. As the sex ratio we use the number of male births per 100 female births. The evidence is based on family data collected by Geissler[1] in 1889 and by ourselves[2,3].

In Table 1 the sex ratio among the *N*th children in the two series of families is given as a function of the number of boys (*N*–1, *N*–2, . . . or 0) preceding this child. From these data two rules emerge: (1) Children of a certain parity tend to be boys if all the preceding children of the family have been boys, and they tend to be girls if all the preceding children have been girls. (2) If the 'unisexual' families exhibiting the above tendency (the highest and lowest figure in each column of Table 1) are excluded, it will be found that the sex ratio is the lower, the greater is the number of preceding male pregnancies. For this comparison, families with four or more children can be used (the encircled areas in Table 1). The only column which does not follow this rule is that of the fifth children of our series, and in this column the sex ratios are based on small numbers of families tested. From Table 2 it can be seen that in Geissler's series of families the downward trend of the sex ratio with the growing number of preceding boys is statistically significant. In our own series there is an identical 5 per cent decrease in the four-child families, but owing to the smaller number of families tested it is not statistically significant.

Table 3 shows that after one boy and two girls the sex ratio of the fourth child is high and after two boys and one girl it is low regardless of the order of birth of the preceding children. Thus the excess of boys or girls is not due to a switch of some families from a gynecophilic to an androphilic period or vice versa, an event postulated by Schützenberg[4].

The data can be explained by postulating that, among other factors, there are the following two

Table 1. SEX RATIO OF THE SECOND, THIRD, FOURTH AND FIFTH CHILD OF A FAMILY COMPARED WITH THE NO. OF BOYS PRECEDING THIS CHILD

fmm	2,689	101·1
ffm	2,666	105·1
fmf	2,568	107·1
mff	2,749	102·1

affecting p (the probability of a coming child being a boy): (1) p is inherently different in different families. This factor manifests itself in the tendency of certain families to have predominantly boys, and others to get predominantly girls. This was postulated by Edwards[5] in 1958. (2) Apart from the tendency mentioned here, male pregnancies render couples less likely to obtain further boys. This could come about if male pregnancies immunize a small portion of mothers against male (Y) antigens, and this immunization is then harmful to subsequent male fœtuses. The third male fœtus of a mother would be often affected, the fourth more so still, etc.

Our analysis does not give information as to whether the second or even the first boy of a couple could be affected, but data given by Novitski and Sandler[6] may be relevant in this respect. They show that the sex ratio decreases with the increasing age of the family. Supposing that this decrease is mainly caused by the immunization of mothers against male antigens—not necessarily a correct assumption—the data show that generally the first boy is not affected, because the curve is not a 'one hit' curve. On the other hand, the data do show that the second boy can be affected, because the sex ratio of the second child is much lower than that of the first.

The above hypothesis needs an extra assumption, that the undisturbed (not disturbed, for example, by immunization deaths) sex ratio of, say, the fourth child is higher than the sex ratio of the first child. This does not seem inconceivable although there is no direct evidence favouring this assumption.

The hypothesis would lead to certain predictions which lend themselves to investigation. One of them is that among still-births and abortions there should be an excess of boys, and this excess should be greater if boys have previously been born to the family. Some studies on this line have been made, but the results are contradictory[7,8]. Another prediction is that the sex ratio should decrease with increasing parity. This has been demonstrated[6], and there are data indicating that the decrease is dependent on the paternal age and/or birth order rather than on maternal age[9].

A detailed report of this study will be given elsewhere[3]. The investigations have been supported by the Sigrid Jusélius Foundation.

Kidney Transplantation in the Rat

THIS report describes a new technique for transplantation of the rat kidney from one animal to another by vascular anastomosis[1]. The rats were all members of an inbred line of the Lewis strain, originally obtained from a colony at the Wistar Institute. Skin grafts from one member of this colony to another are accepted uniformly. In the present experiment, the kidney donor weighed approximately 100 gm. It was first anæsthetized with 'Cyclopal' (Upjohn) and then the left kidney, including its vessels and ureter, was exposed through a midline incision. All the vascular branches of the abdominal aorta and vena cava, except the left renal vessels, were tied and divided from the level of the superior mesenteric artery to the origin of the iliac artery and vein.

The donor was then given 1,000 units of heparin intravenously to prevent clotting during the surgical procedure. Small slits were made in the aorta and vena cava above the origin of the iliac vessels; through these openings, plastic tubes were inserted. The tubes were pushed forward until they extended a few centimetres above the origin of the renal vessels. The aorta and vena cava were then divided at the level of the mesenteric artery. The vessels tend to shorten when cut so that the plastic tubes protrude. To prevent the tubes from slipping, ties were placed on the plastic supports where they enter the slits in the abdominal vessels. The remaining vascular connexions, located below the distal ligatures, were cut; and then the kidney was lifted from the abdomen of the donor and placed in the neck of the host (Fig. 1).

The recipient was a 450-gm. Lewis strain rat. It was anæsthetized, placed on its back, and the carotid artery and jugular vein were isolated, clamped and divided. The diameter of these vessels in the neck of the recipient approximates the calibre of the abdominal aorta and vena cava of the 100-gm. donor. The arterial anastomosis was begun by placing

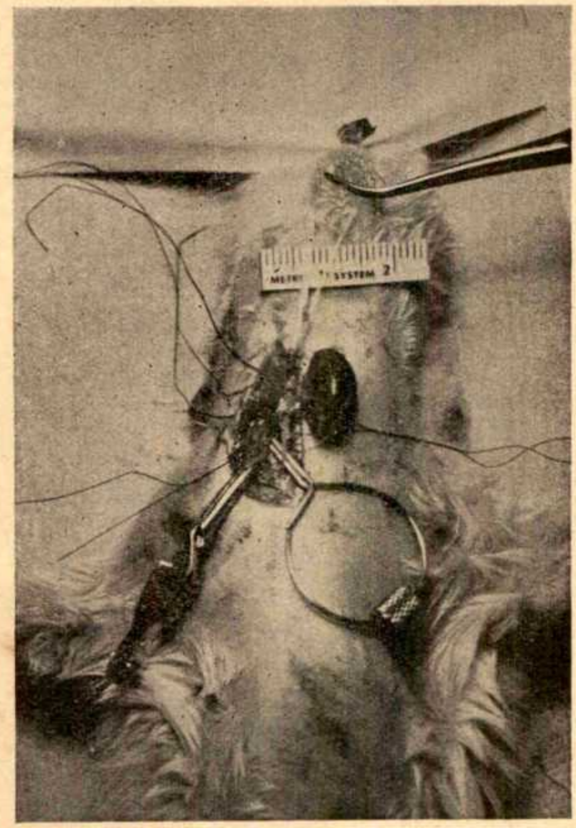

Fig. 1. The donor kidney is shown in the neck of the recipient. The plastic tubes are inserted into the recipient vessels and the arterial holding sutures have been secured. After completion of the anastomoses the plastic tubes will be removed

two silk sutures to connect the aorta and the proximal stump of the carotid artery (Fig. 1). The plastic tube protruding from the anterior end of the aorta was inserted into the carotid artery. The arterial vessels were anastomosed by means of a continuous suture technique. The plastic tube aids in the suturing by preventing collapse of both the donor and the host arteries; it also helps insure against accidental closure of the vascular lumen. On completion of the anastomosis, the plastic tube was removed through the open end of the aorta. The aorta was then tied off just above the renal vessels. When the arterial anastomosis was completed, the vena cava was connected to the jugular vein by a procedure similar to that used for the arteries. On removal of the vascular clamps, blood flowed from the host's carotid artery into the donor's aorta and renal artery. The return flow was through the renal vein and vena cava of the donor to the jugular vein of the recipient. The kidney was secured under the skin and its ureter brought to the exterior through a separate stab wound.

The important features of the procedure are the following: (1) the use of a T-section of vessels, so that the aorta and vena cava are available for anastomoses; (2) the temporary insertion of plastic tubes to maintain the patency of the vessels during surgery; (3) the transfer of a kidney from a 100-gm. rat to a 400-gm. rat, so that the large abdominal vessels of the donor will match the carotid artery and jugular vein of the recipient.

When these precautions are followed it is possible to obtain long-term transplants within the Lewis strain. In some of our early experiments, difficulties were encountered when scar tissue closed the ureteral opening on the skin. In some instances, repeated reconstruction of the ureteral opening has been necessary to avoid hydronephrosis. Infection in the transplant was controlled by administering sulphamethazine, substituting a saturated solution of this compound for the drinking water.

In a series of isologous transplants, six out of seven consecutive operations were successfully completed. Four of these kidneys were biopsied 35 days after the operation. There was no evidence of the rejection process in histological sections. One rat survived 71 days after its own kidneys had been removed. This animal died of an unknown cause; but the transplant had not been rejected.

It is believed that this type of vascular anastomosis on very small vessels may find application in fields of surgery other than transplantation.

This work was carried out during the tenure of an advanced research fellowship of the American Heart Association to Dr. Nathan. Nerve Endings on Chromaffin Cells in the Rat Adrenal Medulla

SINCE Fusari[1] and Dogiel[2] published accounts of the adrenal medullary nerve plexuses many different opinions have been expressed concerning the question of nerve-endings in relation to chromaffin cells. The majority of workers claim to have seen extracellular endings in the form of platelets or *boutons* and Willard[3] described end-*boutons* and *boutons de passage*. Nerve fibres ending in a terminal anastomosing net of neurofibrils—the so-called 'terminal reticulum'—were described by Stöhr[4] and Sato[5]. Hillarp[6], however, using a methylene blue technique found no evidence of nerve-endings and stated that the nerve fibres run in fine bundles in a terminal Schwann plasmodium, the composite mass forming the 'nervous ground plexus'.

Using a cholinesterase technique for the demonstration of nerve fibres and supporting elements, Coupland and Holmes[7] demonstrated a coarse three-dimensional network composed of Schwann cell cytoplasm and fine nerve fibres in the adrenal medulla. This net was found to correspond in general form with Hillarp's 'nervous ground plexus'. However, the same workers also noted that the histochemical technique for the demonstration of true cholinesterase revealed not only the coarse network, but also fine branches which left the main net and exhibited swellings, corresponding in size and shape to Willard's end-*boutons* and *boutons de passage*, in relation to chromaffin cells.

The problem has been pursued further using electron microscopic techniques. Adrenal glands of Sprague–Dawley albino rats were sectioned and fixed in Caulfield's buffered osmium tetroxide (*p*H 7·3)–sucrose mixture, embedded in araldite and sectioned on a Cambridge–Huxley ultramicrotome. Sections were stained on the grid with an aqueous 1 per cent solution of potassium permanganate and examined with a Metropolitan–Vickers *EM* 6 electron microscope.

Nerve fibres and endings have been observed in large numbers in all specimens. In the rat adrenal medulla the majority of fibres are unmyelinated and less than 1 per cent of all those seen in sections exhibited evidence of myelination. The unmyelinated axons are always associated with Schwann cell cytoplasm (Fig. 1) and run in bundles between groups of chromaffin cells. From these bundles of axons fine axis cylinders arise and may be traced for a variable distance between adjacent chromaffin cells before ending. As each fine axis cylinder runs between chromaffin cells it is accompanied by an extension of Schwann cytoplasm; this initially surrounds the whole fibre, but as the nerve-ending is approached it covers only one aspect of it with a tongue-like process.

Nerve fibres exhibit synaptic-type endings on or 'in' chromaffin cells (Fig. 2). At the nerve-ending the axis cylinder contains numerous pre-synaptic vesicles and mitochondria. The pre- and post-synaptic membranes are thickened (Fig. 3): especially the latter. Some multiple synaptic-type endings have been seen on single chromaffin cells and appear to involve the same nerve fibre.

A minority of nerve fibres invaginate the plasma membrane of chromaffin cells before terminating at a variable distance from the cell centre in a typical synaptic-type of ending. During its 'intra-cellular course' the nerve fibre is surrounded by a tubular invagination of the chromaffin cell's plasma membrane: protoplasmic continuity never occurs. This unusual arrangement may well account for the so-called 'intra-cellular nerve-endings' described by some earlier workers, including Fusari[1] and Alpert[3].

The findings indicate that chromaffin cells, which are developmentally and functionally closely related to the autonomic nervous system, also resemble neurones in so far as they are associated with synaptic-type nerve-endings.

Furunculosis in Salmon Kelts

INVESTIGATIONS into the occurrence of furunculosis among spawning or spawned salmon were undertaken in Scotland during the spawning seasons of 1958–59 and 1959–60[1]. In the former season 96 salmon kelts were examined and 85 of these had furunculosis; in the latter season, up to the time of going to press, 9 out of 24 kelts examined had furunculosis. In the same season 14 kelts were examined in England and Wales and 11 of these gave a positive reaction.

In order to determine to what extent furunculosis occurred among kelts in Ireland it was decided to collect dead and dying kelts from four Irish rivers during the 1960–61 spawning season. In all, between December 15, 1960, and May 17, 1961, a total of 159 kelts were examined from the following rivers:

River	No. of kelts examined	Hatchery or naturally spawned
River Owenea (Co. Donegal)	121	Majority hatchery stripped
River Erne (Co. Donegal)	17	Majority naturally spawned
River Shannon (Co. Limerick)	12	All hatchery stripped
River Boyne (Co. Meath)	9	All naturally spawned

With the exception of one fish from the Owenea River all were negative for furunculosis. It is hoped to continue these investigations during the next spawning season 1961–62.

I thank Mr. E. Hirsch and his staff of the Veterinary College of Ireland, Ballsbridge, Dublin, who undertook bacteriological examination of these fish.

Differences in the *p*H Optimum of the Photosynthetic Fixation of Carbon Dioxide in Isolated Whole and Broken Chloroplasts

RECENTLY, Gibbs *et al.*[1–4] emphasized the differences between whole and broken chloroplasts regarding their sensitivity against inhibitors during fixation of carbon dioxide and the distribution of carbon-14 in the sugars so formed. In our experiments an additional difference, the markedly lower *p*H optimum of fixation of carbon dioxide in whole chloroplasts, as compared with broken chloroplasts, was observed.

Chloroplasts were isolated from spinach leaves by the method of Arnon *et al.*[5] and Gibbs *et al.*[1,2], using 0·35 *M* sodium chloride solution with 0·015 *M* *tris*-hydrochloride *p*H 7·5 and 0·01 *M* sodium ascorbate. In order to obtain broken chloroplasts, washed whole chloroplasts were resuspended in 0·01 *M* sodium ascorbate solution. All experiments were carried out at light saturation (25,000 lux).

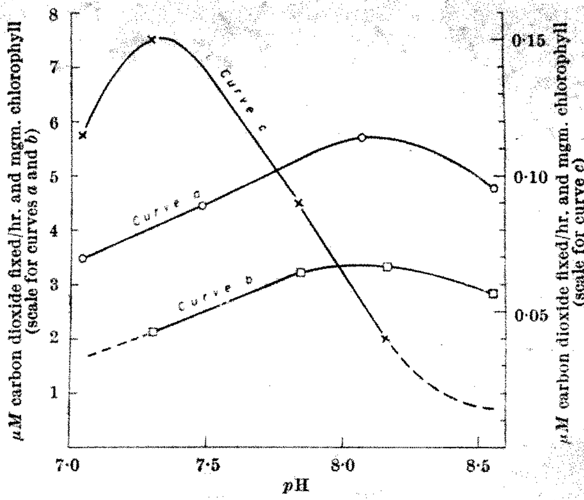

Fig. 1. *p*H optimum of the photosynthetic fixation of carbon dioxide by whole chloroplasts without (curve *c*), and with co-factors (curve *b*), and by broken chloroplasts (curve *a*). $t = 20°$ C.; gas phase nitrogen. 1 ml. of the reaction mixture contained: curve *c*, 200 μgm. chlorophyll; in μ*M*, sodium chloride 350; *tris* 35; manganese chloride 0·8; magnesium chloride 2·0; sodium ascorbate 10; $Na^{14}HCO_3$ 2, specific activity 24·47 μc./μ*M*. Curve *b*: like curve *c* plus ADP 2·0; TPN 0·12; FMN 4×10^{-4}; R-5-P 1·0; GSH 3·0; $Na^{14}HCO_3$ 10, specific activity 0·28 μc./μ*M*. Curve *a*: broken chloroplasts, conditions like curve *b*, plus chloroplast extract equivalent to 400 μgm. chlorophyll minus sodium chloride

The results of a typical experiment are shown in Fig. 1. The curve for broken chloroplasts (*a*) shows a flat maximum at 8·1, whereas the curve for whole chloroplasts (*c*) has a marked optimum around 7·3. When the co-factors are given to whole chloroplasts, the total fixation is increased by more than 10-fold, thus reaching the level of broken chloroplasts. In this case the *p*H optimum is identical with that of the broken chloroplasts (curve *b*).

This behaviour probably results from the presence of only a small portion of physiologically intact chloroplasts compared with a big portion of physiologically defect and broken chloroplasts in the preparations of the so-called 'whole' chloroplasts. Jacobi and Perner[6], as well as Erikson *et al.*[7], came to the same conclusion in their morphological work. Then, after the addition of co-factors, the fixation by broken chloroplasts exceeds that of the whole chloroplasts to such an extent that practically only the *p*H optimum of the first is measured. Also the strong variation of the rate of fixation of carbon dioxide of the whole chloroplasts expressed in Table 1 may best be explained by the assumption that the percentage of really intact chloroplasts varies greatly, depending on the condition of the leaf material.

Furthermore, it can be seen from Table 1 that the *p*H optimum of the fixation of carbon dioxide in whole and broken chloroplasts is not shifted by a variation of the absolute level of fixation. For whole chloroplasts it is between 7·0 and 7·5, whereas for broken chloroplasts between 8·0 and 8·5. So far as whole chloroplasts are concerned, our results are in agreement with Gibbs and Calo[1]. In the case of broken chloroplasts, however, their results[2] differ from ours, since they obtained the same *p*H optimum as with whole chloroplasts. While measuring light phosphorylation, Allen *et al.*[8] found a *p*H optimum around 8·3 for broken chloroplasts.

The difference between whole and broken chloroplasts, in the *p*H optimum of their photosynthetic fixation of carbon dioxide, may be explained in three ways: (1) the *p*H dependent permeability for the

Table 1. pH-Dependence of the Photosynthetic Fixation of Carbon Dioxide of Whole Chloroplasts without Co-factors and of Broken Chloroplasts with Co-factors in Different Preparations with a Varying Activity of Fixation of Carbon Dioxide. (For Reaction Conditions, see Fig. 1)

	Date of experiment	μM carbon dioxide fixed per hr. and mgm. chlorophyll at the corresponding pH					
		7·15	7·30	7·70	8·00	8·30	8·50
Whole chloroplasts	12.8.1960	1·35	1·27	0·78	0·46	—	—

	7.8.1961	0·04	0·05	0·02	0·01	—	—
	9.8.1961	0·05	0·07	0·02	0·01	—	—
	29.8.1961	0·13	0·15	0·11	0·06	—	—
Broken chloroplasts	5.5.1961	—	2·65	6·37	8·80	9·90	—
	10.5.1961	—	1·35	3·05	6·95	7·90	—
	30.6.1961	—	—	3·00	4·47	4·90	4·33
	3.7.1961	—	—	2·83	3·73	3·85	3·60
	23.8.1961	—	—	3·00	4·45	4·90	4·68

bicarbonate ion or the carbon dioxide molecule, respectively, is the limiting factor for the assimilation of carbon dioxide in whole chloroplasts; there is no such restriction in broken chloroplasts since the permeability barrier is absent.

(2) By 'breaking' the chloroplasts, reactions of the mechanism of photosynthesis with a more alkaline pH optimum become limiting for the fixation of carbon dioxide compared with the pH-optimum of those which are limiting in whole chloroplasts.

(3) The reaction mechanism of the photosynthetic fixation of carbon dioxide and reduction in whole chloroplasts is different from that in broken chloroplasts[9,10].

Changes in Endogenous Gibberellins in Relation to Chilling of Dormant Seeds

EMERGENCE from the rest period in potato tubers has been correlated with an increase in the level of endogenous gibberellin[1]. There have been no reports of similar observations with respect to breaking of seed dormancy although a 'germination stimulator' has been demonstrated in after-ripened ash embryos[2]. No difference in gibberellin-level was found between light-activated and dark-imbibed lettuce seeds[3]. Increases in gibberellins, however, have been demonstrated in connexion with the induction of flowering both by low-temperature treatment[4] and by long photoperiods[4-6].

An examination was made of gibberellins in hazel (*Corylus avellana*) and beech (*Fagus sylvatica*) seeds, both of which are dormant at the time of harvest and require several weeks' moist storage at 0–5° C. for after-ripening. A chilling period of about 12 weeks was necessary for intact nuts to show a high germination percentage. Wheat coleoptile and oat mesocotyl section bio-assays had been carried out on 80 per cent methanol extracts of chilled and unchilled seeds, no significant differences being found in the levels of growth promoters and inhibitors. In both beech and hazel seed extracts an auxin-like growth promoter was found at R_F 0·4–0·6 following paper chromatographic separation with the solvent isopropanol/1/100 × 0·88 s.g. ammonium hydroxide (4 : 1).

For gibberellin studies seeds were crushed and extracted at room temperature with 80 per cent methanol. Following removal of the methanol by distillation under reduced pressure the aqueous residue was purified by a procedure based essentially on that described by Radley[7]. The purified material was dissolved in a small volume of 'dry' methanol and stored at −15° C. Attempts to bio-assay such 'purified' extracts directly with dwarf (d–1) maize and dwarf (variety, Meteor) pea seedlings were unsuccessful due to the presence of inhibitory or toxic substances having a damaging effect on the leaf to which the extract was applied. Further purification was therefore carried out using paper chromatography. Several solvents were tried, butanol saturated with 1/100 × 0·88 s.g. ammonium hydroxide being found the most satisfactory for separating gibberellin and inhibitor zones in the case of hazel extracts.

Two bio-assay techniques, which were more convenient for use following paper chromatographic separation, were used. These were: (1) a lettuce hypocotyl test[8]; (2) a maize leaf section test. The latter was based on a technique described by Boyarkin and Dmitrieva[9] with the difference that 'dwarf-1' mutant maize seedlings were used in place of normal maize seedlings. This test was used in preference to the lettuce hypocotyl test, being more sensitive to gibberellins and apparently less sensitive to the presence of inhibitory materials in the extract. The maize-leaf section test was carried out as follows: Maize grains were sown in sand in the dark at 26–28° C. and dwarf seedlings were selected after 7–8 days, when the first leaf had unfolded. Seedlings were divided into several arbitrary groups on the basis of degree of unfolding of first and second leaves, as a means of randomizing seedling sections among the various treatments. The mesocotyl of each seedling was cut 5 mm. below the coleoptilar node and the coleoptile plus enclosed leaves cut 20 mm. above the node. 12 such leaf-plus-mesocotyl sections were used per treatment and were placed in a vertical position in 3 ml. of the solution under test with the mesocotyl end of the section dipping in the solution. Prior to the bio-assay chromatogram segments (R_F 0–0·1, 0·1–0·2, etc.) were cut into small pieces, placed in 1·7 × 5 cm. specimen tubes and eluted overnight at 5° C. with 3 ml. distilled water. Specimen tubes with leaf sections were kept in the dark at 25° C. and the length of the first leaf was measured after 2 days. The two extreme measurements from each treatment were discarded, the mean increase in length of the first leaf being based on 10 replicates. The response of 'dwarf-1' maize leaf sections to various concentrations of gibberellic acid is shown in Fig. 1.

In a preliminary experiment an extract of wheat grains, known to contain gibberellins[7], was assayed using the above techniques. Gibberellin activity was demonstrated at R_F 0·2–0·3 in butanol/dilute ammonia. (Gibberellic acid has an R_F of about 0·26 in this solvent.) The gibberellin contents of two independent extracts of unchilled hazel seeds (imbibed

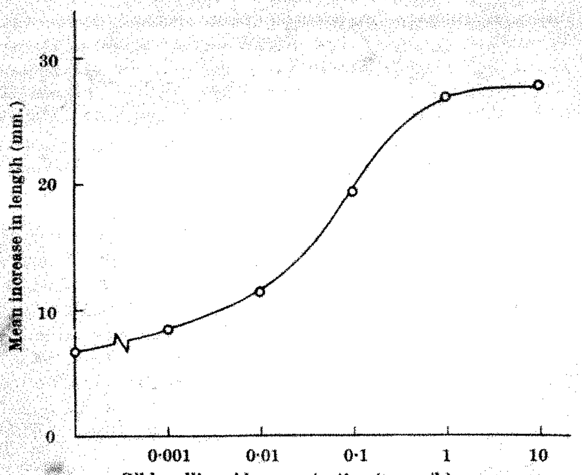

Fig. 1. Effect of gibberellic acid on extension of first leaf in leaf-plus-mesocotyl sections of 'dwarf-1' maize seedlings. *L.S.D.* (for $P = 0·05$) is 3·5

48 hr. at room temperature) were compared with those of extracts of 6-week chilled and 12-week chilled seeds. The equivalent of 100 gm. dry weight of seed was used for each bio-assay. No significant gibberellin activity was detected in extracts of unchilled seeds but two zones of activity, at R_F 0–0·1 and R_F 0·2–0·4, were found in chilled seeds (Fig. 2). The gibberellin growth response obtained was very small, being roughly equivalent to 0·02–0·1 µgm., gibberellic acid per kgm. dry weight of seed. The failure of unchilled seed extracts to give a gibberellin response was not due to the presence of inhibitory material. A chromatogram eluate (R_F 0·1–0·4) of unchilled seed extract only slightly decreased the response of maize leaf sections to 0·01 mgm./l. gibberellic acid.

In the case of beech a comparison of gibberellin contents was made between unchilled (imbibed 48 hr. at room temperature) and 12-week chilled nuts. The chilled nuts were germinating with radicles 0·5–3 cm. in length (beech nuts, unlike hazel, germinate readily at the chilling temperature). Gibberellin activity was found in both unchilled and chilled nuts although there appeared to be qualitative differences in the chromatographic pattern of activity. In unchilled extracts there was a significant response at R_F 0·2–0·3 and evidence of activity at R_F 0·5–0·6, whereas in chilled extracts there was a response at R_F 0·4–0·5 only.

In both hazel and beech nuts there were changes in gibberellin content during after-ripening, although only in hazel was there a simple increase in the level of gibberellin. These observations, coupled with the fact that gibberellic acid will stimulate the germination of dormant hazel and beech seeds[10], provide some evidence that endogenous gibberellins are involved in the after-ripening process in these seeds.

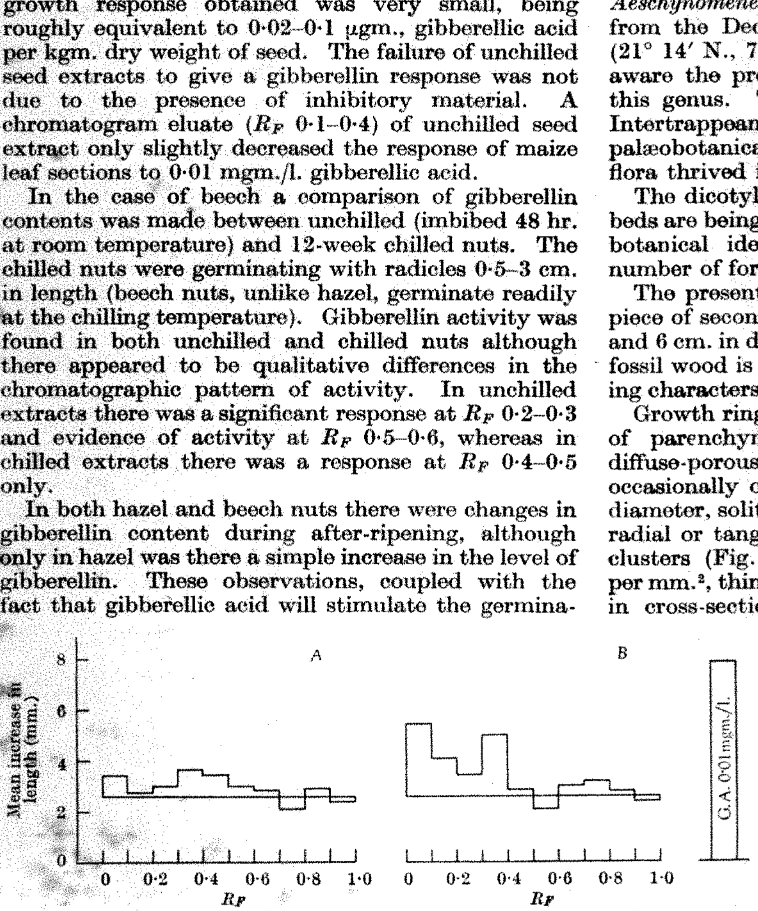

Fig. 2. Maize leaf section bioassay of purified extracts of hazel seeds. *A*, Unchilled; *B*, chilled 12 weeks. Following paper chromatography with butanol/dilute ammonia. Extension of control sections, 2·6 mm. *L.S.D.* (for $P = 0·05$) is 1·2

Part of this work was carried out with the financial support of a grant from the Agricultural Research Council.

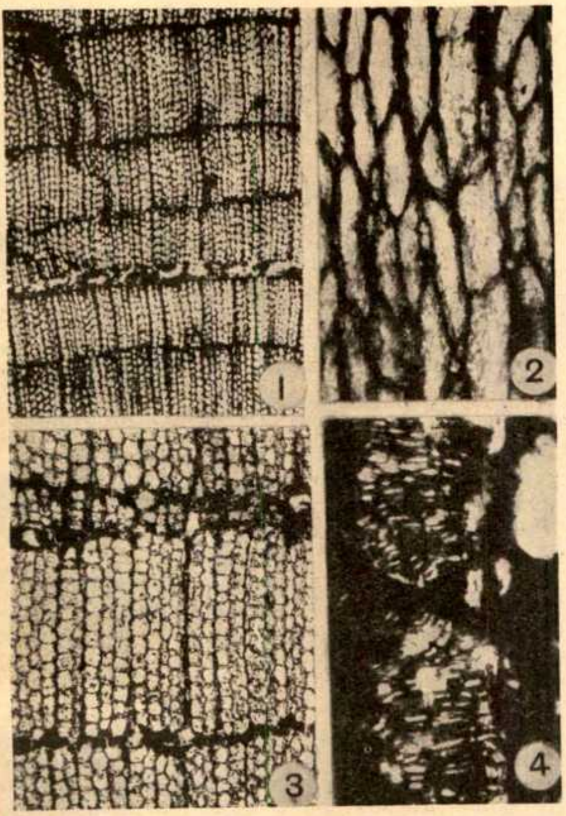
Aeschynomene tertiara, a Fossil Wood from the Deccan Intertrappean Beds of Mahurzari, near Nagpur

In the present communication, a new species of *Aeschynomene* (Leguminosae), *A. tertiara*, is described from the Deccan Intertrappean beds of Mahurzari (21° 14′ N., 79° 1′ E.) near Nagpur. So far as I am aware the present description is the first record of this genus. The existence of *Aeschynomene* in the Intertrappean beds furnishes further proof to the palæobotanical evidence that most of the Deccan flora thrived in pools, lakes and swampy habitats.

The dicotyledonous woods from the Intertrappean beds are being intensively studied with regard to their botanical identification and interpretation and a number of form genera have now been determined.

The present material consists of a single petrified piece of secondary xylem measuring 11 cm. in length and 6 cm. in diameter. Structural preservation of the fossil wood is remarkably good. It shows the following characters:

Growth rings inconspicuous, with tangential bands of parenchyma simulating growth rings; wood diffuse-porous (Fig. 1). Vessels usually small, occasionally of medium size, 45–110µ in tangential diameter, solitary as well as in pairs and sometimes in radial or tangential rows of 3–5 cells, very rarely in clusters (Fig. 3), widely spaced, about 2–3 vessels per mm.², thin-walled, mostly angular, sometimes oval in cross-section. Vessel elements short, 150–210µ long with truncated ends. Perforation plates exclusively simple, horizontal to slightly inclined. Intervascular pit-pairs bordered, alternate to opposite or sub-opposite and often almost of scalariform-type with linear to extended apertures (Fig. 4). Tyloses absent but vessels commonly plugged with gummy deposits. Parenchyma scanty, occurring either as 1–2 (3–4) seriate, narrow, continuous or broken tangential lines (Figs. 1, 3), almost parallel to each other or as 1–2 or few diffuse cells, also sometimes in



Figs. 1–4. *Aeschynomene tertiara.* Fig. 1, Cross-section showing thin tangential parenchyma bands simulating growth rings. (× 13·5). Fig. 2, Tangential longitudinal section to show the distribution and type of xylem rays. (× 75). Fig. 3, Cross-section magnified to show the vessels, fibres and parenchyma cells. (× 35). Fig. 4, Intravascular pit-pairs. (× 260)

association with the vessels; cells usually tangentially elongated in cross-section, 40–50μ × 15–25μ in size, rarely crystalliferous; both fusiform and strand parenchyma appears to be present. Xylem rays homogeneous composed of procumbent cells, mostly uniseriate (Fig. 2), rarely partially biseriate and unstoried; 1–11 (usually 1–6) cells or 40–560μ high; up to 8–12 rays per mm. Ray cells usually oblong or narrow and vertically elongate as seen in tangential section. Imperforate tracheary elements fibres forming the ground-mass of the secondary xylem, quadrangular to polygonal in cross-section (4–6-sided), 45–80μ × 41–100μ in size, walls thin with a large lumen (Fig. 3); cells fusiform (Fig. 2), short, about 188–408μ in length; unstoried; pits simple, more numerous on the radial than on the tangential walls. In cross-section fibres look very much like the vessels except that the vessels are slightly thicker-walled and often plugged with black deposits.

Structural features of the fossil wood indicate that its closest affinities are with the modern genus *Aeschynomene*. A survey of all available woods of this genus shows that the nearest resemblance of the fossil is with *Aeschynomene* sp. from Siam (Yale Wood Collection No. 16552), although there are some obvious differences between the two, namely, in size of the vessels, length of fibres and in relative thickness and spacing of tangential parenchyma bands.

I thank Profs. Elso S. Barghoorn and I. W. Bailey for many helpful suggestions. I also thank Dr. William L. Stern (then of Yale School of Forestry), curator, Division of Woods, Smithsonian Institution, Washington, D.C., for kindly sending the modern woods of the genus *Aeschynomene*.

MICROBIOLOGY

Relationship between Sugar Utilization and the Action of Cycloheximide on Diverse Fungi

CYCLOHEXIMIDE ('Actidione', Upjohn) is an antibiotic which inhibits growth of protozoa[1], mammalian cells[2] and many fungi[3]. It has been proposed that cells having strong aerobic fermentative capability are especially sensitive to this antibiotic[4]. In the present work, oxygen consumption and aerobic carbon dioxide evolution by 17 fungi grown in glucose medium was measured by standard manometric techniques[5]. Drug sensitivity was determined by the tube-dilution method. No correlation was found between respiratory quotient and susceptibility to cycloheximide (Table 1). Respiration and fermentation of glucose by *Saccharomyces pastorianus* were not inhibited appreciably by 2 μgm. cycloheximide/ml. although 0·5 μgm./ml. halted growth. Cells of *S. pastorianus* fermented maltose when cultivated in maltose medium, but not when cultivated in glucose medium. Fermentation by maltose-adapted cells was not retarded significantly by 2 μgm. antibiotic/ml. but the inductive process was suppressed completely (Table 2). Cells exposed to the drug were still viable at the end of the experiment. Cycloheximide does not inhibit significantly activity of glycolytic enzymes but does prevent new enzyme synthesis. Protein or nucleic acid synthesis, therefore, seems to be one vulnerable site of cycloheximide action[6].

Table 1. RESPIRATORY QUOTIENT (RQ) OF DIVERSE FUNGI AND MINIMAL CONCENTRATION OF CYCLOHEXIMIDE-INHIBITING GROWTH (MIC)

Organism	RQ	MIC (μgm./ml.)
Schizosaccharomyces pombe	> 40	15
Zygosaccharomyces fermentati	3·2	300
Z. marxianus	3·1	> 300
Saccharomyces pastorianus	3·1	0·3
Z. globiformis	2·4	3
Torulaspora rosei	2·4	0·5
Z. lactis	1·9	> 350
Z. casei	1·8	> 300
Saccharomyces fragilis	1·8	> 350
Hansenula saturnus	1·5	0·5
Candida stellatoidea	1·2	275
Cryptococcus sp.	1·2	350
Mycoderma cerevisiae	1	0·5
Pichia membranaefaciens	1	0·4
Endomycopsis lindneri	1	50
Trichosporon sp.	1	75
Debaryomyces klockeri	1	2

Respiratory quotient was determined with 5 mgm. dry weight of washed cells, 100 mgm. glucose, air atmosphere, 0·067 *M* $NaK(H_2PO_4)_2$ buffer *p*H 4·5, with or without 20 per cent potassium hydroxide in the centre well of the reaction vessel.

Table 2. SUPPRESSION OF INDUCTION OF MALTASE BY CYCLOHEXIMIDE

Inducing medium	μl. CO_2 evolved/10 min. from Glucose	μl. CO_2 evolved/10 min. from Maltose
Glucose	177	5
Glucose + 2μgm. cycloheximide/ml.	149	4
Maltose	153	98
Maltose + 2 μgm. cycloheximide/ml.	131	4

Glucose grown *S. pastorianus* cells were incubated aerobically for 2 hr. at 30° C. in maltose or glucose medium with or without antibiotic. Carbon dioxide evolution was measured manometrically with 5 mgm. dry weight of washed cells, 100 mgm. sugar, 0·067 *M* $NaK(H_2PO_4)_2$ buffer *p*H 4·5 and a nitrogen atmosphere.

This investigation was supported by a research grant *E*-4075 from the National Institute of Allergy and Infectious Diseases, U.S. Public Health Service.

Identification of Purported *Agaricus campestris* Strains (*NRRL* 2334, 2335, 2336) as *Beauveria tenella* (Delacroix Siem.)

Comparative morphological and physiological investigations were conducted with different European strains of the cultivated mushroom and with three strains of *Agaricus campestris* (*NRRL* 2334, 2335, 2336) from the Northern Regional Research Laboratory, Peoria, Illinois. These have been described as mutants arising from normal cultivated mushrooms under conditions of submerged culture[1].

These strains differed greatly from the normal strains in substrate demand, speed of growth, mycelium yield, enzymatic qualities, and colony growth as well as in microscopic appearance on solid media and liquid culture. In addition, no fruiting bodies were produced[1-7].

It is, however, improbable that these *NRRL* strains which appeared in 1948 in Humfeld's laboratory during submerged culture experiments, and described by him as spontaneous mutants, could be mutants. The possibility that so many independent qualities were altered during one or few mutation steps is very remote. In my own experiments with an even larger selection of strains it was impossible to detect such mutants.

An exhaustive examination of these *NRRL* strains in the Centraalbureau voor Schimmelcultures, Baarn, Holland, showed that under certain conditions a form of asexual reproduction occurred. The oval, smooth, hyaline conidiospores (1·8–4·5μ × 1·8–3·2μ) and oblong macrospores (6·6–9·4μ × 2·4–3·2μ) arising thereby developed on sporogenous cells which were usually swollen and bottle-shaped.

According to my observations, these strains do not belong to the Basidiomycetes, but to the Fungi Imperfecti, family Moniliaceae, genus *Beauveria*. Comparisons with authentic *Beauveria* strains confirmed the identity of the *NRRL* strains as members of the genus *Beauveria*.

A repetition of these investigations with *NRRL* 2334, 2335, 2336 strains, again received from Peoria, and the agreement of my own findings with those from previous investigators, eliminated the possibility of an infection occurring since the first description of these strains[2].

It was also confirmed that the *Beauveria* strains, like other Moniliaceae, were able to live saprophytically on the fruiting bodies of cultivated mushrooms. It is therefore possible that the *Beauveria* infection was carried with the inoculum (tissue-culture of mushroom fruiting bodies[1,5]) into the submerged cultures or entered the culture through some other agent. Probably the infection overgrew the slow-growing mushroom mycelium. *Beauveria* species are commonly encountered where mushrooms are cultivated[8].

On the basis of these findings, it is not surprising that attempts to produce mushroom mycelium commercially in submerged culture with the strains *NRRL* 2334, 2335, 2336 have been abandoned because of the lack of the typical mushroom flavour in the mycelium harvested[9].

MISCELLANEOUS

Publication of Proceedings of Conferences and Symposia

I have read with the greatest interest and indeed gratitude the remarks of Sir Lindor Brown concerning the publication of proceedings of conferences and symposia, and the editorial comments on the same subject[1].

Much of the trouble I believe arises because, as Sir Lindor points out, complete publication of a symposium is sometimes achieved only one or two years after the event; in consequence, the report is out of date when it appears, and few of those who presented papers have been able to resist the temptation to publish their material elsewhere. But this delay, though unfortunately common, is quite unnecessary. Some years ago I attended a symposium on biological problems of grafting in Liège, which I had hoped would have served as a model for the future. Communications had to be submitted a few weeks before the symposium, and when we arrived they were all in galley proof. Each participant received a proof of his own contribution with firm instructions to correct it immediately and return it to the secretariat. The discussion was taken down more or less verbatim, typed, and distributed to participants just after dinner each evening. We were then expected to edit our own discussion and return an acceptable version to the secretariat of the conference by breakfast time the following morning. The result was that when we left Liège all the contributed articles were set up in type, and the discussion was ready to go to the printers. Publication of the report of the symposium was not quite as quick as had been hoped; but the delay was partly due to the fact that two languages were used at the meeting. I should have thought that if this pattern were followed at a meeting where only one language was used it should be possible to have an official report of the symposium on sale 4–6 weeks after the meeting.

I fully agree with the view that there should be many symposia of which no reports are published; clearly, however, publication is sometimes worth while, and in this event it should, and could, be done quickly.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Wednesday, April 25

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m. Prof. L. F. Lamerton: "Health Aspects of Ionizing Radiation—Facts and Fancies".

British Institution of Radio Engineers, Television Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Discussion on "Television Standards Conversion" opened by Mr. A. V. Lord and Mr. B. Marsden.

Society of Chemical Industry, Food Group—Nutrition Panel (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Annual General Meeting, followed by meeting on "Foods Low in Phenylalanine". Dr. L. I. Woolf. "Clinical Aspects"; Dr. F. A. Robinson: "Manufacture and Technological Difficulties".

Oil and Colour Chemists' Association (at the Criterion Restaurant, London, W.1), at 8 p.m.—Twenty-fourth Annual General Meeting.

Thursday, April 26

Institution of Mechanical Engineers, Thermodynamics and Fluid Mechanics Group (at 1 Birdcage Walk, Westminster, London, S.W.1), at 10 a.m.—Symposium on "Some Developments in Techniques for Temperature Measurement".

Institution of Mining and Metallurgy (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. E. O. Lilge (University of Alberta): "Hydrocyclone Fundamentals".

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. J. W. S. Cassels: "Arithmetic on an Elliptic Curve".

Society of Instrument Technology, Control Section (at Manson House, 26 Portland Place, London, W.1), at 5 p.m.—Exposition—"Self-Adaptive Control Systems".

University of London (at the London School of Economics and Political Science. Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. Gilbert Ryle. "A Rational Animal" (Fifth Auguste Comte Memorial Lecture).*

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. B. Bleaney, F.R.S.: "Radiospectroscopy" (Fifty-third Kelvin Lecture).

Society of Chemical Industry, Microbiology Group (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Sir Cyril Hinshelwood, F.R.S.: "The Chemical Basis of Cell Properties".

Thursday, April 26—Friday, April 27

British Institute of Radiology (at Church House, Westminster, London, S.W.1—Twenty-third Annual Congress and Exhibition.

Friday, April 27

Institution of Electrical Engineers, Measurement and Control Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Symposium on "Flameproofing, Intrinsic Safety and other Safeguards in Electrical Instrument Practice".

Institution of Mechanical Engineers, Graduates' Section (at 1 Birdcage Walk, Westminster, London, S.W.1), at 6.30 p.m.—Mr. A. Salek: "The Air Cylinder—a Versatile Aid to Production".

Monday, April 30

University of London (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. John R. Raeburn: "Economic Development and Growth: Agricultural Aspects".*

Institution of Electrical Engineers (at Savoy Place, London, W.C.2), at 5 30 p.m.—Discussion on "The Applications Engineer—Control Schemes and Automation".

Monday, April 30—Saturday, May 5

Production Exhibition (at Olympia, London, S.W.7).*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer or Lecturer in the Department of Philosophy—The Registrar, University College of Wales, Aberystwyth (April 30).

Keeper (with an honours degree and/or Museums Diploma, and some knowledge of anthropology and primitive art) of Ethnology—The Director, Liverpool Museums, William Brown Street, Liverpool 3 (April 30).

Lecturer or Assistant Lecturer (with special interests and qualifications in palæontology and stratigraphy) in Geology—The Registrar, The University, Manchester 13 (April 30).

Lecturer (Grade I or Grade II) in Physical Chemistry—The Registrar, The University, Leicester (May 1).

Lecturer or Assistant Lecturer (with a special interest in the plastic deformation or fabrication of metals, and preferably with research, teaching or industrial experience) in the Department of Metallurgy—The Registrar, University College, Singleton Park, Swansea (May 1).

Lecturer (preferably with an interest in thermodynamics) in Physical Chemistry—The Registrar, The University, Leicester (May 1).

Assistant Lecturer (preferably with an interest in cryptogamic botany) in Botany—The Registrar, The University, Nottingham (May 4).

Assistant Lecturer in Statistics—The Registrar, The University, Sheffield (May 5).

Temporary Lecturer or Assistant Lecturer (with special interests in inorganic chemistry) in Chemistry—The Registrar, The University, Sheffield (May 5).

Assistant Lecturer in Physics—The Principal, Royal Holloway College, Englefield Green, Surrey (May 7).

Senior Lecturer (with considerable teaching and research experience) in Chemistry; and Lecturers or Assistant Lecturers in Applied Mathematics, Physics, Botany and Zoology at the University College of Cape Coast, Ghana—The Assistant Registrar (London), University of Ghana, 15 Gordon Square, London, W.C.1 (May 7).

University Demonstrator in the Department of Geography—Dr. I. D. Muir, Department of Mineralogy and Petrology, The University, Downing Place, Cambridge (May 10).

Lecturer in Metallurgy, and an Assistant Lecturer in Metallurgy—The Registrar, The University, Sheffield (May 12).

Lecturer in Refractories and Ceramics Technology—The Registrar, The University, Sheffield (May 12).

Lecturer (with a good honours degree in physics or mathematics and some experience in research) in Astronomy—The Secretary, The University, Edinburgh (May 12).

Lecturer or Assistant Lecturer in Statistics—The Registrar, The University, Leeds 2 (May 14).

Lecturer (with qualifications in either pure or applied mathematics) in Mathematics—The Registrar, (Room 22, O.R.B.), The University, Reading (May 14).

Assistant Lecturer or Lecturer in the Department of Philosophy—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 15).

Assistants (2) in Mathematics—Secretary of University Court, The University, Glasgow (May 15).

Reader in Meteorology—The Secretary of the Faculties, University Registry, Oxford (May 15).

Reader in Physical Metallurgy at the Imperial College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 17).

Dewar Research Fellow, to engage in research in radiation chemistry—The Secretary, The University, Edinburgh (May 18).

Lecturer in the Department of Biochemistry—The Deputy Registrar, The University, Edgbaston, Birmingham 15 (May 20).

Geologists (with at least a first- or upper second-class honours degree in geology, and preferably specialized in petrology) with the British Antarctic Survey, for service in the Antarctic for two years—Crown Agents, 4 Millbank, London, S.W.1, quoting Ref. M3C/53810/TA.

Lecturer in Educational Psychology—The Warden, Goldsmiths' College (University of London), New Cross, London, S.E.14.

Lecturer in Numerical Analysis—Head of the Department of Mathematics, Imperial College of Science and Technology, London, S.W.7.

Lecturer (with a Ph.D. degree or equivalent, also teaching and research interests in one of the following fields· genetics of lower plants; morphogenesis, or host-parasite relationships) in Botany—Dr. E. R. Waygood, Head, Department of Botany, University of Manitoba, Winnipeg, Manitoba, Canada.

Master (graduate) to teach Chemistry to Sixth Form-level and Lower School General Science—The Headmaster, Monmouth School, Monmouth.

Principal Lecturer (with experience of supervising research of an academic standard); a Senior Lecturer and a Lecturer in the Physics Department—Clerk to the Governing Body, Northern Polytechnic, Holloway, London, N.7.

Reader in Civil Engineering, and a Reader in Mechanical Engineering—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C 1.

Research Assistant (preferably postdoctoral, with some experience in neuroanatomy) in Neuroanatomy, for a joint research programme of the Department of Zoology and the Institute of Experimental Psychology, scheduled to last five years—Dr. Juan Delius, Department of Zoology Annexe, The University, 13 Bevington Road, Oxford.

Research Assistant (with a good honours degree and appropriate research experience) in the Department of Zoology and Applied Entomology, Imperial College of Science and Technology, to work with Mr. M. J. Way at the College Field Station at Ascot on the ecology of crop insects—The Director, Silwood Park, Sunninghill, Ascot, Berks.

Senior Lecturer and a Lecturer (with the qualifications and experience to teach mathematics for Diploma in Technology courses and for degree courses in engineering and general science) in Mathematics—The Registrar, Bradford Institute of Technology, Bradford 7.

Temporary Research Assistant or Technician—The Secretary, Wright–Fleming Institute, St. Mary's Hospital Medical School, Paddington, London, W.2.

"NATURE"

> "The idea was put out by Norman Lockyer, the astronomer and spectroscopist, in 1868. Huxley, Tyndall and nearly all the leading men of science of that day promised their support. Alexander [Macmillan], convinced that science would benefit by the devotion of a journal to it, did not hesitate . . . so he helped Lockyer by calling upon his scientific friends, by publishing the paper, as *Nature* itself has lately recorded, 'for several decades at a financial loss', and, above all, by giving to the editor an absolute editorial independence. . . . In 1943, they [the then joint editors] were able to write that 'today as much as ever, if *Nature* feels that, in the interest of science, any book, whether published by Macmillan's or not, should receive adverse criticism, then it gets it' . . . good to read in a naughty world".
>
> Charles Morgan : *The House of Macmillan* (1843–1943)

NOT even the present Editor's work is excepted; it is not so long since a book of which he was co-author received an adverse review in the columns of *Nature*. But, even *Nature* can make a mistake, not, one hopes, as often as those we see in the weekly and daily Press for there is not in *Nature* the same excuse of the deadline. There are some errors, however, which even the demands of time cannot excuse. The great Lord Northcliffe would never accept an excuse for an error of fact which could have been checked either by reference to the person concerned or elsewhere. He would, therefore, never have excused 'Atticus' for writing in the *Sunday Times* (London) of April 15 that "the Prime Minister's son, Maurice Macmillan, M.P. . . . edits 'Nature', the scientific journal". A small error one might think, which could do little harm. In fact, this wound, though unobtrusive like that of a stiletto, pierces deep and causes hidden injury, since it thrusts into the heart of the policy carried out by *Nature* itself and by Macmillan and Co., Ltd., its publishers, since its foundation. Some botanists claim that the least important characteristic of a plant is its name. Be that as it may, it is certainly true of editors. The first editor of *Nature*, the astrophysicist Sir Norman Lockyer, occupied the editorial chair for exactly half a century, from the foundation in 1869. The *names* of those who followed him and that of the present Editor are of no account. The main characteristic of *Nature* is that it is a scientific journal, known and used throughout the world of science. As such, it has always been, and still is, owned, but only owned, by the House of Macmillan. Scientists should be grateful, for although Macmillan do all they can to help and promote the journal they never attempt to influence, much less to interfere with, its policy. This is an attitude to publishing for which *Nature* can be grateful and the House of Macmillan proud.

It may be true that the least important characteristic of a plant is its name, but the recent statement in the *Sunday Times* (that it is the "Prime Minister's son" who edits *Nature*) shows that it is certainly not true that a rose by any other name smells just as sweet. For there is real and deep concern that it may in some sense be true that there is some outside interference in the editorial policy of *Nature*. After all, the Prime Minister himself is a member of the family which publishes the journal: his son is also a Member of Parliament. As Charles Morgan said, this is "a naughty world", and we have become suspicious of such coincidences. In these days when science is exerting such a profound influence on society it is all the more important that a scientific journal such as *Nature* should remain independent.

Nature must not only be independent, but also must be seen clearly to be so, for it goes to every part of the world where scientific research or teaching is being carried out. If the statement made in the *Sunday Times* were accepted as true in these countries it could be unfortunate and, in some cases, disastrous. 'Atticus' has made a silly error of fact. One day perhaps there will be a scientific Macmillan capable of editing *Nature*. There is no doubt that if there were he, too, would be as independent in his editorial policy from the rest of the family and from the firm that publishes *Nature* as is the present Editor and as have been the editors of the past.

Nearly twenty years ago Charles Morgan wrote the lines quoted at the beginning of this article. If he were alive to-day he could write them again with the same truth.

INTERNATIONAL INVESTMENT IN SCIENCE

THE eleventh annual report of the National Science Foundation[*], covering the year ended June 30, 1961, is similar in pattern to the previous year's report. Following the short statement of the director, Dr. A. T. Waterman, almost half the report is occupied by accounts of the programme activities of the Foundation. The remainder of the report comprises appendixes detailing the membership of the Board, its staff, committees and advisory panels, financial report, lists of research grants, fellowship awards and of publications (see p. 341 of this issue of *Nature*).

Of special interest at the present time is the section of the report dealing with the measurement and appraisal of the national investment in science, including the intensive study of science and technology as stimulant of growth in the national economy. The total research and development effort of the United States is now about 14,000 million dollars, or some 2·5 times the expenditure of 1953. A report issued by the Foundation in July 1961, *Investing in Scientific Progress*, estimated that the expenditure during 1961 for scientific and engineering education and for basic research in colleges and universities of 3,000 million dollars should grow to more than 8,200 million dollars in 1970, of which about 2,700 million dollars would be for basic research at universities. The figures in this report are based on the work of the Foundation's Office of Special Studies, which is engaged in collecting, analysing and publishing facts regarding the scientific resources of the United States. These studies, which have established the predominant role of the Government or public sector in the finance of research and development, are now being broadened to cover all scientific activities in relation to the economy, including the organization and management of science and their relation to the broad structure of social and economic institutions in the United States.

The statistics do not indicate the direction policy should take, but they reflect, quantitatively, some of the inter-relations which have been the subject of much public discussion. When full account is taken of the inquiry into the management of research in Britain, made under the chairmanship of Sir Solly Zuckerman, it must be admitted that Mr. Denzil Freeth's reply in the House of Commons on February 27 to a question regarding the staffing of the Office of the Minister for Science would have been more convincing were there evidence that the Minister had already at his disposal the information required for sound objective decisions on the many matters of scientific and technical significance which call for his attention. Only too often, as in hydrological research or nature conservancy, he has to admit that the information has still to be obtained.

The National Science Foundation's report shows, it is true, that frequently the essential information has still to be obtained in the United States also. There, as in Britain, greater understanding is needed as to what types of economic and technological conditions and managerial motivation lead some industries as a whole or certain firms within an industry to make the risk decisions to invest in research and development while others do not take this step. The President's Science Advisory Committee, reporting on *Scientific Progress, the Universities, and the Federal Government*, discussed some of the questions in this field that are just as critical in Britain as in the United States. However, in Britain more information is desirable before it will be possible to reach wise decisions as to the expansion of the research resources in the universities and colleges of technology, or of the appropriate use of other research institutions, including Government research stations and national or international institutions in particular fields.

Commenting on this study, *Investing in Scientific Progress*, in his statement, Dr. Waterman remarks that the steadiness of the increasing trend in output of scientific manpower, which is expected to double by 1970, suggests real interest and purpose on the part of the younger generation in the values of such careers. This trend must be maintained and possibly accelerated to meet the estimated needs during this decade, and this goal should be achieved without drawing on more than about 4 per cent of the United States highest talent in intelligence quotient. Nevertheless, insufficient preparation is being made for these essential increases in trained manpower, and Dr. Waterman adds that the United States is headed steadily towards an accelerating general activity in science and technology without adequate provision for the magnitude and cost of the effort, and he points out that if provision is to be made it must be based on public support and understanding.

Dr. Waterman's statement is of particular interest in its discussion of the factors involved in the provision of an adequate supply of trained manpower, and the interplay of science and technology with the economy. It is not simply that scientific and technical education needs to be expanded in scale: its quality and content also need attention, and it is imperative also to give more care to the ways in which trained manpower is used and especially its creative ability fostered. Here, in words that reflect much of Lord Hailsham's attitude, Dr. Waterman stresses the dependence of the progress of science on the personal initiative and independence of the individuals and groups engaged in research and the pitfalls that beset any attempt at central planning or direction even in respect of the content of programmes or the determination of priorities. He recognizes that national science policy and its supporting organization present a most important and challenging problem, but he neither attempts to define such policy nor suggests that the structure established in the United States is necessarily adapted for use elsewhere. It may well be that due account will be taken of the work and functions of the National Science Foundation, the President's Science Advisory Committee and the Federal Council for Science and Technology by the Advisory Council on Scientific Policy in its continuing inquiry into the organization of scientific research and also in the review of the existing organization for promoting civil science by Government agencies which the Government is now undertaking. Certainly the devices, including methods for improving the speed and accuracy of survey analysis, techniques for dealing with masses of detailed information and methodology based on statistics and communication theory noted in this report, should be utilized to the full in the comparison of needs and priorities with trends and potentialities with respect to manpower, facilities, funds and findings of research.

---

[*] National Science Foundation. Eleventh Annual Report for the Fiscal Year ended June 30, 1961. Pp. xxi+325. (Washington, D.C.: Government Printing Office, 1962.) 1.25 dollars.

It is, in fact, the considerations which have led to the Foundation establishing an Office of Science Resources Planning that have prompted doubts as to whether the Office of the Minister for Science and the Advisory Council on Scientific Policy are adequately staffed and supported for the inquiries they need to conduct. The National Science Foundation system includes adequate provision for individual and local initiative and independence, and those intake elements need not be sacrificed in efforts to acquire the awareness and the information as to activities in progress and the disposition of scientific manpower and other resources which are essential elements in the decisions which must inevitably be taken at the centre. Moreover, leaving on one side the actual support for scientific research afforded through the National Science Foundation or the extensive fellowship and studies designed to extend the opportunities of, and also the qualities of, training in science and technology, the Foundation is making a major contribution in the dissemination of scientific information and in international co-operation in science which at least merits the direct attention of the Minister for Science himself. Its bearing on the effective use of scientific and technological manpower is too important for this to be left entirely to the Department of Scientific and Industrial Research.

The Foundation is seeking to promote development of new and better techniques for handling scientific information and also to improve existing methods for disseminating scientific information, and in all made some 166 grants totalling about 5·38 million dollars during the year for these purposes. While the tendency during the year has been increasingly to support the principle that dissemination of the results of research is an integral element of the total cost of research, generally the report records the continuance of activities along existing lines, with some emphasis on the analysis of existing patterns of scientific communication, and the ways in which scientists and engineers use existing publications and information services. The projects which the Foundation is supporting in the use of notation systems, mechanical translation and the like are, however, of international importance even where they do not call for the immediate co-operation of scientists outside the United States; they illustrate a field in which courtesy alone would suggest that no opportunity of co-operation with the Foundation should be missed by scientists in Britain.

This is clearly contemplated by the Foundation itself, science information and the improvement of the communication of science generally being specifically mentioned among the responsibilities of its Office of Special International Programmes, though in this present report the major attention is directed to educational matters, including the encouragement of contacts between educationists and scholars in the United States and in other countries and the improvement of the content of science courses and the training of teachers of science. Some grants were made to enable outstanding scientists from the United States to visit other countries to prepare research reviews in their special fields, and the Foundation is also exploring experimental approaches to co-operating in international support of scientific centres in developing areas; and one such project, providing partial support for an international team of physiologists in a tour of India, is supported also by the Royal Society.

AN OVERSEAS INDIAN COMMUNITY MADE VISIBLE

Peasants in the Pacific

A Study of Fiji Indian Rural Society. By Adrian C. Mayer. (International Library of Sociology and Social Reconstruction.) Pp. xiii+202+16 plates. (London: Routledge and Kegan Paul, Ltd., 1961.) 35s. net.

ONE of the points of attack on the problems of social and culture change has been comparison of established overseas communities with the society and culture of their homelands. Studies of immigrant groups, especially in the United States, and the number of recent studies on overseas Chinese communities, are cases in point. The author aims this work toward extending the coverage of such studies to overseas Indian communities. His work is done against the background of earlier field work in south India. While he does not attempt any direct comparison with India, he has designed this study to provide material for such comparison. He carried out his field work in Fiji during 1950–51. In his material he compares three rural Fiji Indian communities, chosen to provide clear variations in geographical location and physical setting.

As yet, no single theoretical framework exists for making systematic comparisons of this kind. Such comparative work as has been done is limited to comparing the changes within overseas communities in institutions or cultural complexes specific to the homeland. The author here approaches his communities more holistically. He gives, for example, but passing attention to what has happened to caste among Fiji Indians, on the grounds that he found caste to play only a very minor part in the social relations of his subjects. Contrariwise, he does a superb job of tracing the historical development of settlement patterns among rural Fiji Indian communities, and of connecting this development with ecological factors locally in play. Equally, he shows in excellent detail the way internal differentiation within these communities has been based on felt cultural allegiances to broad regions of origin in India—North India as compared with South India—and to original religious differences, such as Muslim, Sikh and Hindu. There is implicit that these allegiances have acted to replace the caste allegiances which in most Indian rural communities act to produce very similar internal differentiation, though the author does not attempt to draw out any comparative significance.

The main part of the work is concerned with an analysis of local community politics. Politics he defines in terms of the functions it performs, arguing reasonably enough that the relationships he deals with as political do the same thing, on a small scale, that formal political bodies do. He examines such groups as local school committees, cane harvesting gangs, informal councils for mediating disputes, and factional groups the leaders of which are competing for local political power and social influence. He examines in detail the contexts of political action, the modes of leadership, and the accompanying patterns of factionalism. The descriptive treatment is highly convincing. Again, there is obvious comparative significance in the close similarity of factional modes and motivations to those widely reported for India which, true to his approach, the author does not try to underline.

In the final section he does an excellent job of drawing out the diverse strands of opinion and stereotype in the view the Indian community have of the outside—the Fijians, the Europeans, and especially well done, their ambivalent view of India. Throughout, the documentation and illustrative material is of high order, and kept very well under control. If there are any doubts on the work, they lie in the author's intention that his shall be a descriptive contribution to a comparative analysis as yet unframed. His description, to be comprehensive, necessarily has been stretched rather thin over some of his topics, particularly on kinship and economics. The difficulty here is that when some comparative analysis is finally attempted, it is likely that the analyst will find he needs greater depth in the materials he uses than the author provides here. This is no criticism unique to this work, which as a descriptive contribution is outstanding, but is one general to all studies that do not try to tackle the analytical problems of the comparative work toward which they aim to contribute. R. R. Jay

LOCUST RESEARCH IN INDIA

The Desert Locust in India

By Y. Ramchandra Rao. (Monograph, No. 21.) Pp. xix + 721 + 59 plates. (New Delhi: Indian Council of Agricultural Research, 1960.) Rs. 73.50; 111*s*.

SERIOUS depredations by the desert locust (*Schistocerca gregaria* Forsk.) in the pre-partition India in the late 'twenties stimulated the Board of Agriculture not only to initiate measures aiming at saving the crops but also to realize the need for long-term research on this recurrent problem. A scheme for extensive investigations of the biology and ecology of the locust was established and the work, based on Karachi but extending over the locust habitats both in Pakistan and India, has continued for nine years under the leadership of the author of the book with a small staff of both nationalities. The book, however, is not merely a detailed report of the work carried out during the period, but also the results of the latter have been most usefully augmented by the abundant data carefully extracted from a mass of local documents and critically examined in the light of the later findings. The result is a comprehensive monograph of the desert locust problem in the Indo-Pakistan sub-continent on a scale and with the wealth of detail which have no parallel in any other locust-infested part of the world.

An introductory chapter, describing the general physiographical, climatic and vegetational background, is followed by a detailed account of the extensive field investigations. These were of particular value because they concentrated on the study of the local non-swarming locust populations which were suspected as the source of devastating swarms. Methods of routine population counts were elaborated and a network of observation posts established throughout the main locust-breeding areas, where continual observations on the various aspects of locust biology and ecology were organized in the field and in open-air cages.

What is most important, the data assembled were thoughtfully analysed, leading to a series of conclusions, many of which anticipated the results of much later investigations in other countries. These results included original data on the effects of temperature and humidity on the rates of development of the different stages of the locust; its food plants and their effects on the growth and sexual maturation; its natural enemies; the correlation of the annual life-cycle with the seasonal weather; changes in the morphometrics of wild populations in relation to the phase change, etc.

Among the most original and important results was the finding, well supported by field observations, that non-swarming locusts carry out seasonal migrations fully comparable with those of swarms, thus taking advantage of the seasonal shifts in the areas of rainfall which is essential for their breeding. As it was generally believed at the time (and is still maintained now in some text-books and popular works) that the solitary phase of the locust is also non-migratory, the Indian evidence was of outstanding importance for research elsewhere. Moreover, it was also established that migrations of solitary locusts were under the direct influence of seasonal winds, including the regular monsoons and the less-regular cyclonic depressions. A close connexion between the pattern of locust migrations and the dynamics of weather has thus been established for the Indo-Pakistan region many years before the connexion was analysed in more detail by joint efforts of entomologists and meteorologists elsewhere. This finding is amply supported in the later chapters of the book where all available records of movements of locust swarms and breeding are analysed against the background of weather for the locust plague periods 1920–39, 1908–19, 1888–1907 and 1860–88.

This analysis, partly illustrated by annual maps, both of locust distribution and weather, led to another important conclusion that the invasions by the desert locust of India were synchronous with similar events in Iran, Middle East and Africa, and, in most cases, appeared to originate outside India. On the other hand, it was also established that swarms produced in India and Pakistan during the monsoon rains mostly migrated westwards to breed in the winter rain areas in the west, the progeny again invading Pakistan and India in the next year. Thus, the interdependence of geographically very distant breeding areas was confirmed by the Indian work.

The author has also attempted to investigate the periodicity of locust plagues in relation to sun-spot periods and thought that there was some evidence of the outbreaks following the sun-spot minima, that is, relatively dry periods. He was cautious enough to admit, however, that the possibility of forecasting locust plagues must depend on a much better knowledge both of the present distribution and movements of locust populations and of the weather throughout the whole vast region of the pest. A special chapter of the book deals with two other locusts occasionally swarming in India, *Patanga succincta* and *Locusta migratoria*; again, their seasonal cycles and migrations are discussed against the meteorological background.

It was most regrettable that the book, completed in 1945 and actually set in print in 1951, was not published before 1960. Although some of the most important extracts from it were published in England, an earlier appearance of the complete work would not have failed to benefit from the progress of locust research elsewhere and such a long delay in its publication for, apparently, purely administrative reasons, is difficult to justify. The standard of the book's production is very low, the paper being of poor quality; illustrations badly reproduced (though the originals of the coloured plates must have been of high quality); there are innumerable misprints; plates and maps are mostly unnumbered and scattered throughout the book without any relation to the relevant text; and the binding of the unused book is already falling to pieces; all this reflects little credit on the official publishers. Nevertheless, the intrinsic value of the book is so great that it will always remain a classic example of a well-conceived investigation of a major regional problem, carried out with more inspiration and determination than the material resources and resulting in far-reaching conclusions of exceptional general value. B. P. UVAROV

A FOUNDATION-STONE OF PLANT TAXONOMY

Species Plantarum

By Carl Linneaus. With an Introduction by W. T. Stearn and an Appendix by J. L. Heller and W. T. Stearn. Vol. 1: Pp. xiv+1–560. 50*s*. Vol. 2: Pp. xv+561–1200. 60*s*. (London: The Ray Society, 1957 and 1959. Sold by Bernard Quaritch, Ltd., 11 Grafton Street, W.1.)

THE Ray Society and Dr. W. T. Stearn have performed a great service to botanists throughout the world by producing this excellent facsimile of *Species Plantarum* at so modest a price.

Species Plantarum is, of course, familiar, at least by name, to every systematic botanist. It is the starting point of binary nomenclature and established a general system which rendered possible for the first time the organization of information about the rapidly increasing number of plants which were becoming known to botanists in the eighteenth century.

It is, I suspect, seldom studied except by specialists on nomenclature. Indeed, the understanding of its content and of its wider significance has made too great a demand on time and special knowledge for it to be undertaken by most botanists.

Dr. Stearn's introduction to this facsimile, occupying the first 176 pages, is a feast of interesting and valuable information which, in turn, makes Linnæus's great work comprehensible to the modern botanist.

An historical survey summarizes the principal events in the life of Linnæus and traces the development of his work through his travels, studies and publications. In the course of this the reader is given an idea of the range of interests of the 'Prince of Naturalists' as indicated, among other things, by the titles of the 186 dissertations for which he was primarily responsible. A small sample will serve to show the kind and variety of subjects dealt with: *Peloria, Crystallorum Generatione, Surinamensia Grilliana, Taenia, Splachnum, Plantae Hybridae, Noctiluca Marina, Cynographia, Flora Palestina* and *Medicamenta Purgantia.*

Dr. Stearn traces also the history of the major botanical publications such as *Genera Plantarum, Hortus Cliffortianus* and, of course, *Species Plantarum* itself, and makes clear the development of the concepts necessary for classification and of the binary nomenclature. He also explains the methods to be used for, and the pitfalls which beset the unwary in, the typification of Linnean genera and species, matters of practical importance for the taxonomist.

The section on the sources, format, method and language of the *Species Plantarum* is particularly interesting. Linnæus was the creator of botanical Latin with "its avoidance of verbs, its restricted number of nouns . . . and its rich store of adjectives", which has already been a living language for longer than classical Latin was.

Other matters of practical importance discussed in this scholarly introduction are the history and present location of the various surviving Linnean herbaria and of other herbaria to which Linnæus had access, and the meaning of the geographical names used for describing the distribution or localities of plants. These are both of great assistance to those who have to attempt the often difficult task of typifying Linnean species, and, like the rest of the introduction, should be read carefully by systematists as simple-minded as myself.

The appendix to the second volume includes an exhaustive index of authors and books cited by Linnæus which has been compiled with great attention to detail by J. L. Heller of the University of Illinois. This is followed by notes on illustrations and an account of four other Linnean publications by Stearn.

The latter, beside providing some additional nomenclatural information, are of particular interest for the light they throw on Linnæus's methods and concepts; they should be studied in conjunction with the section on his species-concept in the introduction to Volume 1. It becomes evident that the artificial 'sexual system' was no more than an aid to identification and that Linnæus was always searching for a 'natural' classification. But, as he writes in *Ordines Naturales* (1764), "A multitude of *Genera* is a burden on the memory to be lightened by System", and he provided a very useful system.

All three sections of the work are fully indexed, and that to *Species Plantarum* itself is made additionally useful by the indication of the species which have been proposed as generic types.

No systematic botanist should be without this facsimile, even though he be the fortunate possessor of the original work.

T. G. TUTIN

PROGRESS IN BIOCHEMISTRY

Annual Review of Biochemistry

Vol. 30. Edited by J. Murray Luck, in association with Frank W. Allen and Gordon Mackinney. Pp. viii + 758. (Palo Alto, Calif.: Annual Reviews, Inc., 1961.) 7 dollars.

WHEN, thirty years ago, Prof. J. Murray Luck and his three advisory colleagues wrote their preface to the first volume of the *Annual Review of Biochemistry*, they offered an apology for starting a new publication. They need not have apologized, for they were launching what has proved to be one of the most important publications in biochemistry; moreover, they were setting the pattern for the various 'annual reviews' in other biological subjects which were to come from California. The parent *Review* has now reached its thirtieth volume, still under the editorship of Prof. Luck. His thirty-year record of service to biochemical literature certainly deserves special mention and thanks.

The introductory chapter in the present volume was written by Prof. J. H. Northrop, pioneer in crystallization of enzymes. He likens present-day discussions on the nature of viruses to those which were taking place on enzymes fifty years ago. Perhaps his general theme may be summed up by quoting the following provocative sentence: "chemists (and physicists) have great respect for the Reverend Occam's razor and endeavour to limit their assumptions to the minimal number essential for an explanation, in accordance with the principle of the conservation of hypotheses; whereas some biologists have no respect for the Reverend's weapon and fearlessly bolster an ailing (and unnecessary) assumption by another similar one". This chapter is followed by articles on the subjects which are usually covered year by year: biological oxidation, chemistry and metabolism of carbohydrates, fats and proteins, biochemistry of muscle, vitamins and so on. Indeed, many of the chapter headings are the same as those in Volume 1 of this *Review*, and it is interesting and impressive to compare the contents of corresponding chapters thirty years apart. The present volume includes a well-illustrated article on X-ray studies of biological compounds (A. Rich and D. W. Green), and chapters on protein synthesis (P. Berg), nucleotides (A. M. Michelson), nucleic acid biosynthesis (R. Abrams), and on the polyamines spermidine and spermine (H. Tabor, C. W. Tabor and S. M. Rosenthal). The final three chapters deal with the biochemistry of (1) cultured mammalian cells (L. Levintow and H. Eagle), (2) genetic factors (C. Levinthal and P. F. Davison) and (3) the dividing cell (D. Mazia).

The editorial committee has followed the recommendation of the Commission on Enzymes in adopting the coenzyme abbreviations NAD and NADP. This, presumably, will finally seal the fate of DPN and TPN and, incidentally, provide an excuse for a new edition of almost every text-book of biochemistry. Articles on biochemistry in the U.S.S.R. appeared in Volumes 26–28; there have been none since, though there are occasional references to Russian work in the general articles in the present volume. A third decennial subject and author index would normally now be due, but according to the preface of Vol. 29 this will not be published. In view of the usefulness of the separate cumulative indexes covering Volumes 1–20, this decision seems a pity. Biochemists owe a debt of gratitude to the 38 authors from seven countries who have contributed to this volume. To write one of these chapters is no light undertaking.

D. C. HARRISON

SOIL ORGANIC MATTER

Soil Organic Matter

Its Nature, Its Role in Soil Formation and in Soil Fertility. By M. M. Kononova. Translated from the Russian by Dr. T. Z. Nowakowski and G. A. Greenwood. Pp. 450. (London and New York: Pergamon Press, 1961.) 80*s*. net.

THIS book was first published in Russian by the Academy of Sciences of the U.S.S.R. in 1951, but this recent English translation has been revised and brought up to date by the author. The last comprehensive review in English of this subject was the familiar work of Waksman, published twenty-four years ago, and so Mme. Kononova's book is a welcome addition on two accounts: it brings together many of the recent advances which have been made towards the elucidation of the chemical nature and role of soil organic matter, but, perhaps more important still, it provides a full account of the work of the Russian scientists in this field, most of which has not been available in English before.

The first chapter is devoted to a historical account of the development of the subject from the beginning of the eighteenth century and provides a valuable and interesting sidelight on the divergence of ideas relating to the chemical nature of humus. Earlier British and American workers suggested that because of the relative resistance of plant lignin to microbial decomposition, it must be a major component, in a modified form, of humus. On the other hand, Russian and German workers believe that humus is a product of microbial synthesis, plant materials merely acting as a substrate for the micro-organisms. The author then elaborates on the theory that humus is a mixture of heterogeneous polymers produced by random condensation of polyphenols and amino-acids, both products of microbial decomposition, in the presence of oxidizing enzymes. The heterogeneous nature of the polymers is claimed to explain their resistance to microbial decomposition. A great deal of evidence is provided to support this theory, much of it having been obtained by Mme. Kononova and her colleagues at the Dokuchaev Institute.

A discussion follows on the role of soil organic matter in soil fertility and soil formation in the light of this theory. Unfortunately, the section on fertility only touches on nitrification with scarcely a mention of organic phosphorus and sulphur compounds. Its role in soil formation and the changes brought about by different types of cultivation are reviewed at length. Methods of maintaining the levels of organic matter in soils are dealt with, including the rotation theory of V. R. Williams, which is receiving a good deal of attention in the U.S.S.R. to-day. The section on soil formation is placed in perspective by a final short chapter contributed by N. N. Rozov on the major soil types of the U.S.S.R.

Analytical methods are confined to an appendix, thus making for easier reading, and here mention should be made of the excellent work of the translators. It is a pity that the quality of the book has been lowered by the use of inferior quality ink, but on the credit side the value of the book has been enhanced by an offer from Pergamon Press to supply readers with a translation of any article referred to in the text, at a reasonable price.

J. W. Parsons

YOUTH SCIENCE ENCYCLOPÆDIA

Junior Science Encyclopaedia

Consultant Editorial Board: Dr. Maurice Burton, Prof. J. M. Cassels, Sir James Chadwick, Sir John Cockcroft, Prof. L. Dudley Stamp, Prof. F. G. Young, and Prof. J. Z. Young. General Editor: Leslie Basford. Vol. 1: Pp. 1–88. Vol. 2: Pp. 89–176. Vol. 3: Pp. 177–264. Vol. 4: Pp. 265–352. Vol. 5: Pp. 353–440. Vol. 6: Pp. 441–528. Vol. 7: Pp. 529–616. Vol. 8: Pp. 617–703. (London: Sampson Low, Marston and Co., Ltd., 1961.) 104*s.* the set, or 13*s.* each volume.

We are unquestionably living in the golden age of science, at a time when the sciences, the scientists, and their promoters have 'never had it so good'. Since the turn of the century, science has risen to a position of such great political, social, and technological significance that it now seems unnecessary even to apologize for rockets and capsules to the moon, or laboratories and equipment in the schools, or reactors and refineries on the sea-shore. We are also growing accustomed to the ever-increasing number of scientific books which purport to satisfy a long-felt need, or offer no apology for their appearance at all.

Junior Science Encyclopaedia is one such set of books which has appeared on the market without a preface. However, the general editor, Mr. Leslie Basford, does supply on the cover and the title-page of every volume the names of the eminent scientists who form the consultant editorial board. Sir Lawrence Bragg and six of the consultant board have contributed short introductions to the study of physics, zoology, science, electronics, geology, biochemistry and anatomy. These introductions are arbitrarily allotted one to each of Volumes 2–8. I found myself wondering why Prof. Cassels did not contribute an article, and why Sir John Cockcroft did not autograph his contribution. Volume 1 contains, of course, a short introduction to the consultant editorial board.

The reader, therefore, is left to judge for himself the aim and scope of this set of books. This is by no means an easy task. To begin with, the title is somewhat misleading. The word "Junior" usually relates to children of not much more than twelve years of age. However, these volumes have little to offer such children apart from the glossy, attractive covers, and the exaggerated use of vivid colours: the only things in black and white are a few photographs (including those of the above-mentioned scientists) and most of the print. Furthermore, the term "Science Encyclopædia" rather implies a wealth of scientific information for both the young and the old. However, the cover illustrations and the presentation of the material indicate clearly that these volumes are not primarily designed for the adult. It would appear, therefore, that they are intended for children in their early teens.

The topics range widely from absolute temperature to calorimeters (Volume 1), Cambrian period to Doppler effect (Volume 2), double stars to graphs (Volume 3), gravitation to loglines (Volume 4), longitude to petrified forests (Volume 5), petroleum to satellites (Volume 6), saturation to triple-expansion steam engines (Volume 7), and tropical medicine to zoology (Volume 8). The last volume also contains an index with ample cross-references to related topics, short articles on subjects of recent scientific research and on scientific method, a supplementary glossary of scientific terms, and forty-eight charts of the night sky. There is a superabundance of illustrations which are invariably highly coloured. Some of these, such as the domestic electricity meter on p. 194, the camera lens on p. 336, and the guns on pp. 269–270, are quite impressive. However, many, such as the amphibians on p. 19, the distillation apparatus on p. 172, and the minerals on p. 381, are very poor: this is the result of rather inferior colour printing and inaccurate draughtsmanship.

Since Sir James Chadwick ends his introduction to the study of science with the comment that "there is some relief to be found in the fact that it is now easier than it was to have access to reliable sources of information", there seems to be the suggestion that these books are reliable sources of scientific information. The editor must, of course, omit much of interest and importance. He must also omit unnecessary complications and admit convenient simplifications. He must then run the risk of creating a false impression and of publishing a less-reliable source of information. A most surprising omission from the list of 116 famous scientists (pp. 532–540) is the name of John Dalton, 'founder' of the atomic theory.

On pp. 45–46, the relative sizes of the atoms are indicated by spheres in an assortment of colours from yellow and green to mauve and chocolate-brown. These colours are of little significance since a different set of coloured spheres is used on p. 111 to represent 'molecules' of sodium chloride and other well-known ionic compounds. These illustrations are fortunately small. The calcium carbonate 'molecule' also appears on p. 388. This time, for no apparent reason, it is inverted and occupies half the page. In both these illustrations the relative sizes of the atoms are preserved and the links between them are in accord with their valencies. Unfortunately, it is well established that all three oxygen atoms are attached to the carbon atom. The linking between oxygen atoms represented by these illustrations probably occurs only in ozone and ozonides.

Certain small errors were also noticeable to me. For example, chemists rarely ever do acid-base titrations using litmus indicator (p. 21), a colloidal solution is called a 'sol' and not a 'soll' (p. 131), the illustration of the structure of graphite is slightly inaccurate (p. 155), and 'allotrope' rather than 'allotropy' is intended in the glossary of terms (p. 696).

The overall impression of this set of books is likely to be that they have something of interest to offer the budding young scientists, but that they are too expensive at 104*s*.

Michael C. Cox

Introduction à l'Astrophysique : les Étoiles

Par Prof. Jean Dufay. (Collection Armand Colin: Section de Mathématique, No. 352.) Pp. 218. (Paris: Librairie Armand Colin, 1961.) 4.50 N.F.

PROF. DUFAY gives us an account of present-day techniques in stellar spectroscopy and photometry, but deliberately omits any discussion of variable stars or extra-galactic objects.

A preliminary chapter introduces the definitions of absolute and apparent magnitude, and discusses the effects of atmospheric absorption and agitation. The account of selective absorption by the constituents of the Earth's atmosphere is very condensed. The final chapter is taken up by a discussion of Saha's equation and its consequences, together with a brief account of the theory of stellar evolution.

The main portion of the book describes the instruments and methods of stellar spectroscopy and photometry in the optical and near ultra-violet regions in considerable detail, attention being directed to the corrections required for each method. The spectra of the main classes are described, and the characteristic features of spectra of Wolf-Raynet and other peculiar non-variable stars are listed. The continuous spectra are classed in terms of colour gradient, and a brief account of three-colour photometry given. The three-parameter photometric classification of Barbier, Chalonge and Diran is described.

The book should be of interest to those reading honours courses in astronomy. Its usefulness for other purposes is marred by the author's failure to give any references when citing a paper, an inadequacy not removed by the short selection of other works listed in the bibliography.

M. R. C. McDowell

Introduction to the Dynamics of Automatic Regulating of Electrical Machines.

By M. V. Meerov. Translated by J. S. Shapiro. Pp. xxii+411. (London: Butterworth and Co. (Publishers), Ltd., 1961. Published in association with the Department of Scientific and Industrial Research.) 100*s*.

PART of the interest in reading this translation of a text first published in the U.S.S.R. in 1956 lies in meeting an approach to familiar material which differs in flavour if not in substance from British conventional fare. The core of the book is a study of the stability, quality and synthesis of regulating systems. Stability is assessed by conventional techniques—the *D*-partition theorem of Neimark turns out to be a slightly generalized form of the Nyquist diagram. A criterion of aperiodic stability is also presented. Quality is assessed by a modified form of the Routh–Hurwitz criterion, various integral criteria and the use of the frequency response characteristic to estimate the transient behaviour of the system. Some of the integral criteria are interesting as they are not usually met in our texts: one of these, due to Krasovskii, develops a Lyapunov function which is then minimized with respect to certain parameters of the system; another minimizes the 'closeness' of the regulating system to a standard linear system. Synthesis is achieved by adding stabilizing links and various configurations utilizing such links are analysed.

The book commences with a fairly detailed analysis of electrical machines, amplifying and measuring devices and includes sections on sampled-data systems, non-linear systems and systems with time delays. The author also devotes a chapter to the examination of the effect of neglecting small parameters in the analysis of a system. The book is a competent study of a limited field—the deterministic behaviour of regulating systems incorporating electrical machines.

D. Q. Mayne

Carbon-14 Compounds

By John R. Catch. Pp. vii+128+5 plates. (London : Butterworth and Co. (Publishers), Ltd., 1961.) 30*s*.

IT is probably true to say that carbon-14 is used more extensively than any other radioactive isotope as a radioactive tracer, and a very large body of literature has built up during the past decade, largely in the form of research papers. The aim of this book is to provide a guide to the literature of carbon-14 preparations which will be particularly useful to the newcomer in the field of tracer work. It takes the form of a series of reviews covering the production of carbon-14, chemical synthesis of labelled compounds, biological methods of labelling, peculiar features of carbon-14 compounds, the analysis of labelled compounds, measurement of carbon-14, and precautions in the use of carbon-14 compounds. A short appendix summarizes recent work which appeared during the preparation of the book.

The literature of the subject is now so extensive that a book of this type must inevitably be selective in its treatment and thus tend to invite criticism on the grounds of omissions. However, the newcomer should indeed find it a very valuable guide, and the expert may well profit from it, too, outside his own narrow field of specialization. The chapters dealing with the peculiar features of carbon-14 compounds and the significance of analytical purity are most useful in directing attention to those factors which must be clearly understood if errors are to be avoided in the interpretation of experimental results.

H. Barker

The Year Book of the Royal Society of London, 1962

Pp. 320. (No. 66.) (London: The Royal Society, 1962.) 21*s*.

THE *Year Book of the Royal Society* continues in its tradition of providing a compendium of useful information concerning the Society. In its 320 pages, details of Fellows and Foreign Members are shown, together with membership of the many committees and boards, standing orders, Council procedure, medal awards, special memberships and appointments, and a report of Council for the year ended September 30, 1961. Reports of holders of Royal Society research fellowships and professorships are appended, and short histories of bequests and endowments made for the purposes of research are included elsewhere. The remaining appendixes list the representation of the Society at international scientific meetings, Parliamentary grants-in-aid for scientific investigations and publications, and additions to the Society's library. It is a pity that the *Year Book* is published immediately before the annual election of new Fellows. This renders the list of Fellows and Foreign Members given at the front of the book out of date within a few weeks of publication. A delay of only a month or so before publication would surely make it possible to include the new Fellows.

PINCHED LIGHTNING

By B. T. MATTHIAS and S. J. BUCHSBAUM

Bell Telephone Laboratories, Inc., Murray Hill, New Jersey

WE have obtained what we believe to be a unique photograph of a pinched lightning discharge.

The photograph was taken in late August 1961 at Los Alamos, New Mexico, during a severe thunderstorm. The camera (Elmar 3·5 : 1 lens, focal length 50 mm., *f* number 22) was pointed from behind a window-pane in a darkened room at an approaching thundercloud which was estimated to be about a kilometre away. The camera was inclined to the horizontal at an angle of about 15° and was, of course, focused at infinity. Six frames of Kodachrome colour film *ASA* speed 10 were exposed for 15 min. each. Four were found blank, one showed a standard lightning stroke, and the sixth is reproduced in Fig. 1. Over the years we have taken hundreds of photographs of lightning discharges, and this is our first photographic evidence of a pinched lightning.

We estimate the distance of the lightning to the camera at between 200 to 1,000 metres, and thus, the transverse dimension of the lightning between 1 and 5 m. Somewhat puzzling is the apparent much larger intensity of the integrated luminosity of the pinched lightning when compared with the luminosity of the aforementioned standard lightning stroke.

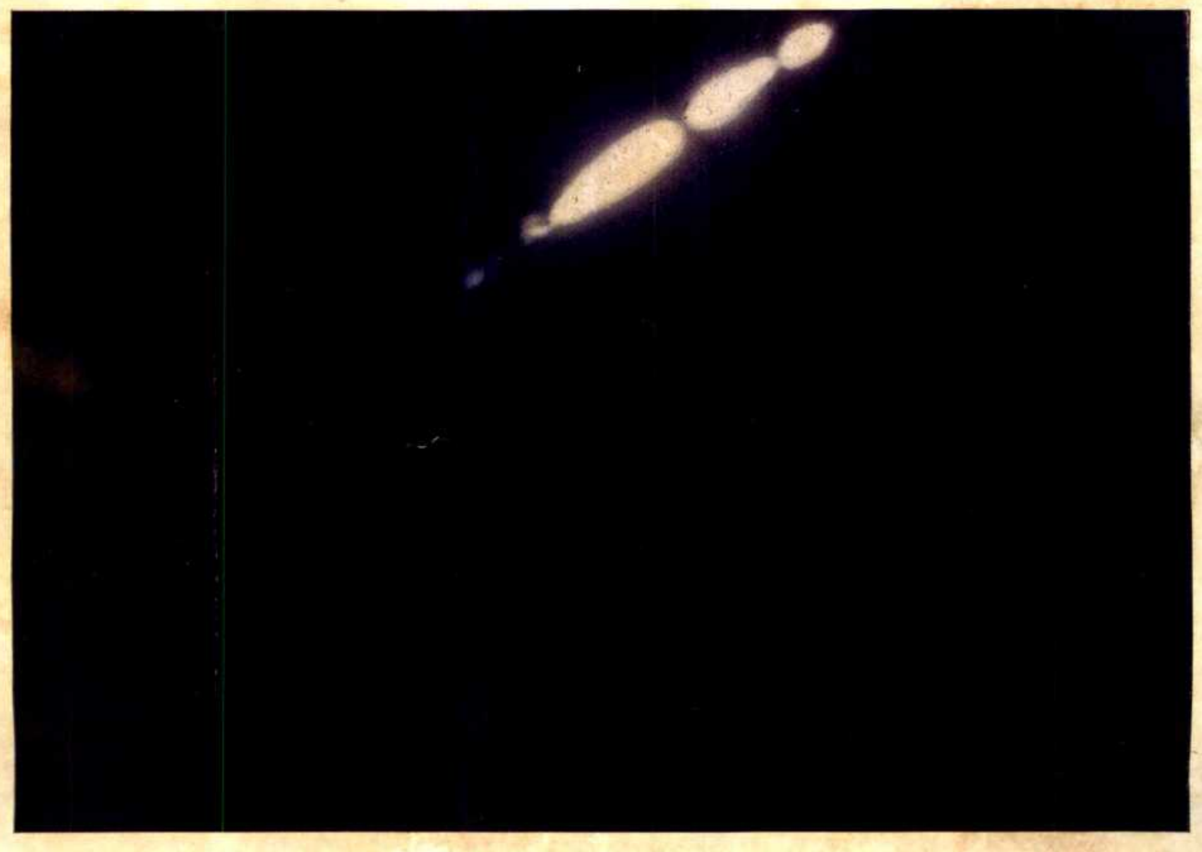

Fig. 1. Photograph of pinched lightning

DATING THE GALAXY BY URANIUM DECAY

By Prof. R. H. DICKE
Palmer Physical Laboratory, Princeton University

ARP[1] has recently discussed the metal content of stars in clusters of various ages. One striking thing about Arp's data is the indication that the heavy elements were generated primarily by early stars in the halo population. He finds that the very old galactic cluster *NGC* 188 (16 × 10^9 years old) has approximately the same heavy element content in its envelope as does the Sun. While there is an indication of slightly more heavy element in very young clusters than in *NGC* 188, the increase is small (~ 30 per cent) and it may not be statistically significant. While the data are not so firm as to make this conclusion certain, I propose to assume here that the heavy elements were formed primarily by the halo population.

There existed in the early halo population a type of star no longer present in the Galaxy, the massive Population II star. This star may have been supernova prone; it may have been the chief source of the heavy elements.

There appears to be no systematic variation, from one cluster to another, in the ratios of the heavy element abundances. This suggests that uranium was produced at the same time as the other elements, and that Arp's data can be assumed to apply also to the production of uranium.

With this assumption it is easy to obtain an age for the Galaxy based on the radioactive decay of uranium-235. The technique is similar to that first used by Fowler and Hoyle[2]. However, the end result differs by a factor of 2. The production ratio (uranium-235/uranium-238 = 1·64) obtained by Burbidge, Burbidge, Fowler, and Hoyle[3] is used. To show how uncritical this assumed production ratio is, ages are calculated also with assumed ratios of 2·0 and 1·0.

Designating by N the fractional abundance of uranium-235 (or uranium-238), that is, the number of atoms of uranium in the interstellar medium per atom of the interstellar medium, N satisfies the differential equation:

$$\frac{dN}{dt} + \gamma N = S(t) \qquad (1)$$

Here γ is the decay constant ($\gamma_{235} = 0{\cdot}97 \times 10^{-9}$ years^{-1}; $\gamma_{238} = 1{\cdot}54 \times 10^{-10}$ years^{-1}), and S is the fractional production-rate of the isotope ($S_{235}/S_{238} = 1{\cdot}64$)[3].

Possible production distribution curves are plotted in Fig. 1 against time expressed in units of the present age of the Galaxy (T). Curve (1) is determined by the requirement that the heavy elements be generated prior to the time of formation of *NGC* 188 ($t = 0{\cdot}4T$).

This relative time of formation of *NGC* 188 and the other clusters plotted in Fig. 1 is based on the stellar evolution time-scale which is here being questioned. There is considerable uncertainty about the linearity of the stellar evolutionary time-scale, first because of uncertainties in the evolutionary theory, particularly of Population II stars, secondly because of a possible secular decrease of the gravitational constant, a variation which, if it occurred, would serve to stretch substantially the time-scale for older stars, making an old star appear much older than it actually is[4–7].

If Salpeter's model[8] of stellar evolution is used, stars being produced at a rate proportional to the amount of gas present in the interstellar medium, it is found that the duration of the halo-forming period is about $0{\cdot}2T$. There is an indication from the very large velocity dispersion in the halo population that even this short period is too long. It is generally agreed that these stellar velocities are fossil remains of the initial high turbulence velocities in the primordial gas of the Galaxy, the stars continuing to move with the original velocities of the gas out of which they were formed. The relaxation-time for this early turbulence to die out was probably less than 2 × 10^8 years (ref. 9). If the turbulence was maintained for a longer period by radiation from massive stars in the initial population, the duration would be limited by the life-time of these stars to less than 10^9 years. These possibilities are mirrored in curve No. 2 of Fig. 1.

If, as is suggested by Arp's data, the heavy elements were not produced completely by the early Population II stars, but are still being produced to some small extent, it would be reasonable to assume, for the fractional production-rate, the function plotted as curve No. 3 in Fig. 1. This curve represents 60 per cent production associated with the function S_2 (curve No. 2), and 40 per cent distributed uniformly from 0 to T. Consistent with Arp's data, this production distribution curve would give an excess of heavy elements in young clusters of roughly 30 per cent. The constant value of the fractional production-rate, after the halo formation period, is consistent with Salpeter's model of galactic evolution. Fowler and Hoyle[2] assumed that Salpeter's model implied that an exponential function should be used for the production-rate. While this is true of the total production-rate, the fractional production-rate is approximately constant with Salpeter's model.

The solution to equation (1) giving $N(T–4{\cdot}7)$, the fractional abundance at the time of formation of the solar system, assumed to be 4·7 × 10^9 years ago, is:

$$N(T-4{\cdot}7) = \int_0^{T-4\cdot7} S(t)\,\exp(t + 4{\cdot}7 - T)\,dt \qquad (2)$$

For curves 1 and 2, it is convenient to take $S(t)$ to be in the form of a Gauss error curve:

$$S(t) \sim \exp\left[-\delta\left(\frac{t}{T}\right)^2\right] \qquad (3)$$

and for curve No. 3 it is:

$$S(t) \sim 0{\cdot}4\,\frac{1}{T} + 0{\cdot}6\,\frac{2}{\sqrt{\pi}}\,\frac{\delta^{1/2}}{T}\,\exp\left[-\delta\left(\frac{t}{T}\right)^2\right] \qquad (4)$$

For the three curves of Fig. 1, Nos. 1, 2 and 3, δ assumes the values 24, 72 and 72 respectively. The ratio of the two values of N for N_{235} and N_{238} at the time of formation of the solar system, computed from the present observed ratio of 0·0072, is:

$$\frac{N_{235}(T-4{\cdot}7)}{N_{238}(T-4{\cdot}7)} = 0{\cdot}34 \qquad (5)$$

Table 1. Age of Galaxy from Uranium Decay for the Three Assumed Fractional Production-Rates plotted in Fig. 1

Curve from Fig. 1	Assumed production ratio $^{235}U/^{238}U$ 1·0	1·65	2·0
No. 1	7·1 × 10^9 yr.	7·7 × 10^9 yr.	8 0 × 10^9 yr.
No. 2	6·6 × 10^9 yr.	7·2 × 10^9 yr.	7·50 × 10^9 yr.
No. 3	—	7·4 × 10^9 yr.	—

Equations (2) and (3) or (4) are substituted in equation (5) which is solved for T to determine the present age of the Galaxy. The various results for curves No. 1, 2 and 3, and for the 3 assumed values of the production ratio, are given in Table 1.

Fowler and Hoyle's[2] determination of 15 × 10^9 years for the age of the Galaxy is based on the decay of thorium-232 as well as uranium-235 and uranium-238. Because of the long mean life of thorium-232 (20·1 × 10^9 years), an age determination based on this element is quite sensitive to the assumed production ratio thorium-232/uranium-238 = 1·65 (ref. 3) and to the present abundance ratio, which, because of the difference in chemistry, cannot be determined with precision. Fowler and Hoyle take this ratio to be 3·8 ± 0·3.

Instead of using the thorium-232/uranium-238 ratio to help determine the age, the procedure can be reversed and the above determined ages can be used to calculate a production ratio. With an assumed age of the Galaxy of 7·2 × 10^9 years and a production-rate given by curve No. 2, the assumed present ratio thorium-232/uranium-238 of 3·8 ± 0·3 implies a production ratio thorium-232/uranium-238 of 1·9 ± 0·2. This to be compared with a value calculated from the theory of nucleosynthesis[3] of 1·65 ± 0·15. The agreement is good.

It should be noted that an age of the Galaxy of 7·2 × 10^9 years is perfectly consistent with an evolutionary universe with a Hubble age of 12 × 10^9 years. If, as has been suggested, the universe is closed, but with a large radius, its evolutionary age would be but slightly less than $\frac{2}{3} \times 12 \times 10^9 = 8 \times 10^9$ years (assuming zero for the cosmological constant). This is an encouraging result and indicates that finally the Hubble age of the universe may be settling down to something like its final value.

The difference between the age of 7·4 ± 0·5 × 10^9 years determined here, and the age of approximately 15 × 10^9 years determined earlier by Fowler and Hoyle may be traced to two factors, the different use made of the thorium data and a different assumption about the form of the production curve. These ages also disagree with the present stellar evolution age of 26 × 10^9 years (ref. 10). A possible reason for this was discussed[7] previously.

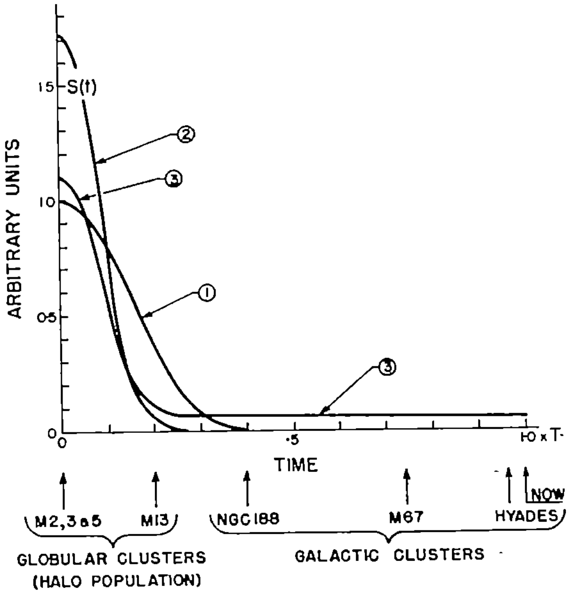

Fig. 1. Uranium production-rate (arbitrary units). T represents the present age of the Galaxy

THE DESERT LOCUST AND TROPICAL CONVERGENCE

By H. J. SAYER

Desert Locust Survey, East Africa High Commission, Nairobi

THE extended use of aircraft against swarms of the desert locust (*Schistocerca gregaria* Forsk.) in eastern Africa during the past decade has provided further evidence that flying swarms of locusts are displaced downwind[1–3], and the net effect of such downwind movement will, in general, bring locusts into zones of wind convergence, which are areas where there is an excess inward flow of air on the horizontal plane, the excess being accounted for, by vertical air currents. In the tropical zone infested by the desert locust there are several regularly identifiable semi-permanent convergence zones often characterized by asymptotic streamlines having easily recognized annual cycles which probably dominate and certainly largely affect the annual movement and breeding of the locust. Locust movement on the inter-continental scale has been extensively studied for many years and is relatively well known[4]; but recently it has been possible to make detailed observations, hour by hour and day by day, on the complex system of swarms and storms which often occurs at a zone of convergence. Of the several regularly occurring tropical convergence zones, the most significant as regards the desert locust is that which is called the 'intertropical convergence zone' or the 'intertropical front', the meeting

Fig. 1. Plots of trajectories of two large swarms across Somaliland during September 25–October 4, 1953. The front at this time and place is beginning to move southwards and therefore the swarms spend longer in the frontal system, while night-roost sites are located successively farther south

place around the tropical belt between the trade winds or monsoons of the northern and southern hemispheres[5]. On most synoptic meteorological charts prepared in tropical Africa, the intertropical convergence zone is identified as lying between stations having large differences in wind direction, and sometimes, though not always, differences in other physical properties of the air-streams, such as temperature and dew-point. Because of the low density of meteorological stations over most of this tropical belt, the exact position of the intertropical convergence zone is often doubtful.

There are three distinct and superimposed movements of the intertropical convergence zone differing in both amplitude and duration. The largest movement is an annual north–south movement following the Sun with the usual month or so of lag common to all Sun-generated weather cycles. This thermally controlled movement is greatest over the continent, especially the deserts, and least over the sea, and can have a range over land of 40° of latitude[6]. The smallest oscillation is a daily movement involving southward movement during the earlier part of the day with a reversal in the late afternoon, and has an amplitude of the order of a few tens of miles. Lastly, there is an intermediate scale of movement which can have an amplitude of the order of one hundred miles or more around a mean position, and which lasts several days.

Detailed observations on the effect of the two latter small-scale movements were first made in Somaliland from September until October 1953 (ref. 5) during the first air control operations in that area, and the map (Fig. 1) shows the trajectories of two swarms followed during that period. It can be seen that swarms moved daily on a zig-zag course, north-east–south-west, making a small net displacement eastwards each day. Wind observations made at that time show that over Hargeisa, a south-westerly was established in the morning followed by a period of doldrums at 13.00–14.00 hr., with a reversal to north–north-easterly during the remainder of the afternoon. The swarms moved away from their night-roost site at about 09.00 hr., progressing north-easterly, reversing their tracks in early afternoon to south-south-westerly and maintaining this course most of the afternoon, followed sometimes by a reversal near sunset, to the night-roost site.

A large-scale infestation of locusts in the same area during the period June–August, 1960, presented an opportunity to make further detailed observations on these complex locust and weather situations characteristic of this area and time of year, and previously described as a chaotic jumble of swarms and storms. Two or three of the many observations made at that time serve to illustrate the most important phenomena which were repeatedly seen in this area during the period.

The east–west elongation of swarms in the late afternoon was demonstrated by a swarm stretching along the Somali coast (on June 14) for 40 miles from Berbera westwards, found in the middle of the afternoon, the coast here being roughly east–west, and on June 28 by another swarm measuring 30 miles east–west and 2–3 miles north–south found to the north-west of the operational base at Borama in the late afternoon. The latter swarm appeared, when viewed along the east–west axis, as a dense black streak sloping upwards for several thousand feet from the ground, with its top towards the south. During traverses made by the reconnaissance aircraft along the 2–3 mile north–south axis of the swarm (the extent of which was recognized by locusts impacting on the aircraft and not by flying over them), a rate of ascent of several hundred feet per minute with a maximum of more than one thousand feet per minute for a short distance near the centre, was recorded on the aircraft instruments. From these and other observations made during the period it became obvious that the towering, sloping masses of flying locusts were situated in a wind discontinuity. Smoke generators dropped from an aircraft showed opposing winds at less than 10 miles apart, and incidental observations made while travelling on a north–south road, suggested a transition even more abrupt than this.

At the intertropical convergence zone in the Sudan, E. Kruger (unpublished results) has similarly recorded opposing winds at stations less than 13 miles apart. From several such air traverses, together with pilot balloon data, made at the base at Borama and at Bawn (about 20 miles north of Borama) and orientated photographs of the locusts it was possible to construct the schematic north–south cross-section shown in Fig. 2, which is believed to be representative of the discontinuity as most frequently found near Borama during June–August. The wind from the south side was almost consistently from 220° to 230°, the south-east monsoon having crossed the equator by some 10° of latitude into the northern hemisphere, and therefore having been deflected by the Coriolis force to a south-wester. The wind from the north side appeared to be more variable between north and north-east, possibly due to the influence of the nearby Ethiopian highlands. Near the ground, a strong upward velocity appeared to be reached at a relatively narrow 'neck'; but at higher levels a more extensive but generally weaker ascent was recorded, probably due to turbulent mixing and entrainment of air from the north and south surfaces. At ground-level there was an area of doldrums, with occasional light puffs of wind from no constant direction. The slope of the discontinuity in this area, indicated by swarm photographs, was about 35° with the top towards the equator, at least to the highest levels recorded (about 5,000 ft. a.g.l.). This slope would seem to be due to the northern air mass, which is of mainly continental origin, being slightly higher in temperature (3° C.) and probably less dense than the air mass from the south, which, on its south-easterly course south of the equator, has come over the Indian Ocean during the latter part of this track.

In its diurnal movement the discontinuity, starting from its most northerly position in the early hours, progresses southward during the day to its southern limit and intensifies until late afternoon, after which there is a weakening and often a reversal of movement at sundown. This daily cycle, it will be shown, together with local topography and the associated change of temperature with altitude, determines the daily changing distribution of the associated adult locust populations. As was first shown in the 1953 observations, any swarms on their night-roost site which are in the south-westerly wind in the morning will depart in a north-easterly direction. The south-westerly wind is strong, 15 or more knots, and the drifting of the locusts away from the roost site for a period of an hour or more results in a low-flying, low-density swarm elongated north-east–south-west. At some time during the early afternoon the northward-moving locusts meet the southward-moving intertropical convergence zone and a striking difference is immediately seen in the swarm appearance. A towering dense mass of flying locusts rapidly rises upwards until a more or less stable appearance is established.

When viewed from either the north or south it appears as a sheet of flying locusts with very dense striations, rising sometimes to several thousand feet above the ground, topped by an undulating, dense mass. Viewed along the east–west axis, the flying locusts appear as a dense black streak sloping upwards with the top nearest to the equator and often with a broad, dense, umbrella-like top (Fig. 3). The density of flying locusts in the front (as determined from photographic records[8]) can be more than a hundred times that of the locusts on the approach to the front. It is suggested that this very obvious change in the appearance of the swarm in the intertropical convergence zone, compared with the pattern outside it, can be interpreted in terms of the structure of the front as indicated in the cross-section shown in Fig. 2. The inflowing air from both north and south has velocities often comparable with or greater than the flying speed of the locust (3·8–4·5 m./sec. (ref. 9)) and even if all the flying locusts were orientated either north or south they would be unable to make any progress away from the front. By analogy with observations on orientation in swarms elsewhere, it is more likely that flying locusts are effectively randomly orientated[10], the front acting as a concentrator on the north–south axis but not restricting movement along the front, that is, along the east–west axis.

The dense undulating appearance of the top of the locusts can most likely be explained as an effect of a combination of the decrease in temperature with height (found to be at the dry adiabatic lapse rate) and the widening and slowing down of the vertical air stream. Since the body temperature of the locusts is very close to that of the air in which they are flying, they will, correspondingly, cool with height. An altitude will be reached at which the locusts' body temperature will be less than the temperature at

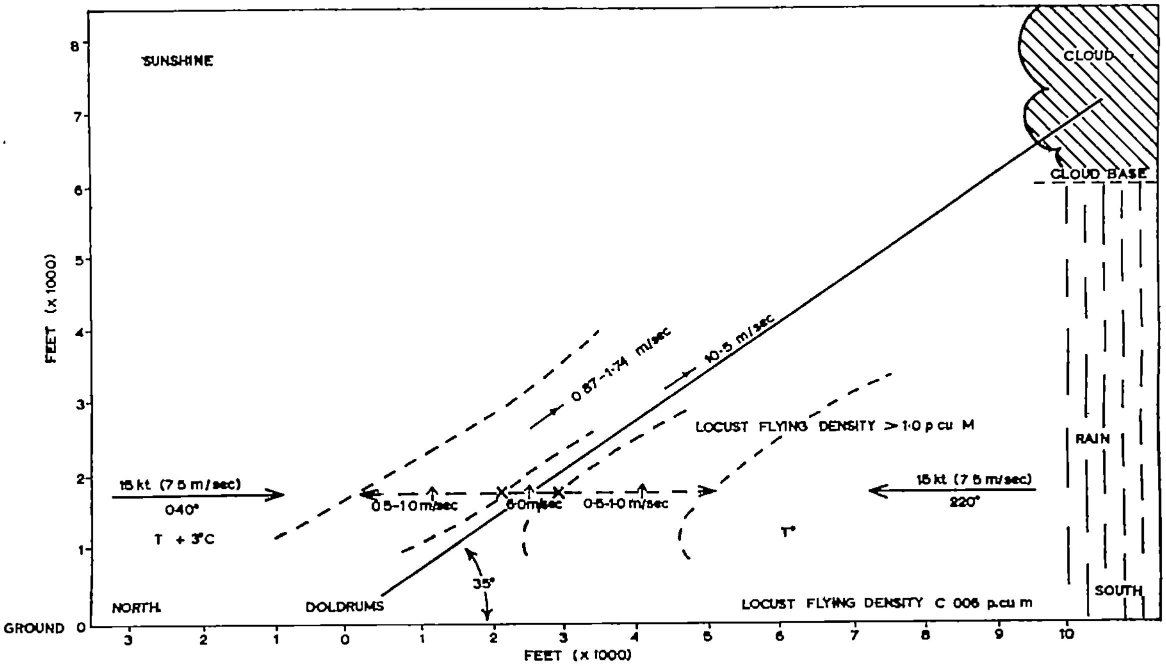

Fig. 2. Typical north–south cross-section of the inter-tropical front as found around Borama, Somali Republic, during June–August, 1960

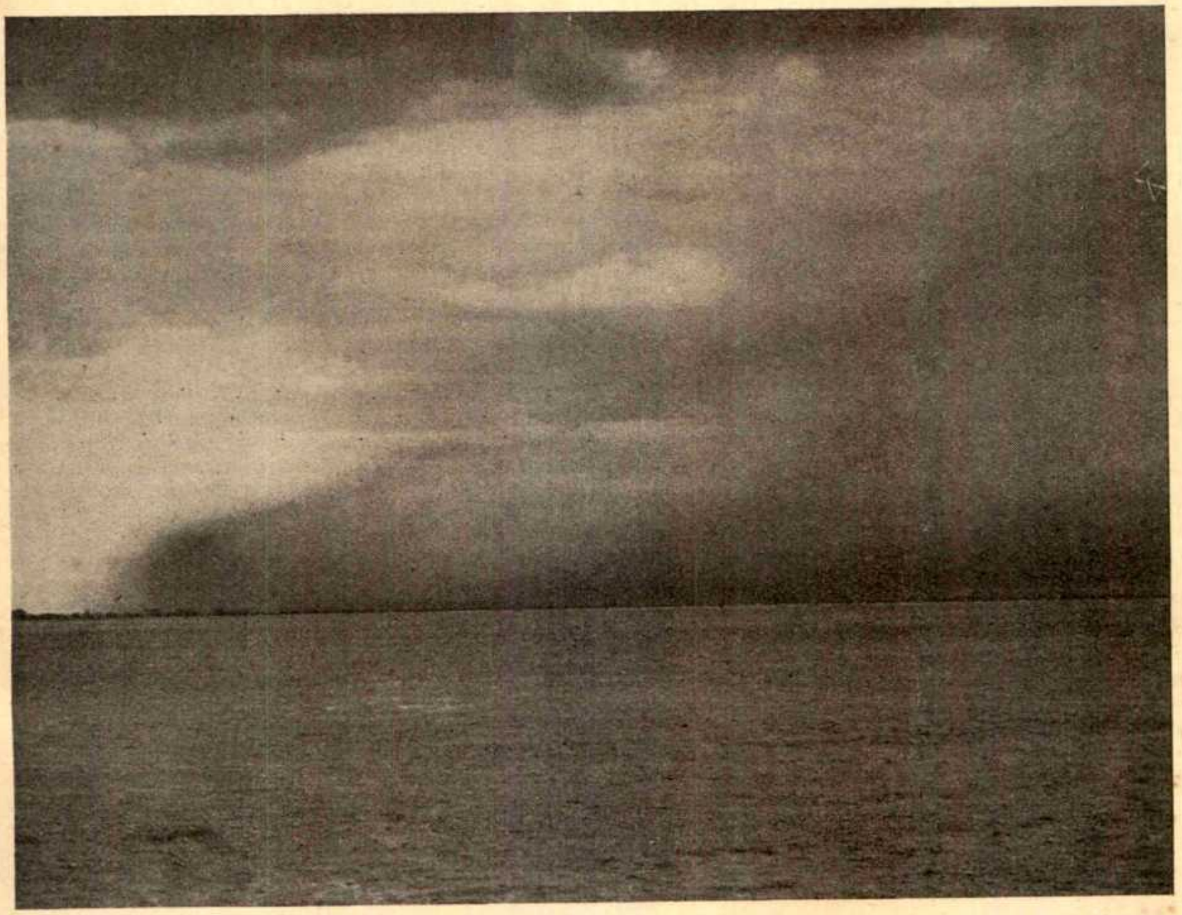

Fig. 3. Large swarm showing typical association with convergence. The camera is pointing approximately towards the north-east from Hargeisa airport (Northern Region, Somali Republic, August 3, 1960). The photograph was taken in the late afternoon and the density of the swarm when it passed over the airfield was such as to prevent aircraft taking off. Photograph by A. J. Wood, Desert Locust Survey

which flapping flight can take place; and there is every reason to believe that, at this altitude, the locusts stop flapping flight and adopt a gliding posture. The gliding locusts will tend to concentrate at an altitude at which a balance is reached between the rate of gliding descent and the rate of air ascent. The highest point of balance will be where the up-draught is greatest near the centre and, thus, the curved umbrella-shaped streaks at the top of the swarm would indicate the decreasing velocity gradient, due to the turbulent mixing and entrainment of more air from the surfaces inwards. Those gliding locusts which, in their various random courses, reach the south face of the discontinuity, will drop down into the south-westerly wind, either to be brought back into the system at a lower level or to reach the ground. Those reaching the edge on the northern face will drop down into the up-draught again. Thus, the northern surface will tend to be more sharply defined than the southern, the system, by virtue of the slope, showering gliding locusts towards the ground on the southern side.

Wind convergence, therefore, together possibly with the adiabatic lapse rate, acts as a concentrator of flying locusts which contrasts with the state existing during the post-frontal movement of swarms, wherein the wind, by virtue of turbulence, both convective and flow, is operating as a disperser of locusts; and wherein the only cohesive factor is the gregariousness of the locusts which are counteracting the wind dispersion and maintaining the identity of the swarm. In frontal flight, gregariousness and meteorological conditions can thus act together to concentrate the locusts, producing some of the highest flying densities ever to be recorded. Thus very high flying densities, averaging about 1 locust per m.^{3}, were recorded photographically in a swarm near Asmara in August 1960, which was seen to exhibit rapid ascent between opposing winds separated by no more than 3 km. Along the length of the front, the third dimension, there is no constraint on the locusts' movement except gregariousness, and, in time, swarms extend along the front, often coalescing with other swarms so that by the end of the day there may be an almost continuous line of flying locusts, two or three miles north–south and tens of miles east–west, as was repeatedly seen to occur.

The winds on each side of the discontinuity near Borama were almost diametrically opposed, and the diurnal movement of the front would be expected, therefore, to produce a negligible net daily displacement of swarms. However, there was always a net movement eastwards from Borama, as can be seen in the 1953 swarm trajectories (Fig. 1).

Elsewhere, such as near Dessie and Asmara to the north-west in neighbouring Ethiopia, a northward displacement of swarms has been observed along the northward inflexion of the front. Two possible

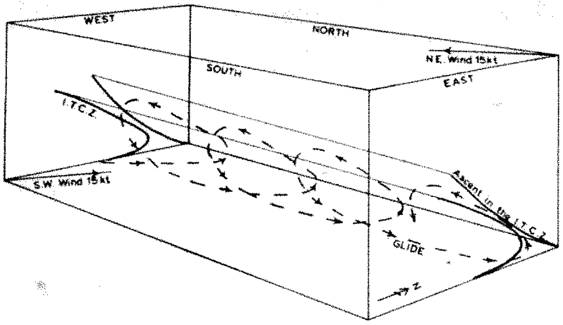

Fig. 4. Suggested average frontal track of locusts. The approach path is along the south-west wind which is followed by a rapid ascent in the updraught at the interface. Release from the convergence occurs by gliding down into the south-westerly wind resulting in a net easterly gain after the return to the front

explanations of this lateral frontal displacement are suggested. All the pilot balloon ascents through the front made at Borama showed that the air in the front was moving eastwards, the wind veering through north-west at the interface. The frontal air, therefore, besides having a vertical motion, was also moving eastwards. The second explanation is that the slope of the front causes locusts to be showered into the south-wester underneath, thus continuously adding an easterly movement to the body of the locusts from the steadily returning locusts in the south-wester (Fig. 4). This suggests that it is the wind beneath the front, the southern side, which largely determines the frontal displacement, the wind from the northern side having a negligible influence in this respect. The two effects may operate together as during these observations at Borama, or sometimes may oppose each other. As a general rule, it appears that locusts in the front are displaced along the front in the direction opposite to that from which the southern hemisphere wind approaches the front. There appears to be a point at or about the inflexion of the intertropical convergence zone near Diredawa, where swarms can arrive at the front within a few miles of each other and yet move along it in opposite directions to become hundreds of miles apart in a week or so. At this point of dispersion or instability, swarms have a small net daily displacement, but farther away along the front, the net daily displacement appears to increase. From these and other observations of locust movements at the front it is reasonable to assume that along the intertropical convergence zone across Africa there are several points of dispersion such as that found near Diredawa, which are also interspersed with points of accumulation (or stability).

The effect of the intermediate order of movement of the intertropical convergence zone, the surge about a mean position lasting several days, superimposed on the daily cycle, complicates considerably the relatively simple picture of the daily swarm movement given above. During the northward movement, the intertropical convergence zone, in this area and season, generally appears sharp and well defined, the cloud-line formed by the middle of the afternoon being fairly narrow and clear, whereas during the southward surge, it is usually associated with a much wider belt of bad weather, the front appearing extremely broken and ragged. A rapid northward movement of the front means that the locusts will have farther to go from the night-roost site, which is generally to the south, in the south-westerly wind to the front, and, consequently, will arrive in the front much later in the afternoon. The time of arrival at the front will also be influenced by the time of departure from the roost site and the wind speed, which are both affected by temperature and, therefore, by the altitude of the ground above sea-level and its distance from the coast. The build-up of clouds at the front was usually seen to start at about mid-day, and by the middle of the afternoon rainstorms were beginning to appear, the rain being a few miles south of the ground-level meeting point of the winds owing to the slope of the discontinuity.

Locusts approaching the front in the late afternoon will, therefore, often have to pass through a belt of rain-storms, which may not necessarily be continuous. Swarms become disintegrated by this storm belt, some locusts ceasing or reducing flying because of the rain, while others may have a rain-free path to the front and be carried many miles away from the locusts affected by the rain. Under such conditions, large swarms become disintegrated and break up into several small swarms connected by a thin, scattered population. Thus, over a period, the front can act at one time as a concentrator, producing a massive, dense swarm containing all the locusts in the area, and at another as a disintegrator producing many small swarms tenuously connected by a thin population. In contrast to post-frontal flight, where individual swarms maintain their identity by means of gregariousness, locusts at the front can only be considered as part of a general population, individuals being successively concentrated and dispersed, and being constantly redistributed by the frontal meteorological conditions.

The results of the effect of convergence can be exploited for aerial control operations, both from the point of view of the daily tactics and from the overall strategy. The indications that by the late afternoon flying locusts may be held balanced at high density in the wind discontinuity suggests that a cloud of insecticide spray droplets of suitable size and therefore terminal velocity, would be held similarly, spraying being envisaged as taking place from the same point of supply as the locusts, that is, underneath. The spray would be dispersed only along the front, and, provided that a suitable non-volatile formulation were used[1,2], thus ensuring efficacy over a long period, the frontal balancing and concentrating conditions affecting both locusts and spray would give a considerably increased chance for spray collection by the locusts, compared with previous post-frontal air-to-air spraying experience.

Aerial reconnaissance for swarms in the past has been based on a knowledge of the post-frontal movement of swarms in an established air-stream, and has been designed to search, usually on a triangular or rectangular course, the air-stream approaching the operational base. Frontal reconnaissance, however, can be designed to search more or less linearly along the front (easily identified by a cloud line at the commonly adopted reconnaissance period, early afternoon). Such linearly directed flights could considerably increase the range and effectiveness of reconnaissance, besides eliminating pointless search in areas where swarms are unlikely to be found. Table 1 shows the approximate time-periods of the various stages of the desert locust life-cycle, together with their displacement rate and, in the case of adults, their flying density. It will be seen that the longest period for the whole cycle is that in which the adult locusts are associated with frontal convergence, and

Table 1. APPROXIMATE PERIODS OF THE LIFE-CYCLE OF THE DESERT LOCUST

	Period (months)	Rate of movement (miles per day)	Representative flying density (locusts per m.^{3})
Egg	0·5–1·5	nil	
Nymph	1·0–2·0	0–1·0	
Total adult	0·5–4·0		
(*a*) Under post-frontal conditions	0·5–1·0	20–100	0·01
(*b*) Under frontal conditions	1·0–3·0	0–20	1·0

this is also the displacement period for adults which gives rise to regularly occurring high-density flight. The efficiency of killing locusts, measured in terms of locusts killed per gallon of insecticide, by air-to-air spraying (which can be the most consistently efficient of all locust control methods) has been shown to be almost linearly proportional to the locust flying density[1], and thus the conditions which can occur in the late afternoon when locusts fly densely in the intertropical convergence zone are, if they can be exploited, of very great importance. The small net daily displacement at the front means that aerial operations can take place against the same locusts from the same air-base for a period of several days, in contrast to post-frontal operations, wherein, in order to apply in the shortest possible time the quantity of insecticide which would be required to control large and therefore economically potentially dangerous swarms, it would often be necessary to move the operational air-base almost daily—an onerous and costly task.

The movement of locusts latitudinally along the front from areas of dispersion to areas of accumulation suggests that these are worth identifying and assessing for control operations, since both may be areas of slow swarm displacement. The convergence zone across Africa, acting as a major concentrator of locusts, appears to produce transient longitudinal inflexions during its annual cycle, associated usually with significant geographical features such as large mountain masses. These frontal inflexions appear to have a retarded movement as compared with the normal annual cycle of movement over relatively flat desert or bush and may therefore be of strategic control value. The greatest surging and the greatest fluctuation around the mean position can be expected where the annual cycle has the largest range and where the geographical background is most homogeneous. On the other hand, preferred positions for the front may be provided where orographic features in themselves tend to produce a front. Thus, in northern Somaliland the coast-line runs roughly east–west with a range of mountains running parallel to the coast a few miles inland, both tending to give rise to a convergence zone a few miles inland in the late afternoon due to the sea-breeze effect and an anabatic wind Such fixed orographic zones of convergence can trap and reinforce the intertropical convergence zone for periods greater than normal, giving rise subsequently to a higher rate of movement across the plains. The two periods of the intertropical convergence zone's annual cycle during which it is relatively static are at the solstices, when the Sun's latitudinal movement is slow, and these two seasons (June, July, August and December, January, February) may be expected to be the most important from the point of view of adult control. Places where the intertropical convergence zone becomes virtually stationary for periods of two or three months are major accumulator points for locusts, and are reflected as maxima in swarm frequency maps.

The swarm movement latitudinally along the front will, over a period, tend to bring locusts to the eastern and western seaboards. Further slow frontal displacement out over the sea would result in exceeding the flight endurance of the locusts with subsequent drowning. Although from time to time large numbers of locusts have been recorded as drowned, the general pattern of coastal movement is the survival of a significant proportion of the arriving locusts. This low overall loss at the seaboards is apparently due to the sea-breeze effect which is strongest in the afternoon at the same time as the locusts are usually flying most actively. The sea breeze at this time of the day regularly produces convergence zones along the coast of Africa which not only tend to stop further seaward movement of the locusts but can also move them along the coastal belt[11] in a way similar to the movement along the intertropical convergence zone. Owing to the differences of surface heating and radiation over the land and sea and consequent differences of latitudinal displacement of the intertropical convergence zone, it is often deflected along the coast, reinforcing the sea-breeze effect at these places. The limits of the area which the desert locust regularly infests do not coincide with the limits of the intertropical convergence zone for the northern solstitial position although very good agreement is shown by the southern limit of the intertropical convergence zone and the known locust distribution. At the same time, the distribution area and the intertropical convergence zone limits are not evenly placed in relation to the equator, both being displaced towards the northern hemisphere. This northern bias is explained by the greater amount of ocean and the lower temperatures over Antarctica giving rise to stronger winds in the southern hemisphere, which penetrate across the equator into the northern hemisphere[12]. Over most of Africa, the southern limit of the intertropical convergence zone is mainly north of the equator except for a deep inflexion over eastern Africa, and the northern limit is generally over 15° north. This suggests that the desert locust has more chance of being involved in subtropical weather in the northern hemisphere than in the south, as may be found reflected in the distribution maps.

Lastly, it is of interest to consider the annual cycle of movement of the intertropical convergence zone and its possible effect on breeding. The solstitial movement of the convergence zone over Somaliland keeps the locusts in front of the rain-belt and therefore over relatively dry terrain. The southerly movement of the front, which occurs in October, November and December, brings the locusts over an area which normally has had recent heavy rain. Since the desert locust requires moisture for successful hatching of its eggs, and it is thought that moist conditions encourage maturation, the southward movement of the front might be expected to be the most conducive to successful breeding. It is perhaps significant that during this period of the year, in the Somali peninsula which has long been recognized as a major high-frequency breeding area, breeding recorded during the southerly movement of the front is often more extensive than during the northerly movement.

I thank Mr. P. R. Stephenson and Mr. R. J. V. Joyce, director and deputy director of the Desert Locust Survey, Nairobi, for making this work possible, and for their helpful encouragement, and also Drs. T. H. C. Taylor, P. T. Haskell and R. C.

NEWS and VIEWS

French Academy of Sciences

Mlle. M. Perey has been elected the first woman corresponding member of the French Academy of Sciences. She succeeds the late Emile Henriot. L'Institut du Radium writes, through Prof. A. Haddow: "L'élection de Mademoiselle Marguerite Perey à l'Académie des Sciences de France est venue récemment couronner sa brillante carrière de radiochimiste. Entrée en 1929 au Laboratoire de Madame Curie, Mademoiselle Perey s'était spécialisée dans la chimie des éléments de la famille de l'Actinium. La qualité remarquable de ses travaux avait permis de mener à bien de nombreuses recherches physiques qui nécessitaient l'emploi de sources radioactives très soigneusement préparées. L'aboutissement de ces travaux a été, en 1939, la découverte par Mademoiselle Perey d'un radio-élément nouveau, le Francium (Actinium K,Z = 87, période 21 minutes). Au cours des années suivantes Mademoiselle Perey s'est attachée à l'étude de la préparation et des propriétés physiques et chimiques du Francium. Ces travaux ont fait l'object de sa thèse de Doctorat soutenue en 1946.

"Nommée en 1946 Maître de Recherches au Centre National de la Recherche Scientifique, puis, en 1949, Professeur à la Faculté des Sciences de Strasbourg, Mademoiselle Perey devait, en 1951, faire une autre découverte importante, celle des propriétés biologiques du Francium, et leur application à des problèmes de cancérologie. Le Francium est, en effet, un alcalin (homologue supérieur du Césium) et malgré la courte période de cet élément, Mademoiselle Perey a pu étudier sa répartition dans les tissus biologiques et constater sur des rats porteurs de sarcomes qu'il se fixe 2 à 4 fois plus vite dans les tissus cancéreux que dans les tissus sains. Mademoiselle Perey a ainsi trouvé un moyen nouveau pour établir le diagnostic précoce du cancer, et plusieurs de ses travaux récents sont relatifs aux propriétés biologiques des radioéléments alcalins. Lauréate de l'Académie des Sciences, Mademoiselle Perey a reçu en 1961 le Grand Prix Scientifique de la Ville de Paris. Malheureusement sa carrière a commencé à une époque où les dangers des radiations étaient mal connus, et malgré le soin avec lequel elle travaillait, elle n'a pas échappé aux atteintes du rayonnement, et elle en subit actuellement les douloureuses conséquences. Nous souhaitons vivement qu'elle en soit rapidement guérie".

Pharmacology at Cambridge :
Prof. E. B. Verney, F.R.S.

Prof. E. B. Verney has retired from the Sheild chair of pharmacology in the University of Cambridge. He went to Cambridge in 1934 from the chair of pharmacology at University College, London. A pupil of E. H. Starling, his early work was on the isolated perfused kidney. This led to his classical studies (with F. R. Winton, Mary Pickford, G. W. Theobald, Marthe Vogt, W. J. O'Connor and P. A. Jewell) on the nervous, hormonal and vascular factors controlling urinary excretion and water diuresis, to the demonstration that the secretion of antidiuretic hormone depends on the osmotic pressure of the blood, and to the identification of the osmoreceptors in the neurohypophysis. He also worked on the reflex regulation of the heart-rate, and on central nervous control of ovulation.

Prof. A. S. V. Burgen

Prof. A. S. V. Burgen, professor in the Department of Physiology, McGill University, Montreal, has been appointed to succeed Prof. Verney. After qualifying in 1945, he had been in Prof. C. A. Keele's Department of Pharmacology at the Middlesex Hospital Medical School, and then joined Prof. F. C. MacIntosh at McGill in 1949. His first major work was on the general pharmacology and kinetics of the anticholinesterases hexaethyl tetraphosphate and tetraethyl pyrophosphate, which led to work on the distribution of cholinesterase in the brain and on factors governing uptake of inhibitors into the brain. With F. Dickens and L. J. Zatman, he has made the only direct demonstration of the mode of action of botulinum toxin. In Montreal he showed, with microelectrode techniques, the characteristic action of the cardiac vagal transmitter, acetylcholine, on the action potential of the auricle and that it was due to an increase in potassium permeability. He later returned to the physiology and pharmacology of salivary secretion, work which is summarized in a recent Physiological Society monograph with N. Emmelin. Most recently he has worked on the turnover of fluid in pleural exudates, on reactions to autologous and non-autologous human plasma, and on the fate in the body of labelled magnesium and folic acid.

The 1961 Wolfe Award : Dr. Keith Froome

Dr. Keith Froome, of the Standards Division of the National Physical Laboratory, has been awarded the £500 Wolfe Award for 1961 for two major advances in the field of accurate measurement. This award is the fourth of ten to be made annually, under the terms of the Wolfe bequest, to the research worker in the Department of Scientific and Industrial Research who makes an outstanding contribution to the Department's research during the previous twelve months. One of Dr. Froome's achievements during 1961 was the invention of the 'Mekometer', an instrument using a beam of light to measure distances from a few yards to several hundred with great accuracy (1/100 cm.). He was also responsible for the production of continuous radio-type (or radar-type) electromagnetic waves of extremely short wave-lengths from the "cathode spot" of an electric arc discharge. Using a new arc microwave harmonic generator, wave-lengths as small as 0·4 mm. have been generated, corresponding to a frequency of 700,000 Mc./s. These short waves will be used to measure the velocity of electromagnetic waves to the full accuracy of the new light-wave definition of length, but they have considerable application to wider fields than this, including the investigation of atomic arrangements of crystals, and the study of powerful electric discharge plasmas needed for controlled nuclear fusion. Dr. Froome was educated at Windsor County School and took his first degree in physics in 1941 at University College, London. After the War he spent four years at the Imperial College of Science and Technology, first as Beit Postgraduate Fellow and then as 1851 Senior Fellow, working on the cathode emission process in transient arc discharges. In 1949 he joined the National Physical Laboratory and was assigned to his present work in microwave radiation. He was promoted to principal scientific officer in 1953 and to senior principal scientific officer on special merit four years later.

Fleming Memorial Fund for Medical Research

VISCOUNT TENBY, chairman of the Fleming Memorial Fund for Medical Research since its inception, has been appointed president in succession to the late Lord Birkett. Viscount Caldecote, at present vice-chairman of Council, has been appointed chairman of the Council. Lord Bossom, a member of the Executive Committee, has been elected chairman of that Committee.

Since the Fund's British and International Appeal was launched in March 1961, with an initial target of £1 million, more than £455,000 has been given or firmly promised at home and abroad. The Executive Committee has decided to keep the appeal open—from covenants already given, for example, moneys will continue to be received until 1970—and further British fund-raising efforts are already planned during 1962.

A grant of £13,000 has been made to the University of Edinburgh for its Bacteriology Department by the trustees of the Fleming Memorial Fund. The grant will be used to provide specialized staff and equipment for medical research in relation to studies on parasite–host cell interaction and intracellular parasitism. The research aims at more intensive electron microscopic studies of the interaction between parasite and host at cell-level, with the view of learning more about the phenomena of cell penetration and intracellular parasitism. Parallel investigation of host–parasite interaction will be made, using phase-contrast microscopy, fluorescent staining methods and cytochemical techniques. The first two grants made by the trustees of the Fund were £48,000 to the University of Oxford for the Sir William Dunn School of Pathology (in October 1961) and £15,000 to the Christian Medical College at Vellore, South India, for intensified leprosy research (in December 1961).

Staff Scheme between the Universities of Reading and Khartoum

THE University of Reading has entered into an arrangement with the University of Khartoum for the joint recruitment of staff. The scheme is designed to help the University of Khartoum in filling posts, but its distinctive feature is that it gives the member of staff a guarantee of re-employment in the United Kingdom for a period sufficient to enable him to find a permanent appointment. An advertisement of the first three vacancies (in physics, mathematics and French) has recently been issued. The persons appointed will normally be expected to serve for a period of up to five years, the first four of which will be spent on secondment in Khartoum and the last in Reading. While in Khartoum, each person will have the salary, rank and status appropriate to the post which he holds. The cost of the fifth year, in Reading, will be borne by the University of Reading, although it is hoped that some assistance will be forthcoming from other sources. Indeed, for the first appointment this cost will be met by a generous donation made for the purpose to the University of Khartoum by an oil company. The needs of countries overseas for British staff in their universities cannot be too greatly stressed. The Reading–Khartoum scheme is but one example of what can be done, and it is a good sign that the Department of Technical Co-operation, which supports the arrangement, is discussing the much wider application of this and similar ventures which have long been advocated in these pages (*Nature*, 193, 101; 194, 1 (1962), etc.).

The Pasteur Institute of Southern India

THE Association of the Pasteur Institute of Southern India was founded in 1906 to make available effective means of preventing the occurrence of rabies, to spread the knowledge of such means among the public, and to undertake research work on rabies and other diseases. The Institute is situated at Coonoor in the Nilgiri District of the Madras State and, since its inception in 1907, has served the needs of the Madras and other States of South India. In recent years the Institute has expanded its activities considerably. It is internationally recognized for its research work on rabies. It is the main laboratory for work on influenza and other respiratory viruses in India. It is now serving as an important centre for research on intestinal viruses, vaccinia and smallpox. Studies are also in progress on cholera and syphilis. It is co-operating with the Central and State Governments in various public health activities. The Institute is actively collaborating with international organizations like the World Health Organization and research organizations in India like the Indian Council of Medical Research in several of their research programmes. It serves as a training centre in rabies, other virus diseases and general bacteriology for workers sponsored by the World Health Organization, the Central and State Governments and institutions in India. The Institute has long been recognized by universities for training candidates for postgraduate degrees in bacteriology and virology. The enormous numbers of patients who have been treated with vaccine prepared at the Institute and the numerous papers of scientific interest which have been published during the fifty-four years indicate the important part which the Institute has played in medical and health work in India. Details of its activities in 1960 are set out in its annual report (The Pasteur Institute of Southern India, Annual Report of the Director, 1960. Pp. i+122. Coonoor: Pasteur Institute of Southern India, 1961).

National Research Development Corporation

THE National Research Development Corporation was set up under the Development of Inventions Act, 1948, to secure the development in the public interest of inventions resulting from public research which, in the Corporation's judgment, are not being sufficiently exploited, and to hold and dispose of rights in inventions arising from such research. Its aims and activities have only in recent years become known to many scientific and medical workers through publicity in connexion with some of the major projects with which the Corporation has been concerned, such as electronic computers, hovercraft, fuel cells, cephalosporin *C*, interferon, and the common cold vaccine. As a result, there has been an increase in the number of inventions notified to the Corporation in communications from universities, hospitals and other research institutions. The Corporation's policy, while not encouraging academic research to become primarily orientated towards the development of revenue-earning inventions, aims at encouraging the proper steps to be taken in securing patent protection where patentable inventions are a by-product of research and are of public interest and where they are in the interest of the inventors and their employers. The Corporation already maintains liaison with research workers in a great many of the faculties of universities and with teaching hospitals and other research institutions, but nowadays patentable inventions, particularly in the instrument field, are liable to originate unexpectedly in disciplines such as phonetics, orthopædics, microbiology and psychiatry. In certain instances the Corporation finances development work on an invention which shows promise. The Corporation has made it known that it would be glad to hear of any device or process which could have a commercial application. It warns, however, that it is necessary to take patent action before the relevant work is published in a scientific journal. Further information can be obtained from the managing director, J. C. Duckworth, National Research Development Corporation, 1 Tilney Street, London, W.1.

Security Procedures in British Public Services

IN the House of Commons on April 5, the Prime Minister, Mr. H. Macmillan, announced that the Government accepted the recommendations of the Radcliffe Committee on Security Procedures in the Public Services, and was putting them into effect as rapidly as possible. The report disclosed no radical defect in existing security procedures, but contained valuable proposals for their improvement and intensification. The report was based on a comprehensive and searching scrutiny of British security procedures, but also demonstrated the unique difficulty of maintaining absolutely effective security in a free society. He had discussed the report with the Leader of the Opposition and some of his colleagues, who concurred in the Government's decision that the White Paper published that day contained as much of the report as could safely be published. The Government believed that publication would help to promote the wider public understanding of the importance and the difficulty of the problem of security. Mr. Macmillan gave a full assurance that the method of implementing the recommendations would be discussed with the staff side of the Civil Service National Whitley Council. A similar statement was made simultaneously in the House of Lords by the Lord President of the Council.

Underground Transmission of Electricity in Britain

IN reply to a question in the House of Lords on April 3, Lord Mills said that research into the underground transmission of electricity was the responsibility of the Electricity Council and the Boards, in consultation with the Minister of Power and the Secretary of State for Scotland. Some related research was carried out by the universities and by the Electrical Research Association. The Electricity Council and the Boards were seeking to reduce the cost of transmission underground by using alternative circulating materials and by investigating possible cheaper cables and methods of installation. However, while it was hoped to reduce the wide difference in cost, there was no real prospect that the use of underground cables would ever be as cheap as overhead lines, especially at high voltages. The question of research into this matter was periodically reported on by the Advisory Council on Research of the Minister of Power, and full account was taken of the progress of research in other countries. Even in regard to high-voltage cables, much research was already proceeding.

British Optical Astronomy

IN a written answer in the House of Commons on March 9, the Parliamentary Secretary for Science. Mr. D. Freeth, stated that in its report of 1959–60 the Advisory Council on Scientific Policy had pointed out that British optical astronomy required access to a large telescope of about 120-in. diameter in the southern hemisphere. Various schemes involving international co-operation had been studied, and there had been consultation with other countries. both within and without the Commonwealth, which might be interested in participating in a joint project. Examination of possible schemes was continuing but no decision had yet been reached.

Britain's First Training Reactor for Universities

THE Ministry of Works has let contracts for the construction of an experimental nuclear reactor at East Kilbride in Scotland for a consortium of universities (St. Andrews, Glasgow, Aberdeen and Edinburgh, the Royal College of Science and Technology, Glasgow, and Queen's University, Belfast). The reactor will be made by Advanced Technology Laboratories of California, in association with G. and J. Weir, Ltd., of Glasgow. The laboratory building in which the reactor will be housed was designed by the Ministry of Works and will be erected by J. Crawford, Ltd., of Glasgow. The capital cost of the scheme will be paid for by a grant of £255,000 from the Department of Scientific and Industrial Research to the consortium. The reactor, which will be next to the National Engineering Laboratory, is designed for a continuous power output of up to 100 kW., and will provide the universities with an extremely versatile aid for teaching and training engineers, physicists, chemists and biologists and for research in chemistry, metallurgy, biology, clinical science, etc. It will be the first university research reactor in Britain.

International Commission on Zoological Nomenclature

NOTICE is given of the possible use by the International Commission on Zoological Nomenclature of its plenary powers in connexion with the following cases, full details of which will be found in *Bulletin of Zoological Nomenclature* (19, Part 2; March 23, 1962): (1) Designation of a type-species for *Carcharhinus* Blainville, 1816 (Pisces). *Z.N.*(*S.*) 920. (2) Suppression of W. G. Tilesius von Tilenau, 1814–1818, "Ueber das nächtliche Leuchten des Meerwassers"; validation of several emendations; designation of a type-species for *Metapenaeus* Wood-Mason, 1891; suppression of *Mangalura* Miers, 1878 (Crustacea, Decapoda). *Z.N.*(*S.*) 962. (3) Validation of Xenophoridae Deshayes, 1864 (Gastropoda). *Z.N.*(*S.*) 1483. (4) Designation of a type-species for *Cyrnus* Stephens, 1836 (Insecta, Trichoptera). *Z.N.*(*S.*) 1491. (5) Validation of *Quinqueloculina* d'Orbigny, 1826 (Foraminifera). *Z.N.*(*S.*) 1494. (6) Designation of a type-species for *Lepidopa* Stimpson, 1858 (Crustacea, Decapoda). *Z.N.*(*S.*) 1495. Any zoologist who wishes to comment on any of the above cases should do so in writing to the Secretary, International Commission on Zoological Nomenclature, c/o British Museum (Natural History), Cromwell Road, London, S.W.7.

British Museum (Natural History)

THE ninth edition of *A Short Guide to the Exhibition Galleries of the Natural History Museum* follows the now accepted lines together with a modern format (Pp. vi+34. London: British Museum (Natural History), 1962). Following a short historical introduction, the various parts of the nearly four acres of exhibition space are described in outline. The *Guide* is devised to help the general visitor and should do much to emphasize the highlights of the exhibition galleries to the non-initiated. The illustrations are chosen to assist the same class of individual, who no doubt will find the geological time scale—brought up to date with the now generally accepted ages in millions of years—to be of service in the elucidation of the names of the systems used in the text. The *Guide* concludes with items of general information and notes concerning the library, lectures and the Children's Centre.

The Lundy Field Society

ANNUAL reports of societies are so often dull and formal that it is interesting to receive that of the Lundy Field Society for 1959–60, which includes much in the way of the results of original work (Pp. 82. Barnstable: John C. A. Dyke, Secretary, Lundy Field Society, 8 Rock Avenue, 1962). A long list, with short notes, of the birds recorded during 1959 is followed by a rather shorter list of migrant birds recorded in 1960. Probably the most interesting one is that of the myrtle warbler (*Dendroica coronata*), which is the first for Lundy Island and only the second for Britain. An interesting paper details the known early maps (prior to 1884) of Lundy, and another deals with remains of the Dark Ages on the Island. The mosses, liverworts and lichens are also tabulated. This Society exists to study and further the conservation of the natural features of Lundy Island, and the thirteenth report gives ample proof that its aims and objects are being carried out by the members.

Art in Nigeria

THE journal *Man* for February contains an article by Philip Allison describing a number of carved stones from the Ekoi country in the River Cross area of Eastern Nigeria. Many regularly shaped natural boulders can be found in the district, and a number of them has been carved so as to show a human face and roughly indicate the body. The carvings stop at the navel and genitalia are not shown. Some small curved lozenges and lines may be intended as tribal marks, but the meaning of a number of spirals, squares and triangles, as well as diamond-shaped figures, cannot be determined. Lists of the sites where these objects occur are given. Nigeria has become famous for its works of art, and mention of these carved stones had been made as long ago as 1903, but the account here given and the excellent plate add a further chapter in the study of Nigerian art. As to dating little can be said, Anything in Africa south of the Sahara before the coming of Europeans has to be classed as prehistoric. These carved stones need not be very old in years, but yet must be said to belong to a prehistoric period.

Awards for Cancer Research

THE Alfred P. Sloan Foundation has announced the establishment of the Alfred P. Sloan Cancer Research Awards, which will initially be confined to members of the professional staffs of the Memorial Sloan–Kettering Cancer Center. To qualify for awards, candidates must have made a significant contribution to basic scientific knowledge relating to cancer, or have advanced the treatment of cancer, or have shown unusual promise of future noteworthy accomplishments in this field. Each award will be worth 10,000 dollars, and the recipients will undertake to engage for one academic year in advanced study or in some other affiliation with a university, research institute, or similar establishment dedicated to research relevant to cancer. Further information can be obtained from the Alfred P. Sloan Foundation, 630 Fifth Avenue, New York 20, N.Y.

Harkness Fellowships of the Commonwealth Fund

THE following have been included in the recent appointments to Harkness fellowships of the Commonwealth Fund: J. B. Adams (Trinity, Oxford), business administration; Miss M. A. Boden (Birmingham), social psychology; J. R. Colbourne (King's, Cambridge), engineering; D. S. Glass (St. John's, Cambridge), organic chemistry; A. L. Rice (Liverpool), marine biology; J. H. M. Thornley (Magdalen and New Colleges, Oxford), physics; Miss P. L. Wells (Girton, Cambridge), sociology; M. D. Yudkin (King's, Cambridge), microbiology.

Heinz Scholarship

A POSTGRADUATE scholarship at the National Vegetable Research Station, Wellesbourne, Warwick, has been endowed by the H. J. Heinz Company, Ltd. The purpose of the scholarship is to enable graduate students to pursue further studies and to obtain training in methods of research at the Research Station. Awards will normally be for two years and be of the value of £500 per annum. It is hoped that the first Heinz scholarship will be awarded this year and will run from October 1. The last date for submission of applications is May 31, and they should be sent to the Secretary, National Vegetable Research Station.

Fritz London Award in Low-Temperature Science

NOMINATIONS for the third Fritz London International Award are being solicited from all low-temperature scientists by the Award Committee. Previous awards were made to Prof. N. Kurti, of the Clarendon Laboratory, Oxford, and Academician Lev Davydovich Landau, of the Institute for Physical Problems, Moscow. The Award is made for outstanding research and advances of fundamental significance in the science of low-temperature physics. Particular attention is directed to distinguishing between research advancing low-temperature science as such, in contrast to research merely utilizing low temperatures as a tool or expediency for advancing science in a different area. The Award is international and selections are made without regard to nationality. Further information can be obtained from Dr. J. R. Pellam, chairman, third Fritz London Award Committee, California Institute of Technology, Pasadena, California.

Announcements

SIR FREDERICK BRUNDRETT has been appointed chairman of the Governing Body of the Houghton Poultry Research Station in succession to Mr. T. H. Turney, who has held this office since 1956. Sir Frederick, who has recently retired from his official position as chairman of the Defence Research Policy Committee and Scientific Adviser to the Ministry of Defence, is chairman and governing director of Sunrise Eggs, Ltd., and is also chairman of the Agricultural Central Co-operative Association.

AWARDS of the Meldola Medal for 1961 have been made to Dr. J. N. Murrell (University of Sheffield) for his work in the field of theoretical chemistry, with special reference to the interpretation of the electronic spectra of organic molecules, and to R. O. C. Norman (University of Oxford) for his work in the field of organic chemistry, with especial reference to the application of modern methods of analysis to the elucidation of mechanisms of reaction of aromatic compounds. The award is made by the Royal Institute of Chemistry with the concurrence of the Society of Maccabaeans.

THE first Gregory Medal, established by the trustees of the Bishop Museum, Honolulu, in memory of Herbert E. Gregory, director of the Museum during 1919–36, has been awarded to Prof. A. P. Elkin, emeritus professor of anthropology, University of Sydney. Prof. Elkin is distinguished by his contribution to anthropological research in Australia and Melanesia, and by his active role in the development of institutions supporting Pacific research.

A SYMPOSIUM on "Methods of Separation of Subcellular Structural Components", under the auspices of the Biochemical Society and the Société Belge de Biochimie, will be held in the University of Louvain during May 11–12. Further information can be obtained from Dr. H. R. V. Arnstein, The Biochemical Society, 20 Park Crescent, London, W.1.

A CONGRESS of the South-Eastern Union of Scientific Societies will be held in Horsham, Sussex, during May 25–27. Further information can be obtained from Mr. F. Edwards, 53 The Drive, Shoreham-by-Sea, Sussex.

THE Laboratory Apparatus and Materials Exhibition, organized by United Trade Press Exhibitions, Ltd., will be held in the Exhibition Hall, Harrogate, during May 14–18. A predominant theme of the Exhibition will be automation in the laboratory. Further information can be obtained from the press officer, Miss Janet Wheaton, U.T.P. Exhibitions, Ltd., 3 Racquet Court, Fleet Street, London, E.C.4.

THE eighth international meeting on "Biological Standardization", organized by the Permanent Section of Microbiological Standardization of the International Association of Microbiological Societies, will be held in Berne during June 18–21. Further information can be obtained from the Committee of Organization, Post Office Box 1560, Berne 2—Transit.

THE third international congress on "Catalysis", organized by the Royal Netherlands Chemical Society, will be held in Amsterdam during July 20–25, 1964. The theme of the congress will be "The Mechanism of Heterogeneous Catalysis", and the topics under discussion will be the molecular description of the catalytic reaction and its intermediate states and selectivity in heterogeneous catalysis. Further information can be obtained from Dr. D. M. Brouwer, P.O. Box 3003, Amsterdam.

THE third international course on "Freeze-Drying", sponsored by the International Institute of Refrigeration in conjunction with the International Association of Microbiological Societies, will be held in Lyons during July 17–28. The subjects under discussion will include: physical aspects of freeze-drying; theory and design of freeze-drying apparatus; pharmaceutical, medical and biological applications of freeze-drying; freeze-drying in foodstuffs industry. Further information can be obtained from the chairman, Prof. L. Rey, Cours Internationaux de Lyophilisation, 97 rue de Vaugirard, Paris 6e.

A SYMPOSIUM on "Enzyme Models and Enzyme Structure", arranged by the Biology Department of the Brookhaven National Laboratory, will be held in the Laboratory during June 4–6. The programme will include: general perspectives; transferases; oxidative enzymes; decarboxylation; condensation and isomerization. The symposium lecture, entitled "Side-Chain Interactions in Protein Structure", will be delivered by Dr. J. C. Kendrew (University of Cambridge). Further information can be obtained from Mr. C. H. W. Hirs, Department of Biology, Brookhaven National Laboratory, Upton, Long Island, New York.

THE Ludwig Maximilians University of Munich, the Bavarian Academy of Sciences, and the International Union of Crystallography are jointly organizing a commemoration meeting on "Fifty Years of X-ray Diffraction" on the occasion of the fiftieth anniversary of the discovery of X-ray diffraction. It will be held at the University of Munich during July 25–27, 1962. In connexion with the commemoration meeting, the International Union of Crystallography and the Section of Crystallography of the German Mineralogical Society will jointly organize a symposium entitled "Recent Advances in the Experimental and Theoretical Methods of Crystal Structure Research", which will be held during July 27–31. Further information can be obtained from Prof. F. Bopp, Institut für Theoretische Physik der Universität München, Schellingstrasse 4–8, München 13, Germany.

THE NATIONAL SCIENCE FOUNDATION

THE eleventh annual report of the National Science Foundation*, covering the year ended June 30, 1961, records grants for research totalling 69 million dollars, compared with 62 million dollars in 1960, requests for support increasing, however, much more rapidly, from 163 million dollars to 256 million dollars. Some 15 million dollars were also made available for research facilities, including 8·5 million dollars for construction and modernization of graduate research laboratories and a further 8 million dollars were awarded to the three national research centres: the National Radio Astronomy Observatory; the Kitt Peak National Observatory; and the National Centre for Atmospheric Research. In the biological and medical sciences support has been afforded in molecular, genetic, developmental, metabolic, regulatory, environmental and systematic biology and psychology. In these fields significant research developments noted in the report are: the determination of the amino-acid sequence of tobacco mosaic virus protein; the successful photographing of unbroken deoxyribonucleic acid; the synthesis of a substance containing 23 amino-acid groups with all the biological properties of adrenocorticotropic hormone; and of luciferan, the light-emitting compound in fireflies. It has also been established that nucleotides play a key part in cell differentiation, that cobalt is essential for the growth of soya bean plants under symbiotic conditions and for the growth of the symbiotic bacteria, that even a few alder trees can play a major part in providing nutrient material for lakes and leaf-fall from alders contains four times as much nitrogen as defoliation from other species, and that carotenoids protect the plant cell from chlorophyll-catalysed photoxidation damage, while further information has been obtained on the structure and function of mitochondria.

In the mathematical, physical and engineering sciences, Project Mohole, a joint venture with the U.S. National Academy of Sciences, was probably the most spectacular project supported by the Foundation during the year, and this deep penetration of the Earth's sub-oceanic crust has established the feasibility of deep-ocean drilling (*Nature*, 184, 140; 1959).

Extra-galactic cosmic particles with an energy 500 million times that generated by the largest accelerator were detected during the year, and an atomic hydrogen maser constructed with an accuracy 100,000 times that of the best time standard yet known. Quantization of magnetic flux in super conductors was confirmed and 17 new exploding supernovæ were discovered during the year.

For the programmes of its Division of Scientific Personnel and Education, the Foundation allocated some 70 million dollars during the year. The 4,196 fellowship awards, totalling 14·1 million dollars, brought the totals since the inception of the programme in 1952 to some 17,000 Fellows and 57 million dollars. The Foundation also supported 771 institute programmes during the year. Of those, 396 were summer institutes attended by 21,000 teachers; 33 were academic year institutes, attended by 1,534 teachers of science and mathematics; 191 were in-service institutes attended by 8,900 secondary school teachers, with a further 13 institutes for 400 participants from elementary schools, all on a part-time basis. Besides containing programmes for secondary schools, such as visits from outstanding scientists and travelling science libraries, and a programme designed to develop co-operation between colleges and secondary schools in improving the quality of education in the sciences, the Division promotes programmes for advanced education in science, including supplementary training for science teachers and studies to improve the extent of courses in science and engineering, the design and development of prototypes of new equipment for teaching science. For this 57 grants were awarded, and since 1958 the Foundation has awarded grants totalling 4 million dollars to the School Mathematics Study Group for projects aimed at improving the teaching of mathematics.

---

TECHNOLOGICAL IMPORTANCE OF INDUSTRIAL DIAMOND

THE name 'diamond' conjures up to many only beautiful costly gemstones, yet diamond is a technological hard material of the greatest importance; indeed, it can be now regarded technically as a fundamental strategic raw material. Of the annual world output of mined diamond, which is some 25 million carats, that is, 5 tons, only 1 ton is used for gemstones, the remaining 4 tons being eagerly consumed in industry largely as a hard abrasive or a cutting material. This 4 tons of crystalline matter, as raw material alone, fetches something like £20 million, and its extraction involves the formidable problem of sorting from something like 125 million tons of diamondiferous ore, the diamond being very thinly distributed indeed.

The technological importance of diamond lies in its immense hardness, which surpasses that of al other materials. The uses of diamond are growing rapidly in two broad categories: (1) single individual diamonds; (2) crushed grit. The range of use is enormous, from lathe-cutting tools to gramophone needles, from the truing and shaping of precision grinding wheels to the cutting and drilling of glass. Then again diamond rock-saws, diamond rock-drills, diamond wire-drawing dies, indeed even diamond microtome cutting-knives, all these are but a few of the multifarious industrial uses of singly mounted diamonds.

The strategic importance of the material, even to the military as well as to industry, is immediately apparent when one considers, for example, such aspects as mass-produced engines, automobiles, etc; for many basic components are rapidly shaped by accurately made silicon–carbide grinders of precise form and dimension. But, of course, the grinders wear and they must be continually reshaped and trued, and with what? In fact, diamond is the only material hard enough to re-true the hard carbide grinders, so a handful of diamonds becomes of strategic importance in these heavy industries.

Of equal importance to industry has been the rapid extension of the use of diamond grit bonded into wheels. Such bonded wheels have a fierce cutting and abrasive action and are extensively used for polishing, grinding, cutting and shaping; for gear wheel teeth, manufacture of hard tools, sawing of rocks, etc. These are but a few of the extensive uses of the newer bonded wheels.

Now it is evident that so ubiquitous a use of a material must have led to development of an extensive technical literature and to an equally extensive industrial patent bibliography.

It was in order to assist technologists in this rapidly expanding field of technical publication that more than twenty years ago the de Beer's South African diamond producing and marketing organization took two steps. First, it established in London the Industrial Diamond Information Bureau (2 Charterhouse Street, London, E.C.1), which offered gratuitous technical information on production and use of diamond; secondly, it founded the journal, *Industrial Diamond Review and Abstracts*. Under its first editor, Dr. P. Grodzinski, this journal made rapid strides and was quickly recognized as the most authoritative monthly periodical dealing not only with diamond and its uses but also with the use of other hard materials, such as the hard carbides.

For some years now the journal has been most competently edited by Mr. Patrick Greene, and, early this year, after remaining unchanged for twenty-one years, it appeared in a new format, which is not only attractive in appearance but also essentially practical. The international *A*4 size has been adopted and colour is introduced. The quality of the reproductions is now admirable, and advertising matter has been removed from the main body to the covers and back pages only.

The principal innovation has been the separation of the *Industrial Diamond Abstracts* into a separate companion journal to the *Review*. These abstracts are effectively culled from four hundred journals, and especially those referring to patents are well and clearly illustrated. The classification of the abstracts is made into no less than twenty-one distinctive categories, typical examples being: *B*, properties of diamond; *K*, wire drawing; *L*, rock drilling; *R*, powder metallurgy; and so on. The cross-reference system is very helpful. Indeed, to anyone interested in either the behaviour, properties or applications of diamond and other hard materials these abstracts are a boon. Linked to the publication is a useful loan photostat and reprint service. The subscription is a mere 30*s*. a year for the two companion journals, which is very little for the monthly service rendered.

There is no doubt that these two publications are performing a very real service, and even if it be admitted that one of their purposes is to encourage increased consumption of diamond, this is in no way a detraction, for diamond is a unique material and its unique physical properties deserve to be used as much as possible to help promote industrial production.

S. TOLANSKY

RECENT NUCLEAR EXPLOSIONS AND EARTH TIDES

ELASTIC deformation of the solid Earth, independent of the marine surface, is called an 'Earth tide'. Because of its rigidity, the Earth will not deform as would a case of the same size but of liquid content. It will assume an intermediate degree of deformation depending on the density and elastic properties of the materials that constitute the solid Earth. This change in shape will cause a change in gravity, value *g*, which is also dependent on the latitude, local geological structure and physical properties of the materials. Thus, the variation in tidal forces caused because of the changes in the position of the Sun and the Moon with respect to the observation station on the Earth will indirectly affect the gravity–time variation curve. The maximum of the tidal action corresponds to a measured minimum of gravity.

Continuous recording of the variation of *g* value with time is being made in the Geology Department, Osmania University, Hyderabad, by S. Balakrishna (*J. Sci. and Indust. Res.* (India), 20 A, No. 12; December 1961). The influence of the oceans on the tidal values on continental stations shows that, at a distance of 66 km. from the seashore, the effect of the oceanic tides can be minimized to a large extent. The Osmania observation station has this advantage besides being located on the so-called stable peninsular shield.

When an earthquake occurs, a certain stress energy is usually released which causes an extra, temporary deformation other than the long-period deformation of the Earth-tide type. This temporary deformation is of short duration and the whole process of disturbance can be observed in the normal gravity–time curve. Many such records have been obtained during the past few months. The most intense earthquake which occurred in the year 1961 was that of Kyushu on February 26, 1961. The gravity record showed a violent disturbance at exactly the same time, but the disturbance was of a few hours duration. In cases where the energy is of high magnitude, as in the case of the Chile earthquake of May 1960, the Earth is thrown into its own free oscillation, the period of which is estimated to be 53 min. 47 sec.

During September and October of 1961, disturbances of a different nature were noticed. The characteristic features of these disturbances are longer duration and constant high amplitude. Nearly thirty disturbances of this nature have been recorded, the first being on September 10, 1961. From the records of the gravity–time curve during these disturbances, it appears that they are not due to the energy that is supplied after an intense earthquake, but are caused by the release of enormous stress energy and are possibly due to a different mechanism. The records of September 10, September 25, October 18, October 23 and October 30, 1961, stand out prominently in that the duration of the disturbances was often for a period of more than 24 hr.

The record on October 23, 1961, when the reported megaton bomb was exploded by the U.S.S.R., showed a minor disturbance at about 0700 hr.; this suddenly became intense at about 1000 hr. and reached its maximum amplitude at about 1430 hr. The disturbance in its intensity, duration and amplitude was of a special nature and quite unprecedented. Such disturbances, it is claimed, have not been recorded in the laboratory previously. On October 30, 1961, when the U.S.S.R. exploded a 50-megaton bomb, there was an intense disturbance at 1430 hr., but the nature of this disturbance was different from that of October 23 or earlier explosions. There was little continued high amplitude, but a series of successive disturbances throughout the night of October 30, each one occurring at an interval of about 2 hr. and corresponding to a miniature earthquake. This type of record may be due to the possibility that the explosion was high in the atmosphere and there was consequently a poor transmission of energy to the epicentre.

The diagnostic features of the disturbances caused in the gravity–time curve which differentiate them from those caused by earthquakes are their longer duration, higher amplitude and sometimes the free oscillation of the Earth which follows them. The period of the Askania gravimeter pendulum is 1·5 sec. and the recording galvanometer has a period of 17 sec. The gravimeter is a static helical spring type without astatixation and damped aperiodically. The sensitivity of the instrument is about 10 cm. per milligal. This means that the response of the pendulum to the disturbances in the Earth's crustal regions is magnified nearly 400,000 times by the gravimeter, which is much more than the most sensitive seismometers used. This is why disturbances caused even in mid-air (pressure waves) have been transmitted into the Earth's crust and are recorded by the gravimeter although they may be of a magnitude that a conventional seismograph of the Milne–Shaw type would normally miss or record feebly.

FROTH-FLOW LAVAS RESEMBLING IGNIMBRITES IN THE EAST AFRICAN RIFT VALLEYS

By Dr. JOSEPH McCALL

University of Western Australia, Nedlands

THE communication by Harkin and Harpum[1] of the Tanganyika Geological Survey was of considerable interest to me. The existence of extensive developments of volcanic rocks, which show eutaxitic structure and a fragmental structure giving them the appearance of welded pyroclastic rocks, that is, ignimbrites, has long been known from a field situated to the north of the field newly discovered by the Tanganyika geologists, and within the same anorogenic zone—namely, the central sector of the Eastern Rift Valley in Kenya. A brief mention of these occurrences was made by me in two introductory accounts of the Menengai volcano[2,3]; at the time of writing these rocks were interpreted as welded tuffs. Since that date, however, much further work has been carried out: a detailed account of many occurrences of these rocks is given in a report awaiting publication by the Geological Survey of Kenya[4] and in addition to this I have, during the past year, been engaged on the preparation of a draft manuscript dealing specifically with the problem of derivation of these unusual fragmental and eutaxitic effusive rocks. It is hoped shortly to publish this work. Meanwhile, it might be of interest to the Tanganyika geologists and others to have a brief summary of the more important conclusions reached.

In Kenya the eutaxitic and fragmental rocks occur in a field within and adjacent to the central sector of the main or Gregory rift valley. They occur not in the oldest volcanic sequence but in the second major sequence of eruptives which post-dated the first major episode of faulting. The age of the greater part of these rocks is probably late Pliocene (ref. 4, Table 2), but there were late eruptions of similar effusives, probably during the Pleistocene. The main sequence can be shown to be much older than the artefact-bearing lake beds of Kariandusi[5], being separated from them by two episodes of faulting. They were associated with broad and extensive shield volcanoes, almost devoid of crater structures, and seem to have been largely fissure erupted. Though cauldron subsidence resulting in the formation of large subsidence calderas has affected many of these shield volcanoes, it is eruptions of pumice lapilli and not of coherent fragmental flows which were directly connected with the caldera formation: the fragmental eutaxitic lavas seem to have formed part of the main sequence of intermittent eruptions which built up the volcanic piles.

The caldera of Menengai[2,3] has, in particular, been the subject of detailed investigations, which have revealed unusual flows of a structurally composite nature: these contain both normal lava (well-crystallized and banded partly vitreous types) and fragmental eutaxitic types within the limits of single flow units. Laterally the structurally composite flows pass into complete flows of normal lava or into complete flows of fragmental and eutaxitic character, and the latter might easily on their own merits be taken for ignimbrite. In fact, entire flows of this character have been loosely termed ignimbrites by several geologists working in Kenya, and attributed to processes of welding. The Menengai rocks are phonolitic trachytes, and while their structural characteristics are remarkably similar to those described from the rhyolite–dacite ignimbrite fields, they possess a much greater degree of crystallization than rhyolitic ignimbrites. What is often called the vapour-phase crystallization[6] has its parallel in these rocks: but the fringing growth of crystals around vesicular cavities drawn out by flow (a form of lithophysal structure) is quite inseparable from the primary crystallization in the unquestionable lava which forms part of the same flow: the development of this lithophysal structure and the fragmental structure, which gives to the rock the appearance of a welded tuff, can be traced outwards from its origin in planar zones of drawn-out lithophysæ within a continuously banded lava : the fragmental character appears when distortion has been sufficient to draw out the laminæ with their included lithophysæ or the laminæ which separate the lithophysal layers into a series of disconnected shreds.

It is thought that the fundamental process involved in the development of the fragmental eutaxitic structure is vesiculation in a glassy lava, expanding as the contained volatiles exsolve. Frothing on the sudden release of volatiles consequent on the rupture of the pressure seal to the magma chamber is envisaged. Locally exsolution is retarded, due to physical controls which are not as yet fully understood, and the structures seen reflect segregation of volatiles but only incipient exsolution, and a high fluidity due to retention of the volatiles in solution. In contrast, where exsolution has been complete, a ruptured product is often produced, a collapsed bubble-froth flow, and there are localized areas in the flow where rupturing rather than a process of drawing out has occurred. The basis of the complex structure so developed and which gives the fragmental character to the rock would seem to lie in Shepherd's discovery[7] that a glass from which volatiles have entirely exsolved is brittle, while a glass which has retained even a small fraction of its volatiles in solution tends to retain its plasticity for a long time: and that it requires considerable time, and a much higher temperature to return a brittle glass to the plastic state. The presence of numerous well-crystallized enclaves in all the Kenya fragmental eutaxitic flows—enclaves formerly explained as accidental xenoliths in welded tuffs—is attributed to early patches of crystallization in the flow: these and the glass areas from which volatiles have been entirely lost have responded in a brittle manner to the onsurge of the still partly mobile flow, while the remainder of the glass has responded plastically. The enclaves are neither accidental nor truly xenolithic.

The combination of autoclastic and plastic deformation structures superimposed on a heterogeneous vesiculating lava which give the effect of a welded tuff can, in my view, be adequately explained as due to the effects of brittle and plastic response to deformation in various parts of the flow, and no recourse to any process of welding is necessary. It is felt that the structurally composite flows, which so closely resemble ignimbrites described from other fields, even to the presence of the remarkable *flamme*, are significant in that they throw some doubt on the necessity to invoke welding to explain such structures in the much more glassy coherent and fragmental flows of rhyolite called ignimbrites. Kennedy[8] and Boyd[9] have suggested an alternative process to the orthodox welding hypothesis using the term froth-flows for the coherent effusive types and collapsed bubble-froth flows for the ruptured effusives, represented by pumice and crystal fragments, and showing a uniformity of fragment size reflecting the size of the vesicles at the point of rupturing. I have applied this hypothesis to the rocks of the Kenya field[10] and am of the opinion that it explains the many anomalous eruptive types far better than the orthodox theory of welding. No recourse to the process of segregation of immiscible liquid fractions as advocated by Steiner[11] to explain similar rocks in New Zealand seems necessary in the case of the Kenya rocks, and indeed, with their sodic-alkaline intermediate composition, they must be considered, on the basis of experimental evidence, as most unlikely subjects for such a process.

The late flows of probable Pleistocene age tend to be very thin and to follow ravines as narrow tongues. The structure is fine, and the name 'claystone' has been locally used. These seem to be extremely watery flows: why they should show the effects of segregation and only limited exsolution giving them abnormal fluidity is not known, but it seems that their flow from source to resting place must have been extremely rapid. Similar types occur in the main (Pliocene ?) sequence to a limited extent.

It seems possible that the Tanganyika rocks in the newly discovered 'ignimbrite' field may, on detailed study, reveal similarities to the Kenya rocks and the first interpretation as lavas prove the correct one, in spite of the obvious resemblance to described ignimbrites.

I thank Dr. W. Pulfrey, commissioner of mining and geology, Kenya, for permission to publish this account, based on work done while employed by the Geological Survey, Kenya, and also for constructive criticism.

ORIENTATION IN OCTAHEDRAL BASIC HYDROLYSIS

By Sir CHRISTOPHER INGOLD, F.R.S., Prof. R. S. NYHOLM, F.R.S., and M. L. TOBE

Department of Chemistry, University College, London

THREE reviews[1] on octahedral substitution appeared in 1958–59. However, in several of the main departments of that subject, the accumulating observations have since been fitting themselves into clearer patterns. This was shown for octahedral aquation, that is, the replacement in aqueous solution of octahedral ligands by water molecules, in an article[2] of 1960. The present article, essentially a continuation, deals in a similarly collative way with the replacement of octahedral ligands by anions in water, in particular, with basic hydrolysis, the best-studied form of such anion substitutions.

(1) *Experimental data.* In order to elucidate the factors which control the rate and direction of any form of octahedral substitution it is necessary comparatively to study the substitution with reference to rates and products over a suitably extensive series of systematically varied original structures.

The one series which has yet been thus usefully studied comprises bisethylenediamine-colbaltic complexes of the general formula $[\mathrm{Coen}_2AX]^+$.

In the examples to be discussed, the 'replaced ligand' X is chlorine or bromine. As the result of an attack by hydroxide ions, it becomes replaced by a hydroxo-ligand. A variable unreplaced ligand A is present, which we call the 'orienting ligand', because its nature and position has a profound effect on the rate of the substitution and on the proportions of its stereoisomeric products. We work with seven orienting ligands which, between them, illustrate the chief recognized types of electronic interaction between a ligand and its transition-metal. These effects of a ligand, untouched in the substitution, on the rate and direction of the substitution, constitute the matter of interest. The data are thus of two kinds, namely, rates of substitution by aqueous hydroxide-ion, and stereoisomeric product-compositions.

The general equation of the substitutions is:

$$[\mathrm{Coen}_2AX]^+ + \mathrm{OH}^- \rightarrow [\mathrm{Coen}_2A\mathrm{OH}]^+ + X^-$$

All these substitutions are kinetically of second order, first in the factor-complex, and first in hydroxide ion. Hence we compare rates by comparing second-order rate-constants. Arrhenius parameters have been determined, but they are not discussed in this article.

For a given A and X, the factor-complex may be either *trans* or *cis*, and, in the latter case, may be either of the two optical enantiomers. The same possibilities of geometrical and optical isomerism are open to the product-complex. In general, any one stereochemically individual factor will, on substitution, give a mixture of all the possible stereoisomeric products. However, the proportions in which the different isomers appear will depend on the stereochemical identity of the factor-complex. Care has been taken to ensure that no reactions other than the single second-order hydroxo-substitution disturbed the determined rates or product-compositions.

The available second-order rate-constants (at 0°), and the product compositions for hydroxo-substitutions of the type formulated and described above are presented in Table 1. Some explanation may be given of the tabulation of product-proportions. *Trans*-factors can yield only *trans*- and racemic *cis*-products. *Cis*-factors were all at first examined in racemic form, and then some of them were re-examined in an optically enantiomeric form. A racemic *cis*-factor can give only *trans*- and racemic *cis*-products; and it will be clear from the tabulation which *cis*-factors were examined only in racemic form. Those *cis*-factors which were further examined in an optically enantiomeric form gave, of course, as much *trans*-product as before, and as much total *cis*-product. But this last was now unequally split between the enantiomers; and therefore, in the tabulation of these results, the proportions of each enantiomer, rather than their sum, is entered. Moreover, these proportions are tabulated, not according to their sign of rotation at a given wave-length, but according to configuration: it is shown which retains a configuration corresponding to that of the factor, and which appears with an inverted configuration. We can do this because our stereochemical rules for aquation are so definite[2], and because aquo- and hydroxo-complexes can always be interconverted without configurational change. Thus, there is never any doubt about which halogeno-, aquo-, and hydroxo- complexes have corresponding configurations.

Table 1. RATE-CONSTANTS (k_2 IN SEC.$^{-1}$ MOLE^{-1} L.) AND ISOMER PROPORTIONS (PER CENT) OF PRODUCTS FORMED IN THE AQUEOUS REACTION:

$$[\mathrm{Coen}_2AX]^+ + \mathrm{OH}^- \rightarrow [\mathrm{Coen}_2A\mathrm{OH}]^+ + X^-$$

* The tabulated rate-constant is one-half of the measured rate-constant for the hydrolysis of the dichloro compound.

(2) *Substitution mechanism.* The kinetic form of the substitutions delimits the possible mechanisms to two. One is the mechanism, labelled S_N2, in which the entering anion attacks the central metal, so aiding release of the ligand being replaced. The other mechanism is that, labelled S_N1cb, in which a pre-equilibrium extraction of a proton from some ethylenediamine ligand by the hydroxide reagent is followed by a rate-controlling dissociation of the replaced ligand, and thereafter by the rapid combination of another hydroxide ion with the metal, and then a final re-protonation of the despoiled ethylenediamine ligand. The arguments for and against each of these interpretations have been presented[1], and, for reasons which need not now be repeated, we favour the former, which we shall use in order to interpret the results in Table 1.

Table 1 discloses that the rate pattern in basic hydrolysis is more complicated than that applying to aquation; and, furthermore, that extensive configurational changes are the rule in basic hydrolysis rather than the exception as in aquation. We did suggest[3] that the kinetic and stereochemical pattern of aquation owes its orderliness to the circumstance that the reagent, water, is ubiquitously available all over the surface of the complex ion, with the result that we have to consider chiefly the internal electronic mechanisms that determine how easily exchange of bonding can occur between the replaceable ligand and neighbouring water, or between the ligand and an adjacent ethylenediamine 'end' internally loosened enough to compete with water.

The situation in basic hydrolysis is evidently different, and we take the first question for consideration to be that of where the substituting anion will present itself, or, in other words, what is the distribution of its potential in the close field of the complex ion, as modified from case to case by the variable orienting ligand. In general, this is an electrostatic question. However, the fact that our reagent is the hydroxide ion is relevant. Transport by Grotthus chain-conduction is allowed to a lyate ion, and concerted proton-transfers to, and through, the solvation shell of the complex, and ending on some particular inner water molecule, will be a main mode of transport of the attacking hydroxide ion. When such a chain-terminating water molecule is firmly localized among the ligands, as by hydrogen bonding to one of them, its position may well determine that of the hydroxide entry.

As to the second question, that of the ease of the eventual exchange of bonding, certain differences between basic hydrolysis and aquation have to be appreciated. One is that, in basic hydrolysis, an anion, expanded by its charge, has to be accommodated in the transition state, wherefore a larger 'hole' in the residual electronic system must be provided; and it results that although, and even because, a bimolecular process is in consideration, loosening of the outgoing ligand will constitute the more advanced of the concerted bond-changes that lead up to the transition state, in contrast to bimolecular aquation wherein water entry initially takes the lead. Another point of difference is that, in basic hydrolysis, the substituting agent is much more nucleophilic than in aquation, and is thus more competent to impel stereochemical change by edge-displacement of a ligand[1], if that is needed for the completion of its binding; wherefore special ligand-loosening mechanisms are much less important than in aquation.

(3) *Electronic properties of the ligands.* The foregoing general principles have to be applied with reference to the effects of the orienting ligands, the properties of charge and potentialities of electron-displacement of which are derived from their constitution. These matters were set out in the former article[2], but we shall summarize them, taking the opportunity to develop one point further.

The inductive effects $(+I)$ of the orienting ligands stand in the following order of decreasing electropositivity $(+I)$:

$$\mathrm{OH,\ N_3 > NCS,\ Cl > NO_2 > NH_3}$$

Induction will change the density of the unshared metal electrons in the same sense everywhere, but most strongly about the *trans*-ligand.

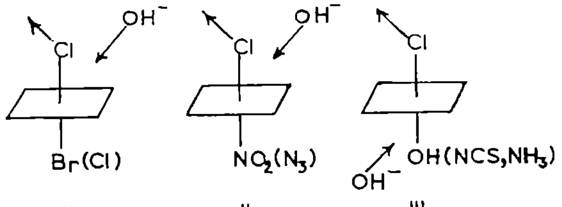
Four ligands, namely, OH, N_3, NCS and Cl, have unshared electrons adjacent to the metal. They are constitutionally capable of an electropositive electromeric effect $(+E)$, which directly loosens ligand bonds, and is *cis*-specific. The order of the groups with respect to this electron-transfer could not be prescribed, either theoretically or even empirically, in the former article[2], because the quantitative data on its most characteristic effect[10], that is, rearrangement in the aquation of *trans*-factors, were then incomplete[11]. But they have now been completed for the replacement by aquation of a chloro-ligand in bisethylenediamine cobalt-III complexes[12]: the *trans*-hydroxochloro-complex thus gives 75 per cent, and the *trans*-dichloro-complex 35 per cent of the *cis*-aquo-product. These results, combined with those reported previously, furnish the complete $+E$-order:

$$\mathrm{OH > NCS > Cl > N_3}$$

Two ligands, namely, N_3 and NO_2, have dipolar canonical structures with an electron-deficiency adjacent to the metal. This constitutional feature allows them an electronegative conjugative effect $(-T)$ by which they can accept metal electrons. Such an electron-transfer will reduce the density of the unshared metal electrons on the remote side of the complex. With respect to this effect, the ligands stand in the well-established $-T$-order:

$$\mathrm{NO_2 > N_3}$$

(4) *Basic hydrolysis of the* trans-*substrates.* The three main types of case are formulated at I–III. The less extreme members of the types are indicated by alternative orienting ligands written in parentheses.



I II III

Orienting halogen is represented in I. The halogens, uniquely, are monatomic and monopolar ligands, and are themselves the only easily replaceable ligands, bromine more easily than chlorine. Therefore, their binding can have only a light covalent content, and thus they must carry a large negative charge, bromine the larger. This will direct the attaching anion *trans*. There, with the loosening halogen, it can form a transition state for bond exchange, wherein both exchanging ligands are only lightly bound, the change in the binding of either from the initial to the transition state being therefore somewhat small. Hence, we can understand the relatively rapid substitutions, the retained configurations, and the minor quantitative differences between the halogens.

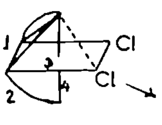
The orienting $-T$-ligands are represented in II. These ligands draw to themselves the cobalt $3d_{\varepsilon}^{6}$ shell during reaction, building up negative charge which directs the attacking anion *trans*, and also tightens the binding of the *trans*-halogen. In order to produce the transition state of the ensuing exchange, a greater loosening of the ligand under release will now be required. Hence, we can understand the relatively slow substitutions, the very largely retained configurations and the minor quantitative differences between the effects of nitro- and azido-ligands.

Included in representation III is the orienting hydroxo-ligand. It is the most electropositive of all the ligands, and, for that reason, as well as because local hydrogen-bonded hydration will cause it to attract a lyate ion (Section 2), it will direct the hydroxide-ion attack adjacently to itself. We see in the result a slow reaction, associated with an almost total change of configuration. The isothiocyanato-ligand stands second in electropositivity, and has a partial positive charge adjacent to the metal. The ammonio-ligand is relatively electronegative, but must still carry a substantial residue of its formal positive charge. It seems that, for these different reasons, these two orienting groups secure hydroxide-ion attack mainly, though not exclusively, near themselves. In both cases, we find somewhat slow reactions, associated with preponderating, but not exclusive, changes of configuration.

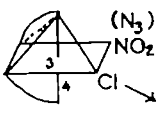
(5) *Basic hydrolysis of* cis-*substrates.* The orienting ligands divide themselves into the same three classes, with broadly distinct properties, though the distinctions are not quite the same as before. Orientation by halogens now leads to high rates and strongly predominating configurational change; by nitro- and azido-ligands to low rates and medium amounts of configurational change; and by hydroxo-, isothiocyanato- and ammonio-ligands to medium rates and minor amounts of configurational change.

The rates for most *cis*-substrates follow the pattern of those of the *trans*-substrates, the *cis*-rates lying below the *trans* by factors of 2·5–5. The few exceptions relate to orientation by the two best electromerically *cis*-activating ligands (Section 3), namely, hydroxo and isothiocyanato. These orienting ligands raise their *cis*-rates above their *trans*- by factors in the expected order, near 20 for the hydroxo-examples, and 4 for the isothiocyanato.

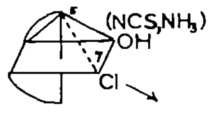
In setting down the stereochemical possibilities, we have to distinguish between the molecular processes of substitution, without and with edge-displacement (to be denoted by *o* and *ed*, respectively), and the macroscopic products of substitution. These are *trans*-products, and stereochemically inverted *cis*-products (to be written inv-*cis*), which are necessarily formed with edge-displacement (*ed*), and *cis*-products with a retained configuration (to be denoted ret-*cis*), which may be formed without or with edge-displacement (*o*-ret-*cis* or *ed*-ret-*cis*)[1]. The hypothesis of edge-displacement implies that all group-shifts are *cis*, and that an end of an ethylenediamine ligand can shift only to a position which is *cis* with respect to both ends. Figs. IV–VI are drawn for one enantiomer in each case.



IV



V



VI

Orienting halogen is represented in IV. A discussion of rates would follow the same lines as in Section IV, and the main new interest is in the product proportions. The halogen being replaced is marked with an arrow. The other is the orienting halogen, and, for reasons explained in Section 4, reagent attack is expected mainly around the point *trans* with respect to it, that is, within the octahedral faces numbered (1)–(4). Attack at the octahedral face (1) marked with three full lines, and on its counterpart (2) below the square, should lead to the qualitative results set out below, where the added numerical illustration results from assuming an exclusive attack equally divided between these faces, and, at either face, leading with equal probability to the possible consequences indicated:

(1) *trans* (2) *trans*, inv-*cis*
(75 per cent *trans*, 0 per cent ret-*cis*,
25 per cent inv-*cis*)

Attack on face (3) completed with a dotted line, and on its counterpart (4) below the square, should lead to the following results, similarly numerically illustrated:

(3) *trans*, *o*-ret-*cis* (4) *trans*, *o*-ret-*cis*, inv-*cis*
(42 per cent *trans*, 42 per cent ret-*cis*,
16 per cent inv-*cis*)

The observed results, bracketed as they are, between these two sets of figures suggest that the four faces considered are attacked to somewhat similar extents.

Orientation by the nitro- and azido-ligands is represented in V. Again, a discussion of the relevant rates would resemble that contained in Section 4, and we may turn at once to the product ratios. The main new factor is that the cobalt $3d_\varepsilon$ shell is swollen towards these $-T$-ligands, a circumstance calculated to widen the angle between the orienting ligand and the departing halogen (the external field of which is wholly negative), so moving the point *trans* to the former towards the latter, and hence concentrating reagent attack, otherwise expected to be spread over faces (1)–(4), particularly towards faces (3) and (4). The results to be expected from attack at these faces are set out above. The observed results for the nitro- and azido-ligands are reasonably similar to the figures illustrated.

Orientation by the hydroxo-, isothiocyanato- and ammonio-ligands is represented in VI. The factors affecting rate are as discussed in Section 4, except for the modification, concerning the hydroxo- and isothiocyanato-ligands, mentioned earlier in this section. As to product proportions, the important consideration is that, again for reasons given in Section 4, reagent attack is now concentrated around the orienting ligand, almost totally around the hydroxo-, and mainly, but not totally, around the isothiocyanato- and ammonio-ligands. Moreover, the relative polarity of the departing halogen should determine that attack on the face (5) marked with three full lines, and on its counterpart (6) below the square, is more important than on the face (7) completed with a dotted line, and its counterpart (8). The stereochemical results to be expected from attack in these positions are given below, and are numerically illustrated with the same assumptions as before:

(5) *ed*-ret-*cis* (6) *ed*-ret-*cis*, inv-*cis*
(0 per cent *trans*, 75 per cent ret-*cis*,
25 per cent inv-*cis*)

(7) *o*-ret-*cis*, *ed*-ret-*cis* (8) *o*-ret-*cis*, *ed*-ret-*cis*, inv-*cis*
(0 per cent *trans*, 83 per cent ret-*cis*, 17 per cent inv-*cis*)

The product compositions observed for the hydroxo-oriented substitutions are fairly similar to the former set of figures, while those observed for the isothiocyanato- and ammonio-oriented substitutions are consistent with the idea that similar directive effects are less exclusive in these cases.

The previous analysis[2] of aquation rates and products not only rationalized them but also disclosed a simple stereochemical rule. Although no all-embracing rule emerges for bimolecular basic hydrolysis, the above discussion of its rates and products does seem to carry a similar qualitative rationality. Though there are other branches of the subject which we must leave for future articles, the general position of orientation theory in aqueous octahedral substitution encourages us to think that we may be on the way to a condition of intelligibility comparable with that of the present theory of orientation and reactivity in aromatic substitution.

SPECIFIC ELEMENTARY PROCESSES IN THE RADIATION CHEMISTRY OF ORGANIC OXYGEN COMPOUNDS

By Dr. T. FFRANCON WILLIAMS

Department of Chemistry, University of Tennessee, Knoxville

ALTHOUGH the primary modes of bond rupture and re-arrangement following the electronic interaction between high-energy radiation and polyatomic molecules in the macroscopic state can often be inferred from kinetic measurements and product analyses, no adequate theory has been developed to enable the prediction of elementary processes as a function of molecular structure; it has been aptly commented[1] that the present status of this subject is the result of empirical growth devoid of a definite theoretical foundation.

It is well recognized that radiation-induced reactions cannot be attributed to a statistical distribution of random bond fractures, and that preferred paths are evident in the reaction sequence. Elsewhere[2], I have argued that reactions of the parent molecule-ion involving low-activation energies probably precede the neutralization process, even in the liquid state; and that the consideration of such reactions affords a simple guide to a qualitative understanding of the radiation chemistry of liquid alkanes as a function of molecular structure. In this article I am adopting the same premise to a discussion of the radiation chemistry of some organic molecules possessing functional groups with oxygen atoms.

A fundamental distinction between the ground-state electronic structure of saturated hydrocarbons and organic oxygen compounds is that whereas the occupied molecular orbital of highest energy (that is, corresponding to the lowest binding energy) in the former is σ bonding, in the latter it is non-bonding (n) and can be considered to be largely derived from the lone-pair $2p$ electrons of the constituent oxygen atom. It follows that the threshold ionization of an organic oxygen compound refers to the loss of a non-bonding electron with the result that the unpaired electron is highly localized on the oxygen atom; thus Mulliken[3] regards $\text{CH}_3\text{—}\overset{+\cdot}{\text{O}}\text{H}$ as the major valence bond resonance structure in the ground-state of the methanol positive ion. Cummings and Bleakney[4] made the original suggestion that ionization in this manner confers trivalency on oxygen, and they proposed that additional bonding between carbon and oxygen could account for the low appearance potential and relative abundance of the major fragment ions in the mass spectra of methanol and ethanol (*vide infra*). In more general terms, it can be stated that the ensuing reactions of the parent molecule-ion are strongly directed by the tendency of the oxygen atom to complete its valence shell of electrons. It is proposed that this factor also represents a key to the interpretation of radiation-chemical changes in many oxygen compounds, but first let us indicate the assumptions on which this approach rests.

When the energy of the incident electron far exceeds the binding energies of the electrons in the molecule, some ionization events would be expected to occur through the removal of electrons below the highest occupied level and also by the possibility of a dielectronic process involving electron promotion to anti-bonding orbitals in the ion. For these electronically excited ions, it is postulated that there follows a radiationless electron re-organization within about 10^{-13} sec. which leaves the electron vacancy in the orbital corresponding to the highest occupied level in the ground-state; and that the excess electronic energy is internally converted to vibrational energy in the molecule-ion. This latter assumption constitutes a pillar of the quasi-equilibrium rate theory[5] of the origin of mass spectra. It is also generally accepted[6,7] that the higher excited states of neutral molecules undergo internal conversion, at least to the lowest excited state of the same multiplicity, in a comparable time (10^{-13} sec.).

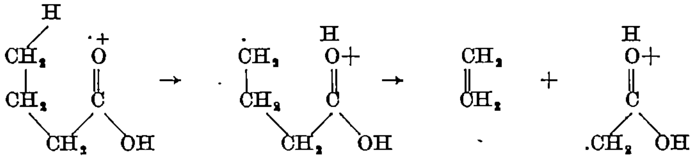
There are two general reactions which can be invoked whereby the ionized oxygen atom in an organic molecule-ion can regain its full complement of valence shell electrons. First, by the inter- or intra-molecular abstraction of a hydrogen atom. An example of the former type is given by the ion-molecule reaction (1) of methanol parent ions[8], ($R = \text{H}$).

$$R\text{CH}_2\overset{+\cdot}{\text{O}}\text{H} + R\text{CH}_2\text{OH} \rightarrow R\text{CH}_2\overset{+}{\text{O}}\text{H}_2 + R\dot{\text{C}}\text{HOH} \qquad (1)$$

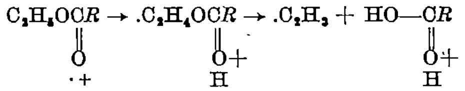
The generality of this reaction (M) for many diverse organic compounds containing oxygen or nitrogen atoms is indicated by repeated observations[9,10] that ions corresponding to a mass = parent + 1 occur in the mass spectra recorded at elevated pressures. The argument for charge localization on oxygen applies with equal force to nitrogen due to the similar property of non-bonding electrons. Since ion-molecule reactions are usually considered to be near-exothermic, it is pertinent to inquire into the factors which determine the energetics of processes akin to equation 1. The exothermicity, $-\Delta\text{H}_r$, of such reactions can be shown to be represented by the equation:

$$-\Delta\text{H}_r = I_M + PA_M - I_H - D_{\text{C—H}} \qquad (2)$$

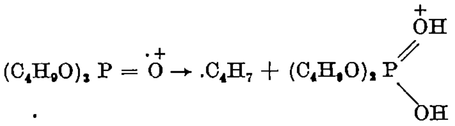
where I_M and PA_M refer respectively to the ionization potential and proton affinity of the original molecule, I_H is the ionization potential of the hydrogen atom (13·6 eV.) and $D_{\text{C—H}}$ is the dissociation energy of the C—H bond involved in the reaction. In a series of compounds where the oxygen functionality remains the same, $D_{\text{C—H}}$ is almost invariant so that $-\Delta\text{H}_r$ in equation 2 is largely determined by the first two terms. Now it can be argued that in any homologous series, I_M and PA_M depend on the condition of the lone-pair electrons in a way that an increase in one of these quantities will be compensated by a decrease in the other, so that their sum remains approximately constant. For example, the decrease of I_M in carbonyl compounds with increasing polarity of the $>\text{C=O}$ bond[11] is attributed[12] to a repulsion of the



(4.1)



$$C_2H_5O\underset{\overset{\cdot +}{O}}{\underset{\|}{C}}R \rightarrow .C_2H_4O\underset{\underset{H}{O+}}{\underset{\|}{C}}R \rightarrow .C_2H_3 + HO{-}\underset{\underset{H}{O+}}{\underset{\|}{C}}R \qquad (4.2)$$



$$(C_4H_9O)_3\,P = \overset{\cdot +}{O} \rightarrow .C_4H_7 + (C_4H_9O)_2\,P(=\overset{+}{O}H)OH \qquad (4.3)$$

lone-pair electrons away from the oxygen atom, which should also increase the basicity (PA_M). Hence, there is some basis for expecting $-\Delta H_r$ to be relatively insensitive to molecular environment. While the assumed exothermicity of ion-molecule reactions has been used to establish PA_M values between definite limits, few independent determinations are available to make a strict calculation according to equation (2). However, for reaction (3):

$$CH_2 = \overset{\cdot +}{O} + HCH = O \rightarrow CH_2 = \overset{+}{O}H + \overset{\cdot}{C}H = O \qquad (3)$$

which represents the prototype for carbonyl compounds, PA_{CH_2O} can be deduced from measurements on the appearance potential of the $CH_2 = \overset{+}{O}H$ ion derived from methanol; from the values[13,14] $I_{CH_2O} =$ 10·9 eV., $D_{C-H} = 3{\cdot}3$ eV. and $PA_{CH_2O} = 7{\cdot}0$ eV., we obtain $-\Delta H_r = 1{\cdot}0$ eV. Similar energetic considerations apply to the intra-molecular transfer of a hydrogen atom, and this process (R) is often favoured where a 'quasi transition-state' can be formed corresponding to a five- or six-membered ring[15]. In many instances the transfer process is accompanied or followed by re-arrangement, as shown in reactions (4.1), (4.2) and (4.3).

The re-arranged even-electron ion formed in (4.2) is a protonated carboxylic acid; an analogous reaction (4.3) for phosphoric acid esters[16] further underlines the important role of the oxygen atom for the occurrence of these reactions.

The completion of the electron octet on the initially ionized oxygen atom can also come about by a second general process (F) in which a π bond is formed between oxygen and the adjacent carbon atom. This step is facilitated by the homolytic scission of a C—H or C—C bond so as to leave a free valence on carbon to couple with the unpaired electron on oxygen. Following Cummings and Bleakney[4], the results of many investigations[17–20] show that reaction 5, for example, makes a major contribution to the fragmentation pattern of alcohol parent-ions in mass spectra.

$$R_1R_2R_3C{-}\overset{\cdot +}{O}H \rightarrow R_1R_2C = \overset{+}{O}H + R_3. \qquad (5)$$

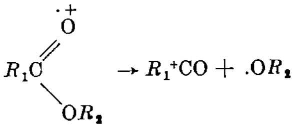
$R_1 = R_2 = R_3 = H$; $\Delta H_r = 1{\cdot}0$ eV. (5.1)

$R_1 = R_3 = H$; $R_2 = C_2H_5$; $\Delta H_r = 0{\cdot}9$ eV. (5.2)

$R_1 = R_2 = H$; $R_3 = CH_3$; $\Delta H_r = 0{\cdot}6$ eV. (5.3)

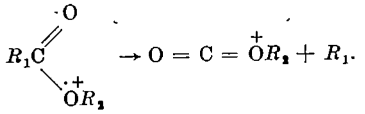
$R_1 = R_2 = H$; $R_3 = C_2H_5$; $\Delta H_r = 1{\cdot}4$ eV. (5.4)

It has been demonstrated by using deuterated alcohols[19,20] that fragmentation occurs by simple bond scission in the manner indicated. To illustrate the general nature of this reaction, examples are given here for carboxyl and carbonyl compounds; in each case the process is known to be of primary importance in the interpretation of the mass spectra[21].



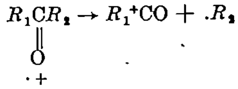
(6)

$R_1 = R_2 = H$; $\Delta H_r = 1{\cdot}1$ eV. (6.1)



(7)

$R_1 = R_2 = H$; $\Delta H_r = 1{\cdot}8$ eV. (7.1)



$$R_1\underset{\overset{\cdot +}{O}}{\underset{\|}{C}}R_2 \rightarrow R_1{}^+CO + .R_2 \qquad (8)$$

$R_1 = R_2 = CH_3$; $\Delta H_r = 1{\cdot}2$ eV. (8.1)

$R_1 = CH_3$; $R_2 = H$; $\Delta H_r = 0{\cdot}8$ eV. (8.2)

Whereas the ion-molecule reactions (M) tend to be exothermic and the measured rate constant[8] for equation (1) suggests the occurrence of reaction on every encounter, the dissociation reactions of type (F) must have activation energies corresponding at least to the endothermicity (< 2 eV.). However, for the n-propanol molecule-ion, there is quantitative evidence[22] that the vibrational energy is stored in only a few degrees of freedom. This finding supports the concept of directed as opposed to random fracture and it has important kinetic repercussions. From the simplified form of the unimolecular rate expression[5]:

$$k = \nu\left(1 - \frac{\varepsilon_0}{E}\right)^S \qquad (9)$$

and assuming ν, the frequency factor for dissociation, to be 10^{14} sec.$^{-1}$ and $S = 12$ effective oscillators, it may be calculated that for parent molecule-ions with initial vibrational energy $E = 3\varepsilon_0$, where ε_0 is the activation energy, the rate constant k for dissociation is 10^{12} sec.$^{-1}$. On the basis of the reasonable values used in the calculation, it follows that (F), as well as (M), reactions can logically be expected to occur before neutralization or thermal quenching intervenes in the liquid state[2]. Moreover, there is no reason to suspect that solvation would adversely affect the rate of reactions (M), (R) and (F) since only homolytic bond rupture is involved and the locus of positive charge remains unaltered. Other fragmentation processes not included in our classification are characterized by high activation energies or very low frequency factors and are therefore of secondary importance, particularly for consideration in the liquid state.

The large majority of the product and fragment ions formed in the above reactions are even-electron ions and are likely to adopt the most stable structure in which all the valence orbitals are filled. Thus, $\mathrm{CH_3\overset{+}{O}H_2}$, $R_1R_2\mathrm{C{=}\overset{+}{O}H}$, and $\mathrm{O{=}C{=}\overset{+}{O}H}$ are protonated molecules while $\mathrm{H^+CO}$ and $\mathrm{CH_3^+CO}$ can be identified as the union of a Lewis base, carbon monoxide[23], with a proton and a carbonium ion, respectively. It is improbable that neutralization of these even-electron positive ions occurs by thermal electron attachment. Eyring, Hirschfelder and Taylor[24] have concluded from the work of Bradbury[25] that, for electrons with low velocities, electron capture only occurs readily for molecules with free valencies. There seems to be no reason to alter this view for the ions discussed above. A similar conclusion appears to follow from an application of the Franck–Condon principle[26]. In order for thermal electron capture to proceed, the potential energy surfaces corresponding to the initial ion and the resultant neutral aggregate must cross. Among typical processes which might be envisaged are the formation of a radical by electronic rearrangement as in equation (10), or of a radical plus neutral molecule as in equation (11):

$$R^+\mathrm{CO} + e^- \rightarrow R\dot{\mathrm{C}}{=}\mathrm{O} \qquad (10)$$

$$R\mathrm{\overset{+}{O}H_2} + e^- \rightarrow R\mathrm{OH\ H} \qquad (11)$$

In general, processes of this type require the gain of vibrational energy by the ion to give the appropriate nuclear configuration of the products before the thermal electron can be captured. It is surmised that while the electron will be polarized in the field of the positive ion, there remains an energy barrier to direct neutralization by attachment. In these circumstances the most appealing possibility is proton or carbonium ion release from the even electron ion, brought about largely by the electrostatic field of the 'free' electron. This type of reaction is illustrated by equations (12–15), and has much in common with the mechanism of discharge processes at electrodes in the electrochemistry of solutions.

$$\mathrm{O = C = \overset{+}{O}H} + e^- \rightarrow \mathrm{O = C = O + H} \qquad (12)$$

$$R_1R_2\mathrm{C = \overset{+}{O}H} + e^- \rightarrow R_1R_2\mathrm{C = O + H} \qquad (13)$$

$$\mathrm{CH_3\overset{+}{O}H_2} + e^- \rightarrow \mathrm{CH_3OH + H} \qquad (14)$$

$$\mathrm{OC^+}R + e^- \rightarrow \mathrm{OC} + R. \qquad (15)$$

The occurrence of equations (12–14) in the liquid state involves a thermochemical change given by:

$$-\Delta \mathrm{H}_r = I_H - PA_M - S_{MH^+} \qquad (16)$$

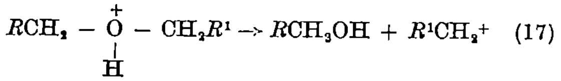
where S_{MH^+} represents the solvation energy of the protonated molecule. In the discharge of a hydrogen atom from a fully solvated hydronium ion $\mathrm{H_3O^+}$ in water, $-\Delta\mathrm{H}_r = 1{\cdot}4$ eV., and it is to be expected that comparable values obtain for the other reactions depicted above. Thus neutralization by discharge as represented here is not a process accompanied by high-energy release, in contrast to the situation that exists if the parent molecule-ion is neutralized before ionic reactions can take place.

It is probable that the discharge processes involve small but necessarily finite potential energy barriers. Therefore, these reactions are unlikely to occur instantaneously but the electron and positive ion can remain associated for sufficient time to represent a distinct and kinetically significant intermediate. It also follows that proton discharge, as in equation (14), would tend to occur more readily by tunnelling, compared to $\mathrm{CH_3^+}$ discharge from $\mathrm{CH_3\overset{+}{O}H_2}$, despite the more favourable overall thermochemical change in the latter case. It is proposed to discuss these reactions more fully in a future publication.

In terms of the foregoing discussion it is now possible to seek an interpretation of the radiation chemistry of representative compounds. McDonell and Newton[27] have shown that the major liquid phase products from the radiolysis of aliphatic alcohols are glycols, aldehydes and ketones. Glycol formation from primary alcohols is consistent with the coupling of $R\dot{\mathrm{C}}\mathrm{HOH}$ radicals, which are formed according to equation (1) and also by abstraction due to atomic hydrogen liberated in the discharge process. The formation of carbonyl compounds is readily accounted for by equation (5), which also explains the higher proportion of ketone to aldehyde with alkyl substitution on the α-carbon atom. On this basis, the results show that hydrogen atom loss in equation (5) occurs with higher probability than the corresponding loss of an alkyl group, and while this trend agrees with the lower activation energy of equation (5.2) relative to equation (5.4), it is doubtful if such fine energy differences can always give reliable predictions regarding the predominant mode of scission. Except in the case of *t*-butyl alcohol, the yield of hydrogen is consistently greater than methane, particularly for the primary alcohols, which again suggests that hydrogen atom loss by equation (5) and in the discharge equation (14) occurs preferentially over the removal of an alkyl group. Although the overall pattern of products is clearly consistent with the specified reactions, it might be thought that other, purely empirical, schemes utilizing free radical intermediates without intervening ions could also account for the products. However, a re-interpretation of Burr's work[19] on hydrogen formation from deuterated ethanols provides strong support for the present mechanism. The total deuterium content of the radiolytic hydrogen gas from $\mathrm{CH_3CD_2OH}$ and $\mathrm{CH_3CH_2OD}$ was found to be 47 and 39 per cent respectively. Burr assumed that all the hydrogen (or deuterium) atoms originate by loss from the α-carbon atom in a primary process (as in equation 5); and hence concluded that hydrogen atom abstraction occurs mainly from the OH (OD) group. Now this latter step must be regarded as intrinsically improbable both in view of the greater bond strength of O—H relative to C—H and the experimental fact that hydrogen abstraction processes proceed most readily on the carbon atom adjacent to an electronegative group. This difficulty is avoided in the present mechanism since the liberation of a hydrogen (or deuterium) atom from the hydroxyl position follows from the discharge reaction analogous to equation (14), and therefore provides a more acceptable route to the formation of HD from $\mathrm{CH_3CH_2OD}$.

The formation of carbon monoxide and carbon dioxide as major products from compounds with carboxyl groups[28] (acids, esters), and of carbon monoxide from carbonyl compounds are described by the (*R*), (*F*) and (*N*) reactions we have considered earlier. According to this mechanism, the formation of carbon oxides and of any molecule, such as the carboxylic acid in equation (4.2), produced in a protonated form prior to discharge should be unaffected by the presence of a free radical scavenger in the system. Careful experiments by Hummel[29] on methyl acetate concur with this theoretical expectation. Since hydrogen atoms and alkyl radicals are also released in the above reactions, the kinetic interplay of abstraction and combination processes, dependent on the initial geometry of formation, will result in hydrogen, methane, etc. It is clear that high yields of methane are expected, and found, for those compounds (acetone, acetic acid, etc.) where initial dissociation (F) and/or subsequent discharge (N) can result in methyl radicals. On the subject of carbonyl compounds, it has been frequently said that the radiolysis results are similar to those obtained in photolysis, and this has inadvertently contributed to the neglect of ionic processes. While it would be remarkable if no correspondence existed between the effects of these differing radiations, closer inspection of the results reveals significant differences. In particular, whereas hydrogen is usually a major product of radiolysis, it is much less important in photochemical studies on carbonyl compounds. Further, the interpretation of radiolysis studies by analogy with photochemistry often leads to difficulties of interpretation which are only partially resolved by recourse to additional empiricisms such as 'molecular' processes and the specification of radical reactivity according to comparative degrees of thermal energy[30]. Since many organic compounds do not show significant light absorption in the conventional photochemical range, photochemistry represents at best a limited guide to the effects of high-energy radiation.

The application of the ionization model can also be illustrated by reference to aliphatic ethers[31] and tri-n-alkyl phosphate esters[32]. In the former case, any attempt to rely on a simple correlation with the mass spectrum is handicapped by the presence of a large number of fragment peaks. On the other hand, the theoretical approach we have outlined leads to the expectation that the ions $R\text{CH}_2-\overset{+}{\underset{|\atop \text{H}}{\text{O}}}-\text{CH}_2R^1$ and $R\text{CH}=\overset{+}{\text{O}}-\text{CH}_2R^1$ will be formed by the processes (M) and (F), respectively. There is independent evidence from thermal chemistry[33] and mass spectra[15] that these ions can further rearrange according to equations (17) and (18):



$$R\text{CH}_2-\overset{+}{\underset{|\atop \text{H}}{\text{O}}}-\text{CH}_2R^1 \rightarrow R\text{CH}_3\text{OH}+R^1\text{CH}_2^+ \quad (17)$$

$$R\text{CH}=\overset{+}{\text{O}}-\text{CH}_2R^1 \rightarrow R\text{CH}=\text{O}+R^1\text{CH}_2^+ \quad (18)$$

The discharge of the carbonium ions may be expected[2] to result in olefine and hydrogen atom formation. It is completely consistent with this sequence that compounds with carbonyl and hydroxyl groups, as well as hydrogen gas and olefines, account for the principal products from the liquid phase radiolysis of aliphatic ethers. In the case of tri-n-alkyl phosphates, a rational description of the radiolysis results[32] is provided by (R) reactions similar to equation (4.3).

In conclusion, it would seem that the success of the qualitative theory presented here militates against the thesis that electron capture by the parent ion necessarily precedes any chemical reaction to liquid systems. Since recent work[34] on radiation-induced polymerization has furnished unequivocal evidence for ionic intermediates, it seems appropriate to reiterate the view[35,36] that the reactions of ions should be considered to represent an integral part of mechanism in radiation chemistry.

CÆSIUM-SODIUM ION EXCHANGE ON CLINOPTILOLITE

By Dr. GALEN R. FRYSINGER

Arthur D. Little, Inc., Acorn Park, Cambridge, 40, Mass.

THE interactions between nuclides and the Earth's soils and minerals have received much attention because of the accidental and purposeful release of fission fragments into the environment. Of particular importance are cæsium and strontium ions due to the combination of abundance and relatively long half-lives. A search has been made to determine which soils and minerals will selectively adsorb either the cæsium or the strontium. A high selectivity for strontium is difficult to find when considering ordinary ion exchange because of the chemical similarity of strontium to the calcium which is found in these soils and minerals in their natural state. Some other type of mechanism must be found to segregate strontium. Naturally occurring soils and minerals, however, generally show a selectivity for cæsium over other alkalis and alkaline earths. Montmorillonite, for example, shows a relatively high selectivity for cæsium[1]. Clinoptilolite is a natural zeolite shown by preliminary experiments to have an even higher selectivity for cæsium. The structure of clinoptilolite is discussed in a recent article by F. A. Mumpton[2]. A representative formula for clinoptilolite is:

$$(Na_2O)_{0\cdot70}(CaO)_{0\cdot10}(K_2O)_{0\cdot15}(MgO)_{0\cdot05}\cdot Al_2O_3\cdot 8\cdot5-10\cdot5\ SiO_2\cdot 6\text{–}7\ H_2O$$

The material often contains up to 25 per cent impurities, mostly quartz, feldspar and montmorillonite.

Clinoptilolite has one very distinct advantage over montmorillonite. This is the mechanical stability of the small chunks when exposed to an electrolyte solution. The material − 20 + 40 mesh can be placed directly in a chromatographic column. A steady flow can easily be maintained. There is no tendency for the column to clog even in the presence of sodium solutions. Montmorillonite, on the other hand, cannot be used in a column in the presence of sodium solutions. The clay will disperse and completely clog the column. Even for columns exposed to other electrolytes the montmorillonite must be suspended on large volumes of a filter aid such as asbestos to prevent clogging or its being washed from the column. Clinoptilolite thus has a tremendous advantage in that it can be used directly in the column and will allow a large variation in flow-rate.

The chunky nature of the clinoptilolite means that all the exchange positions are not equally rapidly available to ions in solution. This is a disadvantage because some type of slow diffusion process will be involved to reach the less accessible positions. The experimental implications of this are discussed later.

Cæsium ion sorption. The saturation and elution chromatograms for the sorption of cæsium ions on clinoptilolite were determined at 25° C. This was done by taking a column containing 2 gm. of clinoptilolite and saturating it with 0·02 *N* cæsium chloride with the radioisotope cæsium-134 added. The saturation chromatogram shows the concentration of the effluent as a function of the volume of solution through the column. When the concentration of the effluent rose to and remained equal to the concentration of the input solution the saturation was complete. The exchange capacity of the clinoptilolite is then just equal to the total number of milliequivalents which entered the column and not found in the effluent. This 'uptake' can be determined quantitatively from the area over the saturation chromatogram.

A more exact determination of the amount of cæsium ions adsorbed was obtained when the sorbed cæsium was eluted with a cæsium chloride solution of the same concentration but which carried no radioactive tracer[3]. This is an isotopic exchange, with the clinoptilolite at all times in equilibrium with the cæsium chloride solution. The elution is considered complete when the counting-rate reaches background. The area under the elution chromatogram is equal to the total amount of cæsium adsorbed. The milliequivalents of cæsium in the column free-volume solution, however, must be subtracted. The free volume is determined from the difference between the wet and dry weights of the column.

The exchange capacity of the clinoptilolite was found to be 1·61 ± 0·01 mequiv./gm. Columns which were exposed to 0·02 *N* electrolyte solutions for a period of four months showed a 3 per cent increase in exchange capacity.

The elution chromatogram exhibits decided 'trailing'. This trailing means that certain of the cæsium ions were delayed in their release from the mineral to the solution. It may be that some of the exchange positions are located deep in the chunk of clinoptilolite. The replacing cæsium ion is then required to travel a path through the mineral. This type of a slower diffusion could account for the trailing. Reducing the particle size may greatly reduce the trailing; but this would adversely affect the column behaviour.

Sodium ion sorption. The sodium ion sorption was not found to differ from that of cæsium. The clinoptilolite sorbs an amount of sodium ion equal to its exchange capacity. The chromatograms, however, are markedly different because of sodium's ineffectiveness in displacing other ions. Most other ions are preferred over sodium by the clinoptilolite. The chromatogram for the saturation of clinoptilolite with 0·02 *N* ^{22}NaCl showed almost immediate front leakage of sodium ion and very much more trailing than in the cæsium saturation curves. Moreover, for this concentration of saturating solution only 80 per cent of the exchange sites actually contained sodium ions when the curve showed that saturation should have been complete. This concentration of sodium chloride was inadequate to convert the natural clinoptilolite to the sodium form.

Monoionic sodium clinoptilolite was prepared by saturating a 2-gm. column with 1 litre of 1 *N* sodium chloride. Isotopic exchange curves on this material were similar to the ones obtained with cæsium. An exchange capacity determination using sodium on this material showed the exchange capacity to be identical to that previously obtained with cæsium. The exchange capacity of clinoptilolite is thus independent of which ion, cæsium or sodium, is used for measuring it.

Sorption from a mixed sodium–cæsium solution. The column can just as easily be saturated with a mixture of electrolytes as with a single cation. At saturation the clinoptilolite in the column is in chemical equilibrium with the mixture of sodium and cæsium ions in solution. The fraction of exchange positions held by cæsium, q/q_0, is a function of the relative concentration of cæsium to the total solution electrolyte concentration c/c_0, where q_0 is the total cation exchange capacity. A plot of q/q_0 versus c/c_0 at a given temperature is called an exchange sorption isotherm.

Exchange sorption isotherms were determined for cæsium–sodium exchange on clinoptilolite at two different temperatures, 50° and 75° C. This was done experimentally by saturating a series of columns with different ratios of cæsium and sodium ionic concentrations and then determining the composition of the total sorbed cations by the isotopic elution technique previously described. Cæsium is determined directly and the sodium by difference. Seven columns were used each containing 2·000 gm. clinoptilolite. Saturation solutions contained 5–95 per cent cæsium with a constant total electrolyte normality of 0·02 *N*. The cæsium was traced by adding cæsium-134. The lower the percentage of cæsium

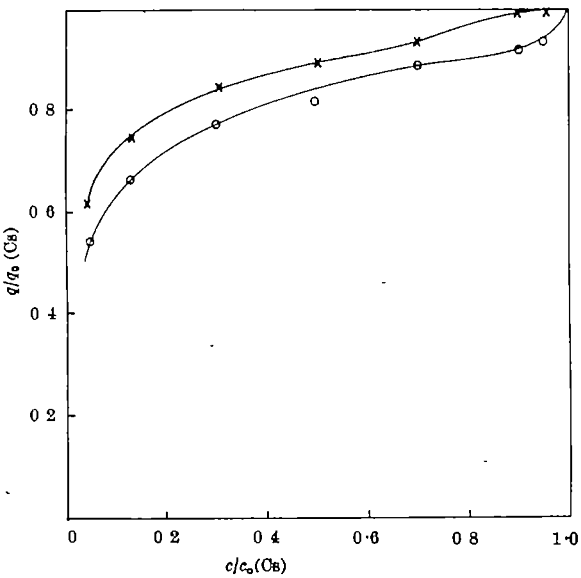

Fig. 1. Exchange sorption isotherm for the sodium–cæsium exchange reaction at 50° and 75° C. ×, 50° C.; O, 75° C.

the larger the amounts of solution which must be passed through the column to bring it to complete saturation. This is due to the high ratio of cæsium in the total amount sorbed even in the case of equilibrium with the low percentage cæsium solutions. A total of seven litres of the 5 per cent cæsium solution was required to equilibrate the column.

The exchange sorption isotherms for clinoptilolite (Fig. 1) show that for a solution of 5 per cent cæsium–95 per cent sodium a mixture of about 60 per cent cæsium–40 per cent sodium is sorbed on the clinoptilolite.

Equilibrium constants for the exchange reaction. From the data used in plotting the exchange sorption isotherms the thermodynamic equilibrium constant can be calculated[4]. For the reaction:

$$\mathrm{Na}^+ + \mathrm{Cs}M \rightarrow \mathrm{Cs}^+ + \mathrm{Na}M$$

$$K = \frac{M_{\mathrm{Cs}} N_{\mathrm{Na}} \gamma_{\mathrm{Cs}} f_{\mathrm{Na}}}{M_{\mathrm{Na}} N_{\mathrm{Cs}} \gamma_{\mathrm{Na}} f_{\mathrm{Cs}}} = K'_c \frac{\gamma_{\mathrm{Cs}} f_{\mathrm{Na}}}{\gamma_{\mathrm{Na}} f_{\mathrm{Cs}}} = K_c \frac{f_{\mathrm{Na}}}{f_{\mathrm{Cs}}}$$

where M equals molarity in solution, N equals mole fraction of ions sorbed on the mineral, γ equals activity coefficient of ion in solution, f equals activity coefficient of ion sorbed on exchanger.

In terms of the experimental quantities:

$$K'_c = \frac{(c/c_0)\,(1-q/q_0)}{(1-c/c_0)\,(q/q_0)} \simeq K_c \,.$$

K'_c is nearly equal to K_c in this case. For a uni-univalent system the quotient of single ion activities in a mixed electrolyte solution is nearly unity. Experimental data on the ion activities at these concentrations in this mixture are, of course, not available. They can be estimated from the Debye–Hückel equations. The only deviation of the quotient from unity in this case would be the contribution due to the slightly different 'a' parameter values for cæsium and sodium.

The thermodynamic equilibrium constant can be determined by integrating K_c over the whole sorbed phase concentration range.

$$\ln K = \int_0^1 \ln K_c \, d(q/q_0)$$

The values of $-\ln K$ and ΔF^0 for the sodium–cæsium exchange reaction at the two temperatures are given in Table 1. Based on these data the standard enthalpy change is $\Delta H^0 = 4{\cdot}92$ kcal./mole and the standard entropy change is $\Delta S^0 = 8{\cdot}98$ e.u.

Table 1. THERMODYNAMIC EQUILIBRIUM CONSTANT AND FREE ENERGY OF THE SODIUM–CÆSIUM EXCHANGE REACTION

T (°K.)	$-\ln K$	ΔF^0
323	3·15	2·02 kcal./mole
348	2·58	1·79

AN UNSTABLE RIBONUCLEIC ACID IN RAT LIVER NUCLEI

By DR. CHRISTOPH SCHOLTISSEK

Max-Planck-Institut für Virusforschung, Tübingen

ACCORDING to a widely accepted view, genetic information for protein structure is coded in the deoxyribonucleic acid (DNA) of the cell nucleus. Thereby DNA does not react directly but rather by an intermediate, believed to be ribonucleic acid (RNA).

Since an unstable RNA-fraction was found in rat-liver nuclei[1,2] and in a bacterial system a similar one (messenger RNA) could be demonstrated, which is more definitely involved in the transfer of genetic information from the DNA to the ribosomal particles (RNP)[3,4], it seems that such a messenger RNA appears in all living cells independently from which species the cells were derived.

This article is concerned with some regulation mechanism by which genetic information might be expressed in the cytoplasm of different organs in the same organism. Certain evidence is presented: (1) that the nuclei of different organs synthesize different kinds of messenger RNA; (2) that the cytoplasm of each organ selects and stabilizes different kinds of RNA molecules offered by the nuclei, depending on the cytoplasm of the organ under investigation.

When rat-liver nuclei, labelled *in vivo* with ^{14}C-orotic acid or phosphorus-32 for differing time-intervals, were incubated *in vitro* in a salt–sucrose medium[1], only about 15 per cent of the total nuclear RNA was lost to the supernatant, when compared with controls. In these experiments the nuclei were left intact[1]. Fig. 1 demonstrates the specific activity of the transferred RNA as a function of the labelling time *in vivo* (time between injection of the label and

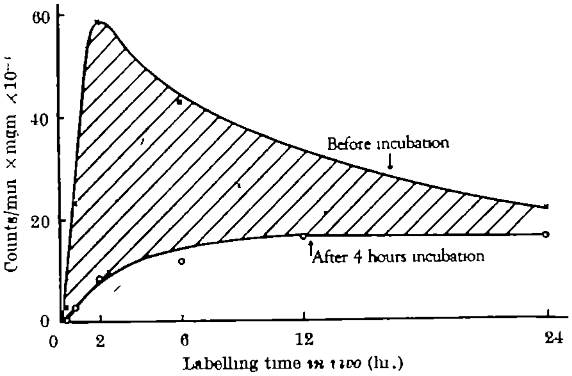

Fig. 1. Changes in the specific radioactivity of the removable nuclear RNA as a function of the labelling time *in vivo*. Rats were injected with ^{14}C-orotic acid and killed at the times indicated on the abscissa. The upper curve shows the specific radioactivity of the RNA of the non-incubated liver nuclei. The lower curve demonstrates the specific activity of the RNA which is stable within the nuclei after 4 hr. incubation *in vitro* in salt-sucrose

death of the rat). The lower curve represents the specific activity of that part of nuclear RNA which cannot be removed during 4 hr. incubation in fortified sucrose (stable RNA). The upper curve shows the specific activity of the nuclear RNA without incubating the nuclei. The removable RNA fraction appears during incubation first in the supernatant medium and is later degraded. The space between these two curves demonstrates the turn-over of the transferable RNA.

This transferable RNA with a high turn-over rate, which amounts to less than 5 per cent of the total cell RNA[1], has the following properties:

(*a*) The oligonucleotide pattern after digestion by RNase is completely different from that of the remaining nuclear RNA (Table 1) and also from the RNA of all other cell components. For the oligonucleotide pattern see refs. 5 and 6. The patterns usually showed variations from one animal to another, but the overall trend was always the same. Therefore, the figures of only one experiment are presented in each case.

Table 1. RADIOACTIVITY IN OLIGONUCLEOTIDES OF NUCLEAR RNA FRACTIONS OF RAT LIVER AFTER DIGESTION BY RNASE, COMPARED WITH URIDINE MONOPHOSPHATE (UMP OR U)

Ratio U/nucleotide	Nuclei after incubation	NPM	NS
C	0·75	1·15	1·00
AC	2·44	2·58	2·43
GC+AAC	1·18	1·41	1·32
GAC+AGC	1·10	1·25	1·32
AAU+AU	3·30	2·72	2·73

The nuclei were labelled *in vivo* by phosphorus-32 for 2 hr. and incubated in a salt-sucrose medium at 30° C. for 20 min. After incubation the nuclei were re-isolated and a postmicrosomal fraction (NPM) was spun down in the Spinco ultracentrifuge from the incubation medium. The final supernatant is called NS (refs. 1 and 2).

C, Cytidine monophosphate (CMP); A, adenosine monophosphate, G, guanosine monophosphate.

(*b*) After 15 min. incubation of nuclei labelled *in vivo* for 2 hr. this RNA appears mainly in a postmicrosomal (NPM) and soluble (NS) fraction[1].

(*c*) In the living animal one finds this RNA first in the nuclei, then in the PM-fraction and afterwards it disappears completely from the cell (Fig. 2). As can be seen from Table 1 the high-turn-over RNA is rich in UMP. For more detailed experiments see ref. 2.

(*d*) This RNA-fraction is very sensitive to degrading enzymes[1,2]. When liver nuclei labelled *in vivo* for 2 hr. were incubated in non-radioactive liver cytoplasm for 4 hr. *in vitro*, less than 5 per cent of the total RNA was degraded, but about 75 per cent of the radioactivity was lost.

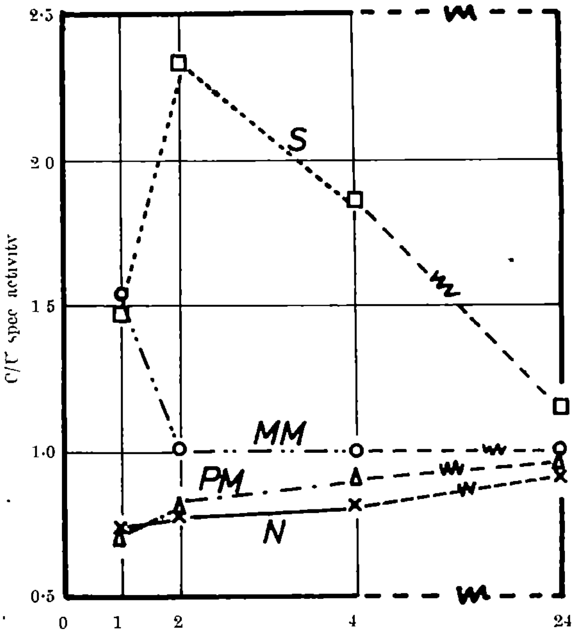

Fig. 2. Changes of the ratios of the specific radioactivities in UMP to CMP as a function of the labelling time *in vivo*. Rats were injected by phosphorus-32 and killed at the times indicated on the abscissa. The livers were homogenized and separated into the subfractions by centrifugation (refs. 1 and 2). *N*, nuclei, *MM*, mitochondria + microsomes; *PM*, postmicrosomes; *S*, final supernatant. The RNA of the final supernatant shows a high end-turn-over of the C-fraction (ref. 2)

(*e*) Its molecular weight is lower than that of the main nuclear RNA[1,2]. This was shown by stepwise degradation with snake venom diesterase. At the beginning of enzyme action the specific radioactivity of the remaining RNA was unchanged. Later, the specific activity dropped to a lower value. This drop was independent of the labelling time *in vivo* (at least from 1 hr. onwards). It seems clear that a highly labelled RNA of smaller molecular weight is used up by the enzyme faster than a rather inert RNA of higher molecular weight.

The foregoing properties of a nuclear RNA fraction of rat liver are very similar to the messenger RNA described by Brenner *et al.*[3] and Gros *et al.*[4] in a bacterial system.

The next question was whether the messenger RNA's of each organ in the same organism were identical or not. For this purpose rat spleen and kidney nuclei were labelled *in vivo* and incubated under the same conditions as the liver nuclei. Table 2 demonstrates that the ratios of the specific activities of CMP and UMP are less than 1 in the non-incubated nuclei of liver and spleen after digestion of their RNA. But the corresponding ratio of the kidney nuclear RNA was higher than 1. In the case of liver and spleen an RNA fraction rich in UMP migrates

Table 2. DIFFERENCES IN THE C/U-RATIOS OF INCUBATED AND NON-INCUBATED NUCLEI OF SPLEEN, KIDNEY AND LIVER

C/U-ratios after digestion by RNase	Spleen	Kidney	Liver
Specific radioactivity of non-incubated nuclei	0·83	1·10	0·74
Radioactivity of incubated nuclei	1·42	2·04	1·17
Radioactivity of supernatant after incubation	0·95	2·62	0·94

The nuclei were labelled *in vivo* for 2 hr. and incubated in salt-sucrose for 15 min. at 30° C.

Table 3. CHANGES IN THE OLIGONUCLEOTIDE PATTERN OF LABELLED RAT-LIVER NUCLEI DURING INCUBATION IN SALT-SUCROSE, NON-RADIOACTIVE KIDNEY OR LIVER CYTOPLASM, RESPECTIVELY

Ratio C/nucleotide	Incubation of rat-liver nuclei labelled *in vivo* for 2 hr. In salt-sucrose	In kidney cytoplasm	In liver cytoplasm
U	1·77	2 06	1·54
AC	3 96	4·92	3·14
GC	1·73	1·74	1 86
AAC	5 55	5 41	4·38

During incubation about 75 per cent of the labelled RNA was broken down The remaining RNA was almost stable. For more details see Table 1.

out of the nuclei during incubation *in vitro*. In contrast to this, the RNA removed during incubation of kidney nuclei contains more CMP[2]. This clearly demonstrates that the messenger RNA's of the three organs under investigation are not identical.

These results are in agreement with the concept that in each organ different genes are active[7], making different kinds of messenger RNA. Pelling[8] showed this directly by his autoradiographic studies on *Chironomus tentans*.

Another point investigated was whether the cytoplasm of each organ is able to select and to stabilize some of the genetic information (RNA) necessary for the function of that organ. Labelled rat-liver nuclei were incubated in fortified sucrose, non-radioactive liver or kidney cytoplasm, respectively[2]. Table 3 shows that although about 75 per cent of the labelled nuclear RNA is broken down during incubation (but less than 5 per cent of the total RNA), the remaining labelled RNA's (almost stable) differ from each other depending on the incubation medium used. The kidney cytoplasm selects a CMP-rich RNA; but the liver cytoplasm an UMP-rich RNA, compared with the RNA of the sucrose incubation. So it appears as if a real selection of some of the messenger RNA by the cytoplasm has taken place.

It is suggested that some messenger RNA is turned over very fast, some has a rather low turn-over rate and again some of the fast-labelled nuclear RNA may not be involved at all in transferring genetic information, but rather in regulation mechanisms. The messenger RNA with a high turn-over rate may be regulated by inducers or suppressors (for example, by hormones[9]), while the stable RNA may be responsible for enzymes or other proteins which cannot be induced or suppressed, but are also characteristic for each organ. A selection of a stable RNA may occur only if a template is present in the RNP particle to conserve the integrity of the messenger RNA. If such a template is not available, the RNA would be broken down. Such a mechanism could help to explain organ specificity and differentiation.

A mechanism, by which an RNA is selected by a pre-existing template, may also explain the carcinogenesis by some chemicals (for example, some azodyes) which do not react with nucleic acids themselves. If it is assumed that those templates consist of proteins and that their synthesis is directed by combination with a messenger RNA, azodyes may react competitively with one special template so that this is lost irreversibly after some time. A special genetic information can no longer be expressed and an irreversible change occurs in the cell without altering the DNA itself[3].

These experiments were performed at the McArdle Memorial Institute for Cancer Research, University of Wisconsin, Madison, and at the Institut für Experimentelle Krebsforschung der Universitat Heidelberg, Germany.

QUANTITATIVE ESTIMATION OF THE HYBRIDIZATION OF RABBIT ANTIBODIES

By PROF. A. NISONOFF and W. J. MANDY
Department of Microbiology, University of Illinois, Urbana

THE major product of the reaction of rabbit antibody with pepsin at pH 4·5 has an average molecular weight of 106,000 and a sedimentation coefficient of approximately 5 S, as compared with 160,000 and 6·5–7 S for the original molecule[1–3]. The pepsin-treated antibody is still bivalent, but is further split into two univalent, 3·5-S fragments, approximately equal in size, on subsequent reduction of a single, highly labile disulphide bond[4]. These fragments correspond closely in a variety of properties[2,5] to the active fractions of a papain digest, described by Porter[6], who first demonstrated the presence of sub-units in the antibody molecule. It was concluded[1–3] that the mechanisms of action of the two enzymes are similar, and that there are one or more regions of the molecule which are particularly susceptible to the action of papain or pepsin. Subsequent to the enzymatic hydrolysis the two univalent fragments are linked by the disulphide bond[2,4]. (Papain, being a sulphydryl enzyme, is used in conjunction with a reducing agent.) Cebra *et al.*[7] have recently degraded the rabbit antibody to 3·5-S fragments by successive treatments with papain, covalently linked to an insoluble polypeptide, and a reducing agent, providing further evidence for a similarity in mechanism of action of the two enzymes.

We recently reported[8] that the active chromatographic fractions of a papain digest, designated I and II[6], do not correspond to two sub-units of an individual molecule, but rather represent univalent fragments derived from different populations of globulin molecules; and that the univalent protein can be further subdivided by variation of the pH of elution. Nevertheless, there is considerable evidence[8] suggesting that the two univalent fragments of an individual molecule may be quite similar, as originally proposed by Porter[6].

The univalent, 3·5-S sub-units of a specifically purified rabbit antibody can be recombined in good yield by oxidation to give 5-S antibody which again has the capacity to form specific precipitates[8,9]. The fact that the sedimentation coefficient agrees very closely with that observed prior to reduction indicated that the re-oxidized, precipitating antibody is bivalent. When a mixture of approximately equal amounts of antibodies of two different specificities was used, the recombined product failed to form a precipitate with either antigen alone, but more than half precipitated when an appropriate mixture of the two antigens was used[10]. This suggested the presence of a large proportion of antibody of mixed specificity.

For random recombination of an equimolar mixture of two antibodies, the proportions of *A–A*, *B–B* and the hybrid, *A–B*, would be 1 : 1 : 2. Since *A–B* is univalent with respect to either precipitating system, it should act as a specific inhibitor. This would account for the failure to precipitate with a single antigen. A mixture of antigens, however, would be expected to form a continuous lattice when added to such a mixture of antibodies.

Although these observations could be explained on the basis of random recombination, the experiments did not show directly that such was the case. The present work was undertaken to provide another type of evidence as to the presence of hybrid antibody and to obtain a quantitative estimate of the degree of randomness of the recombination.

In brief, the method consisted in reducing and recombining a mixture of specifically purified rabbit anti-ovalbumin and anti-*p*-azobenzoate antibodies. The product was tested by treatment with an excess of an insoluble adsorbent specific for anti-ovalbumin. It was expected that hybrid antibodies as well as anti-ovalbumin would be removed by the adsorption, and that this could be demonstrated by measurement of the number of combining sites specific for the benzoate group remaining in the supernatant. The number of such sites remaining was estimated quantitatively by measurement of the capacity to bind labelled *p*-iodobenzoate. In addition, the adsorbent itself was re-suspended after exposure to the antibody preparation and tested for its capacity to bind the same hapten. Controls were carried out with mixtures of the two 5-*S* antibodies (not reduced), and mixtures of the two antibodies which were reduced and re-oxidized separately. The data provide additional evidence for the presence of hybrid antibody and suggest that the recombination is random.

Anti-*p*-azobenzoate antiserum was prepared in rabbits by the repeated injection of an antigen made by diazotizing *p*-aminobenzoic acid in acid solution and coupling to bovine γ-globulin at *p*H 9–9·5 in saline–borate buffer near 0° C.; 40 mgm. of *p*-aminobenzoic acid was used for each gm. of the bovine globulin. The product was dialysed against several 4-litre portions of cold saline–borate buffer at *p*H 8 over a period of about one week. Rabbits were immunized by intravenous injection of 10–15 mgm. portions of the antigen in 1–1·5 ml., administered three times weekly. After 6–8 weeks, weekly partial bleedings were carried out, each followed immediately by an injection of the antigen. A number of antisera of high titre was pooled and purified specifically as described elsewhere[11]. The final steps consisted in dialysing for one week with stirring in ¼-in. tubing against several 4-litre portions of cold buffer, followed by passage through a 7 × 200 mm. column of '*IR*-45' resin and dialysis against cold 0·1 *M* sodium acetate.

Methods used for immunization with ovalbumin are described elsewhere[5]. The antiserum was specifically purified by partial dissociation of a specific precipitate at *p*H 2·5, and fractionation at this *p*H with sodium sulphate[12].

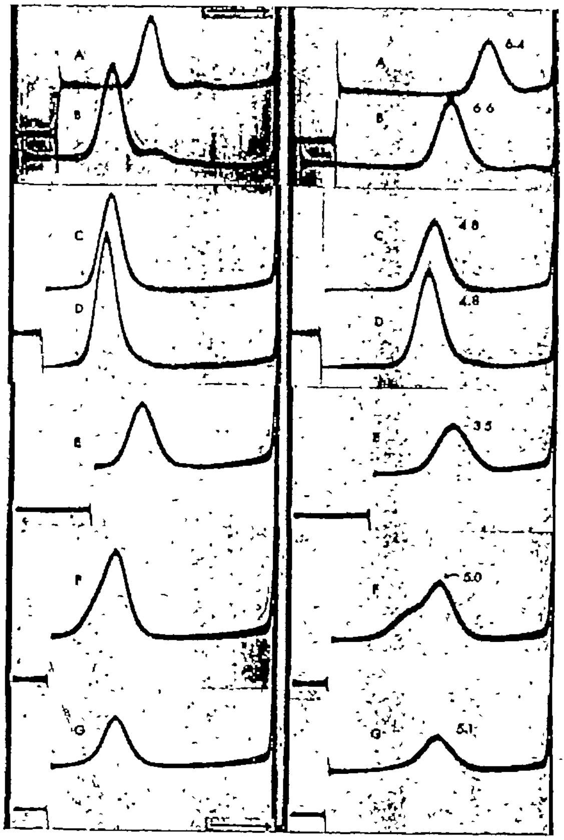

Fig. 1. Photographs of schlieren patterns obtained in the Spinco model *E* ultracentrifuge. Sedimentation is from left to right. Diagrams on left, 48 min. at 59,780 r.p.m.; diagrams on right, 80 min. The numerals are $S_{20,w}$ values. *A* and *B*, specifically purified anti-*p*-azobenzoate antibody and antiovalbumin, respectively; *C* and *D*, above samples, treated with pepsin, precipitated with sodium sulphate; *E*, mixture of equal amounts of above, pepsin-treated antibodies, reduced with mercaptoethylamine; *F*, above neutralized and oxidized; *G*, above precipitated with sodium sulphate. The solvent in each case was 0·1 *M* sodium acetate, *p*H 7·0 except for *E* (*p*H 5·0). (The difference in sedimentation coefficient of 3·5-*S* fragments at *p*H 5 and *p*H 7 is less than 0·2 units)

58 per cent of the antibenzoate and 88 per cent of the antiovalbumin were specially precipitable by a test antigen. The antigen used for testing the anti-hapten antibody was prepared by diazotizing and coupling *p*-aminobenzoic acid to ovalbumin (40 mgm./gm.) and purified by extraction with cold acetone and exhaustive dialysis. Ultracentrifugal patterns of the purified antibodies are shown in Fig. 1, *A* and *B*.

300 mgm. of the specifically purified antiovalbumin and 100 mgm. of the antibenzoate antibody were treated separately with 2 per cent by weight of crystallized pepsin, obtained from the Worthington Co. The reactions were carried out for approximately 6 hr. at 37° C., in 0·1 *M* sodium acetate buffer, *p*H 4·5. The major component was precipitated at *p*H 8·0 with sodium sulphate at a final concentration of 0·18 gm./ml., dissolved in water, and dialysed against 0·1 *M* sodium acetate. Recoveries of the antiovalbumin and anti-*p*-azobenzoate were 137 mgm. and 50 mgm., respectively, of which 72 and 49 per cent were specifically precipitable by an optimal concentration of test antigen. In the ultracentrifuge

at pH 7·0 each preparation migrated essentially as a single, 4·8-S peak (Fig. 1C and D).

20 mgm. portions of each of the pepsin-treated antibodies were mixed and reduced with 0·01 M mercaptoethylamine hydrochloride at 37° C., pH 5·0, for 75 min. In the ultracentrifuge the product now migrated as a single 3·5-S peak (Fig. 1E). After dialysis against saline–borate buffer, pH 8, 800 μgm. of this preparation caused more than 90 per cent inhibition of the precipitation of antiovalbumin γ-globulin with ovalbumin in amounts sufficient to yield 397 μgm. of precipitate in the absence of inhibitor. About 10 per cent inhibition was observed when 1·6 mgm. was present in a mixture containing 470 μgm. of precipitable antibenzoate and an optimal amount of the ovalbumin–p-azobenzoate test antigen. (The 1·6 mgm. corresponds to 0·8 mgm. of antibenzoate antibody.) (We have found that relatively large amounts of 3·5-S fragments are required for specific inhibition of the precipitation of antihapten antibody, as compared with various antiprotein antibodies tested. This is probably attributable to the large number of specific sites on each molecule of the azoprotein test antigen which must be saturated to prevent further reaction with the untreated antibody. A similar explanation may account for the poor inhibition of the homologous reaction by 3·5-S fragments of rabbit antipneumococcus antibody[6].)

The remainder of the reduced material, 35 mgm., was passed through an 8 × 175 mm. column of 'IR-120' resin at pH 4·5 in the cold room in order to remove the positively charged reducing agent. This was done immediately after the treatment with mercaptoethylamine. The bulk of the eluate, containing 31 mgm., was neutralized to pH 8·0 and oxygen was passed over the surface, with stirring, for 2 hr. After dialysis, the sample was treated with oxygen again for approximately 2 hr. and examined in the ultracentrifuge. The solvent was 0·1 M sodium acetate, pH 7·0. It was found (Fig. 1F) that 70 per cent of the material now migrated as a 5·0-S peak (The actual degree of recombination was probably somewhat higher since no correction was made, in measuring areas, for the Johnston–Ogston effect.) After precipitating with sodium sulphate (final concentration 0·16 gm./ml.), washing with sodium sulphate of the same concentration, dissolving and dialysing against 4 litres of 0·1 M sodium acetate, pH 7, the protein migrated essentially as a single 5·1-S peak (Fig. 1G).

To test for hybridization, adsorptions were carried out with an ovalbumin–rabbit antiovalbumin precipitate prepared with an amount of antigen approximately 50 per cent greater than the optimum. The precipitate was first washed repeatedly with saline–borate buffer, suspended in the buffer and dispersed by brief treatment in a tissue grinder. Before removing a sample the suspension was re-dispersed and stirred. Prior to use, aliquots of the suspension were washed three or four times, re-suspended in 1 ml. buffer, agitated for 45 min. with a mechanical shaker, centrifuged, and the optical density of the supernatant was determined at 280 mμ. This process was repeated several times until small and fairly constant amounts of protein were eluted; less than 0·04 mgm. from 8 mgm. of precipitate or 0·1 mgm. from 16 mgm. In determining amounts of protein removed from samples in the subsequent adsorption experiments, corrections were made for the estimated elution that occurred during the shaking period.

The material to be adsorbed was then added to the washed precipitate. The precipitate was re-suspended and the volume of the mixture was adjusted to 1·0 ml. in a graduated tube. After 45 min. of mechanical shaking the mixture was centrifuged, the optical density of the supernatant at 280 mμ was measured, and its capacity to bind p-iodobenzoate labelled[13] with iodine-131 was determined by equilibrium dialysis at 5·0° C. The methods used for measurement of binding have been described in detail[14]. Amounts of radioisotope were determined in a well-type γ-scintillation spectrometer.

The amount of ovalbumin–antiovalbumin precipitate to be used for the adsorption was determined by preliminary experiments, using the decrease in optical density at 280 mμ as a measure of adsorption. It was found that 8 mgm. of precipitate represented an excess of adsorbent for 1·6 mgm. of the re-oxidized mixture. A maximum of 60 per cent of the protein could be removed by the adsorbent.

In the first experiment 8 mgm. of adsorbent was mixed with 1·6 mgm. of the re-oxidized mixture of antibodies in a total volume of 1·0 ml. The mixture was shaken for 45 min., then centrifuged. The effect on capacity to bind p-iodobenzoate is shown in Table 1. Binding experiments were carried out in duplicate with the mean deviations indicated. (A number of samples was dialysed together against a common outer solution so as to permit comparisons with the free hapten concentration constant. Also, the use of

‡ Equilibrium dialysis at 5·0 ± 0·1° C. Free hapten concentration, 6·4 ± 0·1 × 10^{-6} M. Binding experiments in duplicate, with average value of mean deviations for the concentration bound of 0·14 × 10^{-6} M. A number of samples was dialysed together against a relatively large volume of a common outer solution. The results in the table were obtained in three separate equilibrium dialysis runs. Solutions were buffered with saline–borate, pH 8·0, ionic strength 0·16.

§ The adsorbent was washed twice after the adsorption with small amounts of buffer, then suspended in a total volume of 1·0 ml. of saline–borate buffer, pH 8, ionic strength 0·16, for equilibrium dialysis.

‖ Corrected for binding by untreated adsorbent.

a large volume of outer solution permitted accurate control of the final free hapten concentration.)

With a free hapten concentration of $6·5 \times 10^{-6}$ M, the concentration bound by the unadsorbed, re-oxidized mixture (1·6 mgm./ml.) was $4·8 \times 10^{-6}$ M (Exp. 1, Table 1). The concentration of hapten bound by the supernatant after adsorption was $2·9 \times 10^{-6}$ M, which represents a decrease of 39 per cent (Exp. 2, Table 1).

The adsorbent used was then washed twice with small amounts of saline–borate buffer and re-suspended in the same buffer, added to a final volume of 1·0 ml. Binding of hapten by the suspension, dialysed to equlibrium in the same vessel as the supernatant, was $1·7 \times 10^{-6}$ M (Exp. 2, Table 1). Correcting this for binding by the untreated precipitate ($0·3 \times 10^{-6}$ M), we obtain the value $1·4 \times 10^{-6}$ M for concentration bound by the precipitate due to adsorption of the hybrid antibody.

When 16 mgm. of adsorbent was used (Exp. 3, Table 1), binding by the supernatant decreased to $3·2 \times 10^{-6}$ M and that of the washed, re-suspended adsorbent, corrected for binding by untreated adsorbent was $1·7 \times 10^{-6}$ M.

As a control, a mixture of the pepsin-treated (5-S) antiovalbumin and antibenzoate antibodies, each at a concentration of 0·8 mgm./ml., was similarly adsorbed. In this case a maximum of 46 per cent of the protein was adsorbable. With 8 mgm. of adsorbent, there was a small increase in binding, after removal of the adsorbent, from 5·5 to $5·9 \times 10^{-6}$ M (Exps. 5 and 6, Table 1). This is probably attributable to experimental error since significant increases were not observed in any other experiments. Only a slight increase in hapten-binding capacity was observed when the adsorbent used was re-suspended and tested ($0·5 \times 10^{-6}$ M bound as compared with $0·3 \times 10^{-6}$ M for the untreated adsorbent).

Similar results were obtained when 16 mgm., rather than 8 mgm., of adsorbent was used with the mixture of 5-S antibodies (Exp. 7, Table 1). The concentration of hapten bound after adsorption was $5·6 \times 10^{-6}$ M; the concentration of hapten bound by the washed, re-suspended precipitate used for the above adsorption was $0·5 \times 10^{-6}$ M, which was the same as that obtained with 16 mgm. of the unused adsorbent. The results thus indicate that little or no hapten-binding capacity is removed from a mixture of the two 5-S antibodies by the adsorbent.

The possibility was considered that the removal of hapten-binding capacity from the re-oxidized mixture by an adsorbent specific for antiovalbumin might be due, not to hybridization, but to some non-specific affinity for the adsorbent acquired by anti-hapten antibody during reduction and re-oxidation. To examine this question another batch of specifically purified anti-p-azobenzoate antibody was treated in the same manner as described above to yield in succession 5·2-, 3·5- and 5·3-S antibody ($S_{20,w}$ values). Similarly, 4·8-S antiovalbumin was reduced to 3·5-S, re-oxidized and fractionated with sodium sulphate to give 5·0-S antibody. Equal weights of the two protein preparations were mixed and adsorbed with the ovalbumin–antiovalbumin precipitate. The concentration of each antibody in the mixture was 0·8 mgm./ml. and 16 mgm. of precipitate was used. Measurements of optical density at 280 mμ indicated that 45 per cent of the protein was removed. However, there was a negligible effect on the capacity to bind ^{131}I-p-iodobenzoate. At a free hapten concentration of $6·3 \times 10^{-5}$ M the concentration bound by the mixture of reconstituted antibodies was $4·3 \times 10^{-6}$ M. After adsorption this value was $4·2 \times 10^{-6}$ M (Exps. 8 and 9, Table 1). There was no significant binding by the washed, re-suspended precipitate that had been used for the adsorption. (The concentration bound by the reconstituted antibenzoate alone, 0·8 mgm./ml., without added antiovalbumin, was $4·3 \times 10^{-6}$ M). Also, under the conditions of the above experiments, less than 5 per cent of the optical density at 280 mμ was removed when the reconstituted antibenzoate antibody alone was treated with 16 mgm. of adsorbent.

The evidence is now convincing that antibody of mixed specificity is formed in significant amounts when a mixture of two purified 5-S antibodies is reduced and re-oxidized. When pepsin-treated antiovalbumin and antibovine γ-globulin were mixed and treated in this way, the product failed to form precipitates with a single antigen but did precipitate when a mixture of antigens was used[10]. As indicated in the introduction, this was consistent with the presence of a large fraction of hybrid antibody. It contrasted with the results obtained when a single antibody is reduced and re-oxidized; three different rabbit antibodies have now been tested and precipitating activity found to be restored in each case[5,9]. The present results provide further evidence for hybrid formation and in addition permit an estimate as to the amount produced.

On the assumption that activities are proportional to concentrations, the concentration of hapten bound by a homogeneous group of binding sites should be directly proportional to the total concentration of sites, if the free concentration of hapten is held constant. This will be true of a heterogeneous, as well as a homogeneous population of sites, provided that the distribution of K values is not changed as the concentration of sites is varied[15]. Since it appears unlikely that hybridization, or adsorption by the ovalbumin–antiovalbumin precipitate, would be selective with respect to the combining affinities of the antihapten sites, the condition that the distribution of K values not be changed during the adsorption probably holds. Also the free hapten concentration was essentially constant in the various binding experiments. We will therefore make the assumption that the observed concentration of hapten bound was directly proportional to the concentration of combining sites remaining. On this basis, the fraction of combining sites remaining after adsorption of the reconstituted mixture of antiovalbumin and antibenzoate was 61 per cent when 8 mgm. of adsorbent was used, and 67 per cent with 16 mgm. of adsorbent. No significant reduction in the concentration of hapten-binding sites was observed when a mixture of the 5-S antibodies, or a mixture of 5-S antibodies, that had been reduced and re-oxidized separately, was similarly adsorbed.

After adsorption of the hybridized mixture, a large fraction of the binding capacity removed was found in the washed adsorbent. The total recoveries of binding sites, again assuming direct proportionality with concentration of hapten bound, were 89 and 102 per cent for the experiments in which 8 mgm. and 16 mgm. of adsorbent were used (Exps. 2 and 3, Table 1). The adsorbent did not acquire any significant capacity to bind hapten on exposure to a mixture of the 5-S antiovalbumin and antibenzoate antibodies (Exps. 6 and 7) or to the mixture of separately reduced and re-oxidized antibodies (Exp 9).

No appreciable concentration of faster-moving components was observed in any of the re-oxidized materials. The close correspondence in sedimentation coefficient to that observed prior to reduction strongly suggests that all, or nearly all, the hybrid molecules were bivalent.

It is useful to compare the results with those expected for random recombination of a hypothetical mixture of equal quantities of two completely purified antibodies. As already indicated, the proportions of *A–A*, *B–B* and *A–B* would be 1 : 1 : 2; and if *B* represents an antihapten and *A* an antiovalbumin combining site, half the antihapten sites would be present on hybrid molecules. The same conclusion would hold, regardless of the amount of antibenzoate antibody present, provided that half of the sub-units available for recombination contained an active antiovalbumin site; that is, the fraction of antihapten sites hybridized should depend on the number of antiovalbumin sub-units present. As already indicated, 72 per cent of the 5-*S* antiovalbumin was specifically precipitable. If the remaining 28 per cent represents inactive, but reducible molecules, and if recombination is random, 36 per cent (72/2) of the antihapten sites should have been present on molecules also having a site specific for ovalbumin. This probably represents a lower limit since some of the non-precipitating 5-*S* antiovalbumin may have had an active site; also, the precipitation reaction may not go to completion. The expected upper limit is 50 per cent. The results of the adsorptions, in which 33 and 39 per cent of the hapten binding capacity was removed from the supernatants, are thus in fairly good agreement with those predicted on the basis of random recombination. The results are not precise enough to permit the conclusion that the recombination is completely random. However, they are consistent with this possibility and, in any event, show that there is no pronounced bias toward recombination of sub-units of like specificity.

The fact that a large part of the binding capacity removed on adsorption was found on the adsorbent indicates that there is little steric inference with access of the hapten to the antihapten sites on adsorbed antibody molecules. However, there was no reason to believe, *a priori*, that adsorbed molecules would remain completely accessible or be unchanged with respect to their binding constants. Therefore, the values for the fraction of binding sites removed, used in the discussion above, were based on the binding capacity remaining in the supernatant, rather than on that acquired by the adsorbent.

Deutsch and Morton[16,17] have found that the action of reducing agents on 18-*S* human macroglobulins results in a decrease in sedimentation coefficient to about 6–7 *S* and that these fragments re-aggregate on removal of the reducing agent. (No enzymatic digestion is required in this case.) Also, Jacot-Guillarmod and Isliker[18] have recently obtained evidence for the presence of human macroglobulins of mixed anti-blood group A and anti-B specificity, following reduction and re-oxidation of a mixture of the two purified antibodies. The possibility is suggested that the linkage of sub-units of antibodies may represent a general mechanism for constructing molecules of higher valence. Hsiao and Putnam[19] have demonstrated that the γ-globulins of various species can be degraded to 3·5 *S* by the action of papain, suggesting that important structural features are common to the various γ-globulins.

ROLE OF THIAMINE AND AMINO-ACIDS IN THE NUTRITION OF *SHIGELLA SONNEI*

By Prof. MITSURU NAKAMURA and BONNIE L. PITSCH*

Department of Botany, Microbiology, and Public Health, Montana State University,
Missoula, Montana

INVESTIGATIONS of the nutritional requirements of *Shigella* grown in chemically defined media have been carried out by Koser *et al.*[1–4], Kligler and Grosowitz[5] and others[6]. Since then chemically defined media for *Shigella* contained inorganic salts, glucose, nicotinic acid and various amino-acids. Erlandson and Mackey[7] studied a large number of amino-acids and inorganic nitrogen compounds for their activity on the growth of *Shigella flexneri* in a synthetic medium. They found that aspartic acid yielded maximal growth of *S. flexneri*. Mizuno and Kosaka[8] reported that glutamic acid was an essential amino-acid for *S. dysenteriae*. Johnson and Mays[9] reported on a strain of *S. dysenteriae* which required the amino-acid proline. In addition to nicotinic acid, pantothenic acid[6], uracil[10], and purines[11] have been reported as growth requirements for certain strains of *Shigella*. Kligler *et al.*[12] reported that thiamine and nicotinic acid allowed better growth of *Staphylococcus aureus* than nicotinic acid alone. The medium used by Erlandson and Mackey[7,13], which also supported the growth of *S. sonnei*, contained thiamine.

---

* U.S. Public Health Service Predoctoral Fellow (*BF*-10,159).

The purpose of this work was to determine whether or not thiamine was an absolute requirement for *S. sonnei* and to examine the role of amino-acids in the nutrition of this organism. The reason we undertook this investigation was that we felt that it is important to determine the minimum requirements for the growth of this organism in a chemically defined medium in order that the medium may be more competently used for: (*a*) assay of chemotherapeutic agents; (*b*) studies on the nutritional requirements of the *Shigellae*; (*c*) the detection of mutants possessing special growth-factor requirements.

Nineteen strains of *S. sonnei* were included in this work. They were constantly checked morphologically, biochemically and serologically for purity. Cells used for inoculation of the experimental tubes were prepared by growing at 37° C. for 48 hr. on nutrient agar ('Difco') slants, washing 3–5 times in buffered saline, and re-suspending to the desired concentration in buffered saline. The cell suspensions were decimally diluted and used for the inocula; initial counts of the inocula were determined by pipetting 0·1 ml. of the diluted cell suspensions on to nutrient agar plates, spreading over the entire surface of the agar with a bent-glass 'hockety stick', incubating aerobically for 24 hr. at 37° C., and counting the bacterial populations on the Quebec darkfield colony counter. Growth of the bacteria in the test media was determined by pipetting 0·1 ml. of the cell suspensions into test tubes containing 9·9 ml. of media yielding a final volume of 10 m. The tubes were incubated at 37° C. for 24, 48, 72 and 96 hr., transferred to cuvettes, and read in the Coleman junior spectrophotometer with the wave-length set at 575 mμ. The second method of enumerating the bacterial populations in the test media consisted of removing 0·1 ml. from the growth tubes, plating on nutrient agar and counting the numbers of colonies that developed. The third method of determining growth of the organisms in the test media containing factors being assayed consisted of placing 0·1 ml. of the washed inocula on solid synthetic medium plates, spreading the cells, incubating and counting the colonies. It was found that all three of these methods must be used to ensure obtaining of competent data.

The chemically defined medium of Erlandson and Mackey[7,13] contained 0·067 *M* dipotassium phosphate, 0·067 *M* monopotassium phosphate, 1 per cent glucose, 0·05 per cent magnesium sulphate, 0·03 per cent thiamine hydrochloride, 0·85 per cent sodium chloride, 0·001 per cent nicotinic acid, and 0·25 per cent aspartic acid. The medium was prepared with distilled, de-ionized water, adjusted to *p*H 7·0 with concentrated sodium hydroxide or phosphoric acid, and autoclaved at 15-lb. pressure for 15 min. The glucose was sterilized by filtration and added aseptically to the autoclaved medium. Studies with solid synthetic media were performed with the synthetic medium to which 1·5 per cent 'Bacto-Agar' ('Difco') was added. The highest-grade chemicals commercially available were used throughout the work. Experiments were performed in the synthetic medium not containing thiamine, in the synthetic medium not containing aspartic acid, and in synthetic media containing various amino-acids tested singly and in combination.

Inocula of varying sizes were used for the experiments. It was found that a minimum of 10^3 cells were required to ensure growth in 100 per cent of the tubes of synthetic media. All experiments were performed in duplicate and repeated 2–3 times. The results presented are average values from all the experiments.

Eighteen of the 19 strains of *S. sonnei* grew well in the absence of thiamine, and could be sub-cultured indefinitely in synthetic media lacking this vitamin. It can be seen from Table 1 that growth, as measured in the spectrophotometer, was not materially affected by the presence or absence of thiamine nor did the concentration of thiamine alter the growth (at 24 and 48 hr.).

Table 1. EFFECT OF THE CONCENTRATION OF THIAMINE ON THE GROWTH OF *S. sonnei* in SYNTHETIC MEDIA*

Concentration of thiamine (μgm./ml.)	Optical density† 24 hr.	Optical density† 48 hr.
0	0·54	0·70
0·3	0·49	0·69
3	0·48	0·74
33	0·52	0·66
330	0·55	0·59
1,000	0·46	0·72
5,000	0·53	0·71
10,000	0·44	0·65

* Data were similar regardless of the size of the inocula.

† Optical density was measured spectrophotometrically, wave-length 575 mμ.

Table 2. EFFECT OF THE CONCENTRATION OF ASPARTIC ACID ON THE GROWTH OF *S. sonnei* IN SYNTHETIC MEDIA

Concentration of aspartic acid (μgm./ml.)	Optical density at 575 mμ at 48 hr. Size of inocula 1×10^2 cells/ml.	1×10^3 cells/ml	1×10^4 cells/ml.
0	0	0	0
155	0	0	0
310	0	0	0·005
620	0·01	0·05	0·345
1,000	0·13	0·49	0·66
2,500	0·32	0·60	0·69
5,000	0·51	0·62	0·59
10,000	0·57	0·61	0·62

Aspartic acid was present in the synthetic medium at a concentration of 2,500 μgm./ml.; however, concentrations of 1,000–10,000 μgm./ml. were tested. Table 2 shows the relationship between concentration of aspartic acid and growth. Clearly, there is a relationship between the two. Up to a point, increasing concentrations of aspartic acid yielded increased growth of *S. sonnei*. Furthermore, when the size of the inocula was small greater concentrations of aspartic acid were required to produce good growth. As the size of the inocula was increased less aspartic acid was required to produce growth. This illustrates the importance of using small inocula in studies dealing with growth-factor requirements of micro-organisms in synthetic media. *S. sonnei* cannot be maintained in cultures by sub-cultivation unless 620–1,000 gm./ml. aspartic acid is present.

Table 3. GROWTH OF *S. sonnei* IN SYNTHETIC MEDIA CONTAINING VARIOUS AMINO-ACIDS

Amino-acids present (1,000 gm./ml.)	Optical density 575 mμ, at 48 hr.
L-Aspartic acid	0·50
L-Asparagine	0·73
L-Glutamic acid	0·82
L-Glycine	0·06
L-Tryptophan	0·06
L-Arginine	0·01
L-Glutamine	0·01
Aspartic acid + glycine	0·49
Aspartic acid + tryptophan	0·51
Aspartic acid + arginine	0·61
Aspartic acid + glutamine	0·59
Aspartic acid + glycine, tryptophan, arginine and glutamine	0·60

The growth of *S. sonnei* in synthetic media containing other amino-acids is tabulated in Table 3. These results were obtained from cultures inoculated with inocula containing 1×10^3 cells/ml. It should be emphasized that since the volume of the inocula was 0·1 ml., the total number of cells inoculated into the tubes was approximately 1 × 10^3 cells. L-Asparagine, L-glutamine, L-glycine, L-tryptophan, L-arginine and L-glutamic acid were studied in addition to L-aspartic acid. L-Asparagine and L-glutamic acid produced better growth than L-aspartic acid when tested in the synthetic medium at comparable concentrations. Glycine, tryptophan, arginine, and glutamine yielded less growth than aspartic acid. This is in conflict with the data of Erlandson and Mackey[7], who reported that asparagine and glutamic acid produced poorer growth compared with aspartic acid when *S. flexneri* was examined. Growth was not materially increased when aspartic acid was combined with the less active amino-acids. We agree with the conclusions of Erlandson and Mackey[7] that combinations of amino-acids, which some workers have indicated as necessary for growth, may function in a stimulatory rather than an essential role in the nutritional requirements of *Shigellae*. We believe that this chemically defined medium is an excellent tool for the study of nutritional variants of *Shigellae*.

Oxythiamine hydrochloride, a chemical analogue of thiamine, did not inhibit *S. sonnei*. Cocarboxylase, one of the probable metabolites of thiamine synthesis, did not materially affect growth of this organism.

ETHYLENE PRODUCTION BY SUB-CELLULAR PARTICLES FROM TOMATOES

By G. RAM CHANDRA and PROF. MARY SPENCER

Department of Biochemistry, University of Alberta, Edmonton, Canada

ETHYLENE has been identified as the main olefinic volatile produced by fruits during ripening[1,2]. However, controversy has developed regarding attempts by many laboratories to prepare cell-free systems capable of ethylene evolution. Early work in this field suffered from lack of a sensitive, specific method for ethylene assay, and also from the possibility of contamination of the tissue with ethylene-producing micro-organisms[3]. More recently[4] this laboratory reported the production of ethylene by mitochondria from tomatoes. Meigh *et al.*[5] were not able to obtain ethylene from sub-cellular fractions from either tomatoes or apples, but they used methods that differed from ours. Lieberman and Craft[6] detected extremely small amounts of ethylene when thiomalic or thioglycollic acid was added to particles (from apples and tomatoes) prepared in an acidic medium. Burg and Burg[7], using gas chromatography for identification, claimed that the volatile substance produced by the 'acidic' particles of Liberman and Craft was not, in fact, ethylene.

We have now been able to detect the sites of ethylene-evolving systems and to isolate sub-cellular fractions which are quite active in ethylene production. Moreover, we have been able to show that its production is associated with disintegration of sub-cellular particles. When these are aged *in vitro*, or sonically treated, the ethylene-producing system is activated. This discovery offers an explanation for the discrepancies in results from various laboratories. It also poses rather interesting questions with respect to the production and the role of ethylene *in vitro*.

A critical point in obtaining active fractions lies in the method of washing the particles and suspending them in the buffer-substrate mixture. In both these steps, in our earlier work[4], according to common practice, we used a Servall Omnimixer at very low speeds (25–30 V. on the powerstat) for 1–2 min. in the cold. We noted that this procedure produced some unavoidable fragmentation of particles. Omission of Omnimixer washing of the particles and use of the instrument only to suspend them in the final reaction mixture gave particulate fractions more active in ethylene production. (Very gentle washing of the particles with the help of a glass rod had no measurable effect on ethylene production.) In the washings by use of the Omnimixer many of the particle fragments were inevitably discarded, and later work showed that these fragments were primarily responsible for the initial ethylene production. It must also be borne in mind that even the most careful use of an Omnimixer or equivalent instrument causes a certain amount of frothing and, possibly, protein denaturation.

In the present investigation the procedures for isolation of different cellular fractions were based on the one we reported previously[4]. In all experiments we used frozen tomato fruit ('*V*121') in the advanced turning stage, since ethylene evolution has been shown to be at a maximum at this time[8]. The initial grinding of the tissue was done in 0·5 *M* sucrose–0·5 *M* potassium dihydrogen phosphate buffer of *p*H 8·0, and this resulted in a homogenate of *p*H 7. Cell fragments, chloroplasts and nuclei were obtained by centrifugation at 4,000*g* for 7 min. of the homogenate from 900 gm. of tomatoes. As a routine procedure, mitochondria were sedimented at 35,000*g* for 15 min. We found (Table 1) that a centrifugal force of 15,700*g* was sufficient to separate this fraction, but 35,000*g* gave additional active particles packed into easily handled pellets. The obvious advantage of isolation of the fraction at 35,000*g* for 15 min. as a

Reaction mixture: 0·5 *M* sucrose, 0·125 *M* KH_2PO_4, 10^{-3} *M* $MgSO_4$, 10^{-3} *M* $MnSO_4$, 0·05 *M* L-malic acid, adjusted to *p*H 7·0 with sodium hydroxide. This mixture was sterilized prior to use; $1·98 \times 10^{-3}$ *M* adenosine triphosphate and $3·3 \times 10^{-4}$ *M* diphosphopyridine nucleotide were added after sterilization.

* Cell fragments, nuclei and chloroplasts were removed by a preliminary centrifugation at 4,000*g* for 7 min.

routine preparative procedure was higher ethylene production. The amount of ethylene produced by the sonically treated 35,000*g* fraction during the first 4 hr. (0·174 µl./mgm. nitrogen, Table 6) is comparable with the sum total of ethylene produced by the sonically treated 15,710*g*, 22,620*g* and 35,000*g* fractions (0·142 µl./mgm. nitrogen, Table 1). Another fraction, separated at 40,210*g* for 15 min., undoubtedly consisted of a mixture of fragmented mitochondria and microsomes (fragments of endoplasmic reticulum). (When a 'combined mitochondria-microsomes' fraction was used, it was obtained by direct centrifugation, at 40,210*g* for 45 min., of the supernatant from the separation performed at 4,000*g*). The remainder of the 'microsomes' was sedimented at 105,000*g* for 10 min. The soluble fraction was the supernatant liquid remaining after this centrifugation.

The different cellular fractions (unwashed) were suspended in 25 ml. of buffer-substrate mixture of the composition shown in Table 1. For preparation of 'intact' and 'sonically treated' fractions, the particles were suspended directly in the reaction mixture with the help of a glass rod followed by a magnetic stirrer operated at low speed. Sonically treated particles were subjected to 4 min. in a 250 W., 10 kc./s. Raytheon sonic oscillator turned to 1·1 amp., at 2° C. 'Partially disintegrated' fractions were prepared by suspension of the particulate fractions in the buffer-substrate mixture by the use of a Servall Omnimixer run at a very low speed, at 2° C. These fractions were similar to those reported in our earlier work[4].

Ethylene collection was made from at least 20 ml. of the particle–buffer-substrate suspension maintained at 25° C.; the remainder was used for manometric measurement[9] of carbon dioxide production. Ethylene was accumulated for different time-intervals at 0° C. in mercuric perchlorate (0·25 *M*) = perchloric acid (2 *M* solution). The micro-apparatus for quantitative ethylene absorption was essentially the same as that described previously[10], with precautions being taken to maintain an air flow-rate of 25 ml./min. and a 10–13 cm. column of finely foaming mercuric perchlorate solution. With this collection system it was possible to recover 100 per cent of microlitre quantities (0·01–1·0 µl.) of ethylene.

The ethylene collected in the mercuric perchlorate was quantitatively determined by a gas chromatographic procedure[11]. In the gas chromatographic unit balanced columns of squalane-impregnated firebrick and a hydrogen flame ionization detector[12] were used. We obtained the greatest sensitivity compatible with a working stability by use of a mixture of nitrogen and hydrogen each at a flow-rate of 15 ml. per 2·6 sec. With this flow-rate of carrier gases it was also possible to effect very good separation of ethylene from other low-molecular-weight hydrocarbons and from carbon dioxide and air. Ethylene was quantitatively liberated from the mercuric perchlorate collection solution by addition of one-quarter volume of 4 *M* lithium chloride. The gas was liberated inside serum bottles of known volume, and representative samples were drawn into a gas-tight syringe and injected into the column for analysis. With this method we obtain 100 per cent recoveries of ethylene in concentrations of 0·01–1·0 µl./ml. of gas sample. Values less than 0·01 µl./ml. are reported as 'traces'. Standards for gas chromatography were prepared by serial dilutions of stock solutions of ethylene mercuric perchlorate which had been standardized manometrically[3,10]. Standards were found to be stable for one week at 5° C. and unknowns were analysed within one week of their collection. Nitrogen in the particulate suspension was estimated by the micro-Kjeldahl method[13].

In our earlier work[4] we used a micromanometric method[10] for analysis of ethylene. However, with the amounts of ethylene obtained from cell-free systems, we were working at the limits of accuracy of this procedure, and it was obvious that for quantitative comparisons we would have to turn to a more sensitive procedure such as flame ionization detection. The manometric analysis, which is specific for olefinic hydrocarbons[3], and mass spectrographic analysis have been used in the present experiments to provide qualitative corroborating evidence that we are, in fact, dealing with ethylene. Moreover, negative results for ethylene in mercuric perchlorate solutions, aerated at the rate of 25 ml./min. for 4–16 hr. in our collection assembly, eliminated all possibility of contamination. In none of our gas chromatographic and mass spectrographic analyses have we found evidence for the presence of any olefinic volatile besides ethylene. It should be noted that figures for ethylene reported in this article have been obtained from gas chromatographic analysis of collections made in mercuric perchlorate solution, and liberated by addition of lithium chloride, a procedure specific for olefinic hydrocarbons. Burg and Burg[7], on the other hand, injected the complete mixture of gases evolved by the particles directly into the gas chromatograph. Moreover, they found that the 'ethylene-like' substance of Lieberman and Craft was not absorbed by mercuric perchlorate, although authentic ethylene was. (Neither Meigh *et al.*[5] nor Lieberman and Craft[6] have stated either the method or time they used for ethylene collection.) It is therefore evident that in our analysis we are dealing with a true olefinic hydrocarbon, and not with the "ethylene-like substance" noted by Burg and Burg[7]. Moreover, these authors did detect minute amounts of true ethylene from their acidic particles, although they were prepared under very different conditions from those we had reported. As further indication that we were in fact dealing with ethylene, mass spectrographic analysis showed that the gas collected by our technique exhibited peaks characteristic of ethylene. Further confirmation was obtained by co-chromatography with known ethylene and disappearance of chromatographic peaks when the gas was passed through columns of brominated activated carbon. Huelin and Kennett[14] showed that normal olefines from propylene to hexene were not present in proportions exceeding one part of higher olefine to 1,000 parts of ethylene in apple volatiles collected in mercuric perchlorate. They indicated that branched chain or multi-unsaturated hydrocarbons would not be regenerated with ethylene from the mercuric perchlorate solution on addition of lithium chloride, and they could find no evidence of saturated hydrocarbons.

Experiments on the effect of the physical state of the particles on ethylene evolution were conducted, and results are summarized in Tables 2–6. It will be seen (Table 2) that intact mitochondria do not produce detectable amounts of ethylene during the first 4 hr., but as the reaction time progresses, they presumably disintegrate and ethylene evolution occurs. The partially disintegrated mitochondria (which were prepared similarly to those reported in our earlier work) produce much of the ethylene during the first 4 hr., as do the sonically treated particles. Markedly higher ethylene production is obtained with sonically treated particles than with the partially disintegrated or with the intact particles. It is interesting that, in all cases, ethylene production is continued over extended periods of time, at a slow rate.

Reaction mixture as in Table 1.

The fraction isolated at 40,210*g* for 15 min., when untreated, showed maximum ethylene production during the first 4 hr. (Table 3). Again, partial disintegration or sonic treatment resulted in considerably greater production of ethylene. As with the mitochondria, activity is retained for some time.

The purpose behind isolation of a combined mitochondrial : microsomal fraction was to prepare a cell-free system capable of still higher ethylene production. From the results in Table 4, it will be seen that although this preparation is active, the rate of ethylene production on a nitrogen basis is lower than that of either the mitochondrial or the microsomal fraction. (Sonic treatment does appear to activate the system.) While many possible explanations for the inhibition on the basis of possible uncoupling of oxidative phosphorylation[15,16] or the presence of natural inhibitors, etc., can be advanced, further experiments under a variety of experimental conditions need to be conducted before valid conclusions can be reached. It is conceivable that, rather than a simple inhibition of the ethylene-producing system, the combination of the two particles may provide an alternative, preferred pathway for utilization of intermediates in the ethylene-producing system, or even of ethylene itself.

	4–16	9 0	0	—	7 1

Reaction mixture as in Table 1.

The ethylene-producing activity (trace amounts to 0·01 µl./16 hr.) of the supernatant liquid was found to depend on the stage of ripeness of the tomatoes and on the method of preparation of the particulate fractions. For example, more ethylene was found when 0·25 *M* sucrose was used in the buffer in which the tomatoes were originally ground than when 0·5 *M* sucrose was used. The higher molarity of sucrose is known to be beneficial for preservation of the integrity of mitochondria[17], and ethylene production by the supernatant fraction from preparations where 0·25 *M* sucrose was used was probably due to disrupted mitochondria.

The cell fragments–chloroplasts–nuclei fraction (Table 5) produced ethylene in small amounts, with stimulation of production by either partial disintegration or sonic treatment. Thus, under the experimental conditions used, all the sub-cellular fractions have shown ethylene-producing activity, and maximum production was obtained with sonically treated mitochondria.

	4–16	—	—	4 6
Sonically treated	0–4	67·8	12 3	—
	4–16	7·1	0	—

Reaction mixture as in Table 1.

All fractions except the cell fragments–nuclei–chloroplasts produced carbon dioxide (43–58 µl./mgm. nitrogen/0·5 hr.). Our preparations of intact mitochondria showed the typical[17] lag period of 10–15 min. before carbon dioxide production began, but after that continued to produce it at a normal rate during the entire 4-hr. collection period.

In the present series of experiments, sonic treatment has been done on an empirical basis. It is obvious that the efficiency of sonic treatment would depend on such factors as concentration and size of the particles in the medium, viscosity, time and temperature. Another factor to be considered in drawing comparisons is reproducibility. In all our experiments we used the same amount of fruit and followed the outlined procedure closely. However, many steps in the procedure (for example, crushing and pressing the frozen tomatoes to prepare the homogenate) cannot be conducted strictly quantitatively. While nitrogen determinations themselves were reproducible, considerable variation in nitrogen content of the fractions from various runs occurred. Comparisons are thus more valid when

Reaction mixture as in Table 1.

made on different fractions from one run, rather than on the same fractions from different runs.

If the results are examined in the light of these remarks, it will be seen that sonic treatment has always activated the system as compared with the intact fractions. The same conclusions emerge if one compares (Table 6) average values of ethylene production from different fractions. It is clear that sonically treated mitochondria produced the greatest amount of ethylene. From the works of Zeigler[17] and others it is known that the biochemical properties of mitochondria vary greatly with their state of morphological and structural integrity. In our preparative procedure when the fruit is initially disintegrated by a Waring blender or similar device, many sub-cellular particles may be fragmented, just as they are in any further mechanical washing and dispersing procedure. As has been pointed out, the fraction isolated at 40,210*g* has to be looked on as containing partially disintegrated sub-cellular particles enriched with fragments of endoplasmic reticulum. The production of ethylene in relatively large amounts by this fraction could be due to the presence of fragmented mitochondria. The fact that the maximum ethylene production occurs during the first 4 hr., and then tapers off, is characteristic of fragmented particles. If this is the case, it could be concluded that the ethylene-producing system is located in the mitochondria.

It is also clear that the ethylene-producing system is activated by disintegration of the mitochondria. This conclusion is of interest in relation to the climacteric rise in ethylene production in fruits, for it has been reported[18] that mitochondria disintegrate as fruits ripen.

From the foregoing discussion, it is clear that the discrepancies in results from different laboratories may well arise from the use of different techniques for preparation of cell fractions and for collection of ethylene.

Preliminary experiments with sonically treated mitochondria have shown that the ethylene-producing system is heat-labile (when subjected to a temperature of 80° C. for 7 min.) and that the major portion of the ethylene is produced within the first hour, after which the rate of production falls off to trace amounts, difficult to analyse quantitatively even at 1-hr. time intervals. With knowledge of the site of ethylene production, and a technique for stimulation of the system involved, progress in solving the problems of the modes of production and action of this gas in biological systems should now be more rapid.

We are grateful to the National Research Council of Canada for a grant-in-aid of this research.

A TECHNIQUE FOR INVESTIGATING LOCALIZED MICROBIAL DEVELOPMENT IN SOILS

By D. M. WEBLEY and R. B. DUFF

The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen

AN established method for the study of the interrelationships of micro-organisms in soil is the well-known buried-slide technique of Cholodny. Modifications of this technique, using cellulose or deplasticized 'Cellophane', have been devised[1,2] for studying the decomposition of organic matter in microhabitats. In these methods the substrate is, of necessity, an insoluble one capable of removal from the soil, when desired, for isolation, or microscopic examination, of the enriched microflora. No comparable technique is available for soluble substances. Recently, Lehr, Brown and Brown[3] buried pellets of compressed superphosphate in soil, in order to follow the chemical changes which occur during the conversion of superphosphate to insoluble forms. In the technique described here we have adapted the above method for microbiological purposes. Soluble substances (organic and inorganic) are mixed with an inert base and formed into pellets which can be buried in soil. The soluble material is finely ground and mixed in the required proportion (usually 1:1) with the base. Kaolinite has proved to be the most suitable base since it has good binding properties and is inert. The pellets are made in a hardened steel mould similar to that described and illustrated by Ford and Wilkinson[4], but without the outer case,

Table 1. BACTERIA DEVELOPING ON KAOLINITE AND KAOLINITE/GLUCOSE PELLETS BURIED IN A RICH GARDEN SOIL

Incubation (days)	Bacteria (10^6/pellet) Kaolinite	Kaolinite/glucose
0	0·0012	1·14
2	0·080	6·70
4	0·320	14·60
6–7	0·520	20 92
13–15	0·680	15·6
21	0·620	12 52

since evacuation was unnecessary. Further, the base of the mould was recessed to allow the pellets to be pushed out more easily after they had been formed. In the mould 0·2 gm. of the mixture is subjected to a load of 5,000 lb. (in a press). Under these conditions all pellets of a given material are of uniform size. Our mould gives pellets with a diameter of ⅜ in. (9·52 mm.) The thickness of the pellets depends on the nature of the material being used, for example, for 0·2 gm. kaolinite they are 1·35 mm.

In our experiments the pellets are buried in 50 gm. of soil (passing a 3-mm. sieve). Half this soil is placed in a plastic flower pot (2 in. diam.), a pellet is added and then the remainder of the soil. Sterile water is then added carefully to adjust the moisture content of the soil to 26–28 per cent of the dry weight. The moisture content is maintained at this value by check weighing daily and by adding the necessary amount of sterile water. Two series of pots are set up, one containing kaolinite pellets and the other kaolinite/substrate pellets. The pots are incubated under a plastic cover, to minimize evaporation, in a constant temperature room at 25°. At required intervals a pot from each set is removed and the contents are tipped into separate sterile Petri dishes The pellets are removed aseptically with a forceps and placed in known volumes of sterile water in conical flasks. On shaking the flasks in a Microid shaker for 5 min. the pellets break up and dilutions are made from the contents of these flasks in the usual way for plate counts. Table 1 shows the bacterial counts from kaolinite and kaolinite/glucose (1:1) pellets buried over a period of 21 days. The rapid development of organisms on the glucose-containing pellet is clearly seen.

Apart from examining the development of the enriched microflora on the pellets it is also possible to demonstrate the formation of certain metabolic products by the flora. For this purpose the whole contents of the pots are extracted with water at room temperature and the extract evaporated down to a small volume for application to paper chromatograms. Using methods described by Duff and Webley[5] 2-ketogluconic acid has been detected in a rich garden soil during June–October (and also in February) in which kaolinite/glucose pellets had been incubated for 1–4 days. No 2-ketogluconic acid was found in the soil containing the kaolinite pellets. Estimation of 2-ketogluconic acid in the extract was carried out by the method of Lanning and Cohen[6] which uses *o*-phenylenediamine to form the quinoxaline derivative of α-keto acids. In two separate experiments about 1·5 and 3·5 mgm. of the acid was formed per pot after 2 days incubation. Only 0 5 and 2 5 mgm. of the acid remained after 3 days incubation and the glucose substrate was also much diminished or absent at that time. The keto acid estimation is subject to interference by, for example, sugars ; also other keto acids (for example pyruvic) would be estimated together with 2-ketogluconic acid so that the results above represent only rough approximations. There is no doubt, however, that 2-ketogluconate is actually present in the soil since it could be demonstrated on a paper chromatogram of the extract, after concentration at low temperature. No 2-ketogluconic acid has been similarly detected in agricultural soils so far investigated

In addition to soluble organic and inorganic substances, we have also prepared pellets containing finely powdered insoluble organic and inorganic materials, for example, cellulose, chitin, humic acids, calcium phosphates, silicates, etc. It is suggested that the technique may be of value in investigating not only the localized development of micro-organisms in soil microhabitats but also in some cases their physiological activity in these sites.

AROUSAL, CHANNEL-CAPACITY AND DECISION

By REV. A. T. WELFORD
St. John's College, Cambridge

IT is now widely recognized that with increase of arousal or activation many kinds of performance improve up to a maximum but thereafter decline[1]. The improvement is held to be due to an increase of neural activity in the brain which brings the cells of the cortex or some part of it to a state in which they are more readily fired by an incoming signal. Several explanations have been attempted of the fall in performance at high arousal-levels, but none appears to have been much more than an *ad hoc* speculation. Probably the most widely held is the view that, at high levels of arousal, inhibitor centres are activated. The purpose of this article is to indicate what appears to be the simplest possible model which will account for both trends. and to outline a few of its implications.

Let us consider the effects of progressively increasing the level of activity. At very low levels the system will be relatively inert so that all except the strongest incoming signals fail to secure a response. A moderate increase will improve sensitivity and responsiveness, and thus raise the effective strength of incoming signals. At still higher levels, however. cells will tend not only to be rendered sensitive but also actually to be fired. When this happens the system will become noisy, and its channel capacity will be reduced. Once this point has been reached further increases of activity will thus tend to impair performance rather than enhance it. The essential feature of the model proposed here is that it accounts for both the rise and the subsequent fall of performance accompanying progressive increase of activation, without postulating more than one type of process: both follow straightforwardly from the increase of activity in the system.

The great majority of evidence so far gathered does not favour one theory rather than another; but the present model is not, so far as I am aware, contradicted and in at least four cases it either accounts for facts not otherwise covered satisfactorily or provides a more precise lead for further research:

(*a*) If with Lindsley[2] we regard fear and anger as arousing in this sense, it is easy to see why there has been a controversy about whether their effects are 'organizing' or 'disorganizing'. Mild degrees of these emotions could bring the system to an optimum state while stronger ones would impair its ability to deal with tasks requiring a high capacity, and lead perhaps, at very high levels, to a kind of tense passivity and inability to differentiate between alternative, often antagonistic, reactions: the organism would suffer what Darrow termed "relative functional decortication"[3]. If high levels of emotion caused inhibition, performance might become ineffective but not disorganized.

(*b*) The optimum arousal-level would vary with the level of task: for difficult tasks requiring high capacity the optimum level would be relatively low, while for less demanding tasks it would be higher. If incentives can be regarded as activating, as they almost certainly can be, the model thus gives an elegant explanation of the so-called Yerkes–Dodson effect that increase of incentive improves performance up to a point but thereafter disrupts it, and that the point of inflexion becomes lower as the difficulty of the task is raised[4]. There seems to be no reason why a simple increase of inhibition should have effects related in this way to difficulty of task.

(*c*) The model could be tested by examining the details of performance at high activation-levels. If impairment under such conditions was due merely to inhibition, the organism should tend to become inert and performance suffer accordingly. If, on the other hand, the theory outlined here is correct, impairment would result from action being unduly vigorous, impetuous and ill-controlled. Experiments have not hitherto obtained sufficiently detailed results to provide a test. One possible exception is an experiment by Freeman[5] in which times taken to discriminate the stronger of pairs of electric shocks were measured under three conditions of muscular tension. Comparing normal with relaxed conditions the speed and accuracy of discrimination rose, the extent of finger movement in reaction to the shocks increased and its latency shortened. With tension induced in the trunk muscles finger movement increased slightly and latencies shortened still further, but errors of discrimination rose. In short, the increased tension appears to have made performance faster, but at the expense of accuracy. If the errors had been the result of inhibition, latencies would have been expected to rise and finger movement to lessen.

(*d*) Gross increases of arousal from a low level obviously lower sensory thresholds, but the effects on thresholds of smaller changes in activation are conflicting[6]. A fall of thresholds seems likely to result from the facilitatory effects of increased ambient neural activity so long as these are not offset by an increase of neural noise. Various possible effects are made much clearer if activation is considered in relation to the statistical decision model of discrimination proposed by Swets, Tanner and Birdsall[7]. According to this, neural noise can be conceived as varying randomly in intensity at different instants of time so that discrimination is between two distributions of activity in the system, one of signal-plus-noise and one of noise alone. For convenience, the authors cited treat the distributions as normal, although the argument does not depend on their being in any particular form. The subject fixes a cut-off point and treats any level of activity in the system above this as 'signal' and below it as 'noise'. Errors may arise if the distributions overlap, and the cut-off point, can, indeed, be inferred from the relative proportions of two types of error, namely 'omissions', that is, failures to report signals when present, and 'false positives', that is, reports of signals when none in fact is there.

Three possible results of increased activation appear to need consideration in terms of this approach:

(1) A true improvement of discrimination will occur only if there is an increase in the distance, measured in standard-deviation units, between the peaks of the two distributions—in other words, if facilitatory effects raise the signal strength more than the noise-level and thus enhance signal-to-noise ratio. If noise rose more than signal strength, as might happen at very high activation-levels, the distributions would be widened and their peaks moved to higher activation-levels; but both would be moved by the same amount so that the distance between them in standard-deviation units would be reduced and discrimination would fall.

(2) Apparent changes of sensory threshold might nevertheless result either from an increase of noise alone or from a proportionate rise of both signal and noise together. In both cases the distributions would be shifted to higher levels and thus, if the cut-off point remained the same, a higher proportion of signals would be detected. There would, however, also be a rise in the number of false positives—moderate with an increase of both signal and noise together, severe with an increase of noise alone. The same type of result would, of course, be produced if the cut-off point moved to a lower level. This might well occur as an additional effect of increased activation since the cut-off point must represent the threshold of some other mechanism in the brain and this would almost certainly tend to be affected by any general increase of ambient brain activity.

(3) If, however, the subject tried to reduce false positives by moving the cut-off point to a higher level, the proportion of omissions and thus the apparent sensory threshold might either rise or remain unchanged.

It is not easy to distinguish between these various alternatives, but it seems logically possible to do so if psychophysical measurements are made in such a way that omissions and false positives can be counted separately and the results compared with an independent, preferably physiological, measure of activation.

I thank Dr. F. W. Campbell for helpful comments on a draft of this article.

LETTERS TO THE EDITOR

ASTROPHYSICS

Nature of the Peculiar Galaxy *NGC* 5128

NGC 5128 is a peculiar galaxy which is of great interest, especially because it is at the centre of a very strong and exceedingly large source of radio emission known as Centaurus *A*[1]. The galaxy has been illustrated in the plate published by Baade and Minkowski[2] and also in the *Hubble Atlas*[3]. It consists of a very bright elliptical galaxy classified *EO* with a very wide dust lane crossing it and roughly dividing the bright area of luminosity in half. Baade and Minkowski interpreted the structure as being due to a collision between an elliptical galaxy and a smaller spiral system. At that time the only spectra available were those of Hubble[4] and Humason[2]. Neither gave sufficient information from which the true nature of the object could be deduced from the motions of the gas and stars in it, and the collision hypothesis based on interpretation of the direct plates alone has been a subject of controversy.

In 1958 we carried out a spectroscopic investigation of *NGC* 5128 with the nebular spectrograph at the prime focus of the 82-in. telescope at the McDonald Observatory of the University of Texas[5]. Since the grating that was used at that time is blazed in the region of λ 6300, the features which it records most efficiently are Hα and [NII] λ 6583, the emission lines in the red which commonly appear in spiral galaxies. Since *NGC* 5128 is at a declination of – 43°, it can only be observed for 2–3 hr. at McDonald Observatory. With these environmental limitations the results which were achieved were as follows. Spectra taken within the dark lane and also along its edges showed the emission lines Hα and [NII] λ 6583. Those emission lines in spectra with the slit parallel to the direction of the dark lane showed a tilt which is interpreted as rotation of the gas and dust in the sense that the south-east side is approaching and the north-west side is receding. Superposed on this rotation curve are velocity fluctuations of the order of 50 km./sec. which are attributable to random motions in the gas. The slope of the rotation curve over the central region of the dust lane is of the order of 3 km./sec./second of arc. The distance of *NGC* 5128 is uncertain. In the paper just mentioned we took a distance of 5 megaparsec. The value given by Sersic is 4 megaparsec. With a distance of this order, the mass obtained from the rotation measured in the emission features out to a distance ~ 5 kiloparsec. from the centre, on the assumption that rotation alone is present, is of the order of $1\text{–}2 \times 10^{11} M_{\odot}$.

These results still left in doubt the question of whether this object is two previously separate systems in collision, since we were not able to obtain measures of velocity from absorption lines which come from the stars. More recently, Evans and Harding[6] have obtained some velocity measures from absorption features (they assign greatest weight to Ca II λλ 3934, 3968) with the 74-in. telescope at the Radcliffe Observatory and they find, in central regions lying approximately along the rotation axis derived by us, radial velocities uncorrected for galactic rotation lying in the range + 350 to + 550 km./sec. with a mean value of + 434 km./sec. This is to be compared with our value of + 605 km./sec. from the emission lines. Evans and Harding were doubtful whether the difference between these values was significant, in view of the uncertainties involved.

We have now made further observations with a new grating blazed at λ 4000 in the same nebular spectrograph at McDonald Observatory. In June 1961 spectra were obtained with the slit oriented in position angle 120° immediately to the north-east and south-west of the dark absorbing lane and parallel to it. A third spectrum was obtained in position angle 30° approximately in the direction of the rotation axis determined in the first investigation. The absorption features which could be measured over a total extent of about 2′ parallel to the dust lane were Ca II λ 3968, Hδ, and Fe I λ 4383. In addition, in one of the spectra parallel to the dust lane the emission feature [OII] λ 3727 was measured. Results obtained from these features can be expected to give lower precision than results obtained from Hα and [NII] λ 6583. This is because (*a*) there is more contamination from night sky features; (*b*) the dispersion is lower (~ 390 Å./mm.); (*c*) there may be some effect due to residual twilight in the short June nights; (*d*) it is notoriously difficult to measure the tilt of an absorption line.

Bearing these difficulties in mind we can summarize our results as follows:

(1) The mean radial velocity obtained from the absorption features over the central region is about + 470 km./sec. with an estimated error of ± 50 km./sec.

(2) The mean radial velocity obtained from [OII] λ 3727 which was measured on one spectrum alone is + 630 km./sec.

(3) There is evidence from the absorption lines for rotation in the same sense and the same direction as that obtained from the emission lines in the dust lane. However, it appears to be considerably smaller, the slope in the central region only amounting to about 1 km./sec./second of arc.

Our results confirm the velocities measured by Evans and Harding. In addition, the recession velocity obtained from the emission feature [OII] λ 3727 is in good agreement with that obtained from Hα and [NII] λ 6583. If we correct for galactic rotation, the recession velocities are + 400 km./sec. (Hα, [NII] λ 6583, and [OII] λ 3727) and + 265 km./sec. (CaII λ 3968, Hδ, and FeI λ 4383). Thus there appears to be a significant difference such that the gas and dust are moving inwards with respect to the stars with a velocity of the order of 100 km./sec.

Besides the absorption features which have been measured over an extended region, the *G* band, CaI λ 4227, and a blend of Hγ and FeI λ 4325 were also measured in the strongest part of the spectrum. The appearance of all these absorption features confirms spectroscopically that the galaxy has the stellar population normally expected in a giant elliptical.

The comparatively small difference in velocity between the gas and the stars together with the result that the rotation of both components is in the same sense leads us to the conclusion that this is not a collision between a spiral and an elliptical galaxy. This conclusion was also drawn by Evans and Harding. The simplest model which would explain the observations is that of an elliptical galaxy surrounded by a broad band of dust and gas, which is rotating and also falling inward. Motion of the gas inward can possibly be accounted for if it was first ejected from the galaxy and is now falling back. The apparent rotation is not easy to understand. A nearly spherical system is not expected to have any appreciable amount of angular momentum, so that the observational evidence that in the stellar component any rotation at all is detectable is surprising. If the gas were ejected from the central system the conservation of angular momentum would give a much slower rotation velocity for the gas than for the stars farther in.

We may speculate that the peculiar motion of the gas in this galaxy is a direct consequence of the violent event which may have led to its becoming a powerful radio source[7].

GEOPHYSICS

Altered Lavas from the Floor of the Eastern North Atlantic

RITTMANN and others have long argued that basic lavas erupted on the ocean floor under great depths of water may suffer immediate alteration and solidify as rocks of the serpentine–spilite association, and recent experimental work by Clark and Fyfe[1] has directed attention to this possibility. The altered basalts, the physical properties and bulk chemistry of which were outlined in a previous communication[2], were almost certainly extruded under deep water and may provide an example of mild alteration under these conditions. The specimens were dredged from a small abyssal hill, named Swallow Bank, standing 4–5 km. above the Mohorovičić discontinuity under 4,960 m. of water at 41° 21′ N., 14° 28′ W. These specimens, and a second collection from a nearby small seamount (the Western Seamount, summit depth 2,600 m.), have been examined petrographically. In thin section the altered lavas are 50 per cent opaque; none retains unaltered groundmass material, and only three specimens out of four hundred preserve unaltered phenocrysts or glass. The present communication outlines the mineralogy of the alteration process which is believed to have affected them.

At Swallow Bank, the lavas first solidified as ordinary basalts. They were vesicular and hypocrystalline, they contained phenocrysts of augite and bytownite but retained little or no early formed olivine, and their textures were those indicative of rapid cooling and partial devitrification. Mineralogically similar lavas were erupted at the Western Seamounts but were accompanied there by pumice containing microphenocrysts of oligoclase. The Swallow Bank lavas probably belong to a tholeiitic series, but those from the Western Seamount could be alkaline. The lavas exposed on major seamounts or oceanic islands could, conceivably, have originated by melting in the oceanic crust; but consideration of the thermal gradients involved shows almost conclusively that the lavas erupted at Swallow Bank must have originated by melting in the mantle. Several authors have recently suggested that oceanic lavas normally originate in the mantle and it is consistent with their view that the Swallow Bank lavas, which did originate there, reveal none of the mineralogical peculiarities customarily attributed to an unusually deep-seated origin, though the ready formation of chlorophæite in them suggests that the magma had a high initial water-content. It has occasionally been asserted that submarine lavas extruded at depths greater than about 2½ km. under a hydrostatic pressure greater than the critical pressure of water should not be vesicular; but this does not appear to be the case since the lavas from Swallow Bank contain numerous small vesicles. The collection includes pieces of pillowy lava with glassy tops, and there are vitric tuffs which suggest that some explosive activity occurred on the sea floor.

The alteration processes which affected the lavas were as follows:

(*a*) *Hydration and oxidation*. The glassy selvage of sideromelane on the pillowy surface of the flow was converted to palagonite. In the interior of the flow the glassy mesostasis was converted to chlorophæite, the mineraloid described by Peacock as "potential chlorite"[3]. Grey pseudo-fragmental rocks from the Western Seamount typify this stage. They consist of residual grains of hypocrystalline lava set in a matrix of chlorophæite.

(*b*) *Felspathization and zeolitization*. Calcic plagioclase in the cores of the zoned phenocrysts was replaced by a regular arrangement of water-clear plates, each about 0·03 mm. thick. These were first thought to be harmotome; but X-ray powder photographs show that the new mineral is a felspar and not a zeolite, and the remarkably low refractive index of 1·514 ± 0·003 (approximately n_β) indicates that it is probably orthoclase. A very similar example, in which potash felspar replaces the plagioclase of submarine lava fragments entombed in red clay, has been described by Mellis[4]. In the (alkaline) lavas on the Western Seamounts zeolites (natrolite and chabazite) plus calcite formed within the chlorophæite matrix and in cavities.

(*c*) *Argilization*. Yellow palagonite (an amorphous gel) was replaced by a coloured cryptocrystalline aggregate, fibro-palagonite, consisting of montmorillonoids (probably iron-bearing) plus chalcedony. Chlorophæite was replaced by a similar cryptocrystalline aggregate, fibrochlorophæite, consisting of coloured chlorites and colourless montmorillonite, together with abundant limonite and some leucoxene. Montmorillonite also replaces plagioclase in the sodic rims of the phenocrysts and in laths in the groundmass. Thin sections of the most altered rocks show that fibrochlorophæite is capable of replacing all the surviving pyrogenic minerals. Pink pseudo-fragmental rocks dredged from the Western Seamount, where alteration was more wholeheartedly destructive than at Swallow Bank, provide extreme examples of this process. Hand specimens resemble lithomarge.

(*d*) *Weathering*. Yellow fibro-palagonite was converted to grey montmorillonite (probably iron-free). Radioactive pelagite ("manganese") was deposited in cracks and on all surfaces exposed to the sea.

The internal evidence does not indicate the temperature of stages (*a*)–(*c*), but comparison with other known cases suggests that stage (*a*) occurred at high temperature during the initial cooling, stage (*b*) probably occurred at moderate temperature (less than 200° C.) during initial cooling or a subsequent hydrothermal cycle, and (*c*) was probably deuteric (cold) though it might have been hydrothermal. Stage (*d*) certainly occurred at about 0° C. It seems arguable that the type of alteration described here represents an early stage of the process which under more vigorous or more prolonged hydrothermal conditions results in the formation of spilites, poenites and weilburgites, and of the beds of jasper manganese ore and limestone that often accompany them.

The alteration scheme found at Swallow Bank is consistent with what is known of the distribution of clay minerals in deep-sea sediments. Montmorillonite, but not chlorite, is found in the sediments near the sites of basic volcanic activity[5]. Detrital montmorillonite could easily become available for sedimentation since it forms, by diagenesis of the palagonite skin on the surface of the flow, and this skin has been shown to exfoliate readily. By contrast, although abundant chlorite is formed by diagenesis of chlorophæite within the rock, it is difficult to imagine a mechanism by which it could be released to the sediments from the surfaces of the angular fragments of lava which litter the slopes of submarine volcanoes.

I thank Dr. R. M. Perrin, Dr. P. Gay and Mr. K. Rixon for X-ray powder photographs, and Dr. S. O. Agrell and Dr. I. D. Muir for discussion and advice. The work was supported by grants from the British Petroleum Co., and the U.S. Office of Naval Research.

PHYSICS

Determination of Poisson's Ratio Dynamically

This communication describes a novel and practically useful experimental method for determining Poisson's ratio dynamically. The basis of the method is as follows.

When an elastic wave strikes a free surface obliquely, the energy of the wave will be redistributed, appearing partly in the form of a shear wave, the relative amounts of energy in the newly created waves being dependent on Poisson's ratio of the elastic material[1]. During the interaction of the transient stress disturbance with the surface, the surface is set in motion, the direction and magnitude of its movement being governed by Poisson's ratio and the angle of incidence α of the original incident wave. In general, the instantaneous surface particle motion which would be associated with the spherical wave being considered here is illustrated in Fig. 1, where due consideration has been given to the $1/r$ decay of the wave due to divergence. The particle velocity, except for the special point on the axis, is not, in general, perpendicular to the incident wave-front, deviating more and more with increasing angle of incidence. The surface particle velocity decreases with increasing angle of incidence in a complex manner which is not easily expressed analytically, but can be fairly readily computed point-by-point by combining vectorially the normal and tangential particle velocity components of the incident and the two reflected waves.

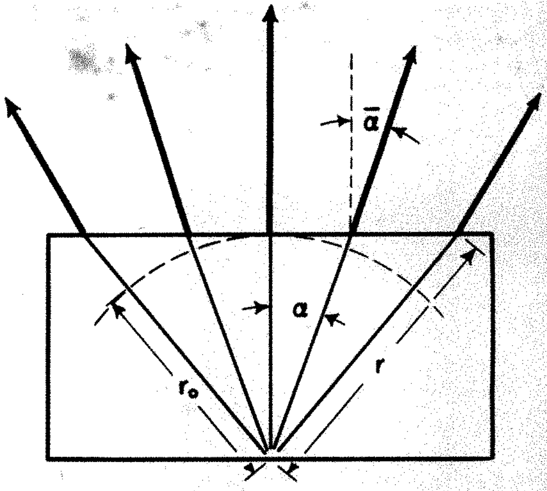

Fig. 1. Diagram illustrating direction in which a small rigidly affixed pellet would fly off when shock wave strikes free boundary obliquely

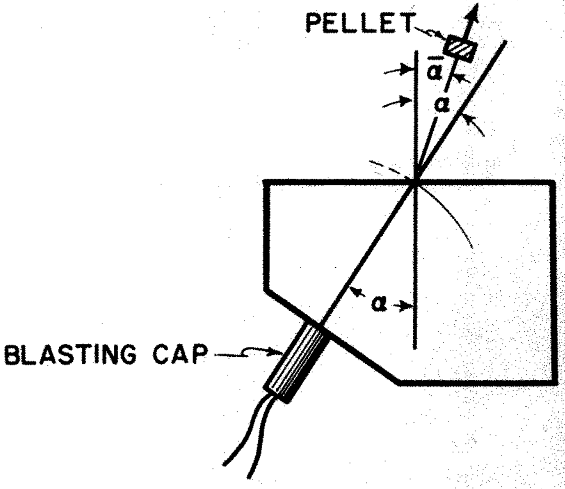

Fig. 2. Angle of emergence plotted against angle of incidence (α, Fig. 1). Solid lines are theoretical curves for three different Poisson's ratios

A small pellet, rigidly affixed to a surface as illustrated in Fig. 2, would be expected to undergo substantially the same movement as a point on the surface. By making the bond between the pellet and the surface of the plate considerably weaker than the 'Plexiglas', the bond can be broken by the tension developed by the reflected longitudinal disturbance, permitting the pellet to detach itself from the plate and fly off. The trajectory which the pellet assumes ought to be directed the same as the movement of a point on the surface of the plate. A number of observations have been made on pellets affixed in

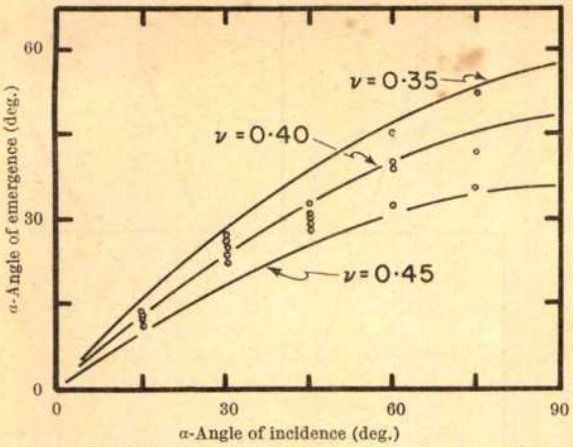

Fig. 3. Experimental arrangement for study of loosely affixed pellets

this way with the results being in excellent agreement with theory. The analytical expression for the direction of motion involves Poisson's ratio through the equation:

$$\nu = \frac{\sin^2\alpha - 2\sin^2(\bar{\alpha}/2)}{2[\sin^2\alpha - \sin^2(\bar{\alpha}/2)]} \qquad (1)$$

where α is the angle of incidence and α is the angle between the trajectory of the pellet and the normal to the surface.

This scheme provides a method for making experimental determinations of the dynamic Poisson's ratio of materials. The results obtained with 'Plexiglas' specimens are illustrated in Fig. 3 in which the angle of emergence is plotted against angle of incidence for a number of tests, the solid lines being the theoretically computed curves for Poisson's ratio of 0·35, 0·40 and 0·45. The experimental points are seen to cluster around the 0·40 curve, indicating a Poisson's ratio for 'Plexiglas' of about this value, a value identical with that computed from measurements made on the same 'Plexiglas' of longitudinal and transverse wave velocities.

Source of the Light recorded in Photographs of Shocked Granular Pressings

ABOUT ten years ago Stewart Paterson[1] illustrated by means of several wave-speed photographs the previously discovered[2] fact that a large part of the light from a detonating charge was due to the system of shock waves produced in the surrounding air. Further, he showed that the light still reaching the camera when light from these shock waves was eliminated did not arise from chemical reaction of the explosive. He accomplished this by observing the light from a water-surrounded high-explosive charge which included in its length short sections of granular sodium chloride kept dry by a thin plastic tube. The explosive parts of the charge gave very faint wave-traces, but the salt layers gave very intense bursts of light as the disturbance passed through them. Additional photographs showed that a similar brilliant light was produced by explosives when in a granular loose-pressed form.

We have recently performed a simple extension of Paterson's experiments. The explosive part of the charge was 'Composition *B*–3' (60/40: RDX/TNT) at a density of 1·72 gm. cm.$^{-3}$ made up in cylinders 2 in. in diameter. After a suitable length of charge to ensure a full-strength detonation, two separate short layers of granular salt were alternated with explosive sections, followed by two open sections filled only with gas, similarly alternated with explosive. The arrangement is sketched in Fig. 1. The new aspect of the experiment consisted in filling the first salt layer and the first open space with methane while air remained in the interstices of the second salt layer and in the second open space.

The resulting rotating-mirror wave-speed photograph is shown in Fig. 1. First, the contrasting intensities of the light from the shocks in the open spaces are to be noted for methane and for air. On the negative the methane shock is only faintly visible, while the trace from the air shock is quite dense. This difference is then to be compared with the relative intensities emitted by the salt layers, the first permeated by methane and the second by air. An examination made on the negative of the distance over which the intense light was scattered ahead in the salt pressings showed that the light from the air-permeated pressing was slightly more intense than from the methane-permeated pressing. However, the difference was not nearly as large as one might expect if the light were coming entirely from com-

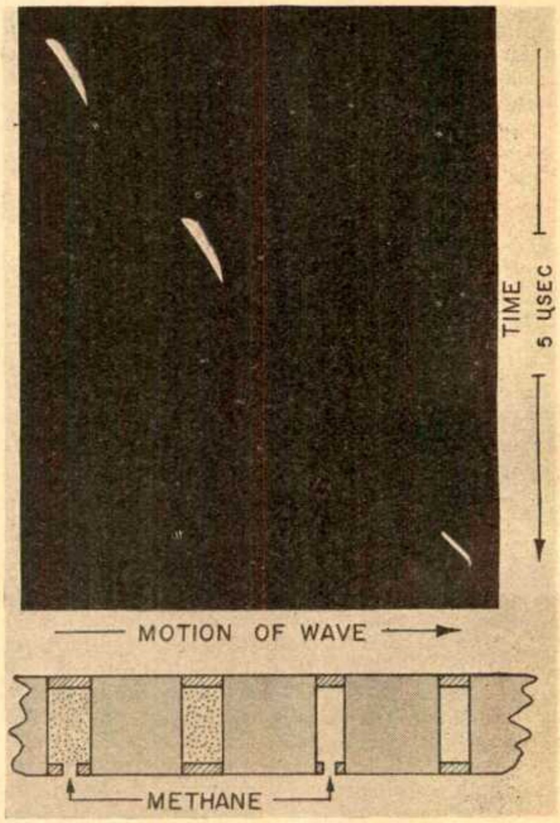

Fig. 1. Side-on photograph of composite charge fired under water. Dotted portions, sodium chloride; shaded portions, 'Composition *B*'; lined portions, polymethylmethacrylate tubing

pressed pockets of the two gases within the pressings. The luminosities given by the traces in the open spaces give a qualitative indication of the temperatures achieved in these two bases by free-running shocks driven by 'Composition *B*'. This temperature differential will not be greatly changed within the range of shock strengths to be expected from possible interactions within the pressing.

From these results we conclude that in a shocked pressing of granular sodium chloride there is an intense source of light which is independent of the nature of the interstitial gas. For a given shock strength this independent component represents a minimum amount of light that will be present for any gas or even when the pressing has been evacuated to 10μ. Experiments which confirm this have been conducted for a different geometry in a number of gases and in vacuum. Since this light does not arise from the gas, we have concluded that it must instead be emitted by hot sodium chloride.

The mechanism by which a part of the sodium chloride can reach a sufficiently high temperature to emit the observed intensities cannot be inferred from the photograph in Fig. 1. Other experiments indicate that the high temperature is produced by stagnation of rapidly moving material. In the present case, the sodium chloride is broken up and accelerated across the open spaces by the action of the shock, locally intensified by the interactions that are expected in a random assemblage of crystals.

A more complete report on this light is being prepared which presents evidence verifying this mechanism. As indicated by Paterson the same type of light exists in detonations of granular explosives pressings, and we would propose that it is produced by the same mechanism. We believe that stagnation hot-spots are important in determining the shock sensitivity of granular explosives pressings.

This work was carried out under the auspices of the U.S. Atomic Energy Commission.

ENGINEERING

Spark Track in Air at Very High Voltages

In an investigation[1] now in progress into the mechanism of triggered spark breakdown in air at voltages in the region of 1 MV., observations were made on the trigatron spark track. The track taken by the spark was found to bend sharply at a distance from the anode equal to a few per cent of the gap spacing. Between the anode and the point of bending the spark track was straight, and directed along the axis of the gap, whereas between this point and the cathode the spark path was of random shape. The length of the straight part remained approximately constant for given voltage and gap spacing. Observations showed that filamentary streamers occurred from the point of bending, directed towards the cathode. These appear to represent alternative spark tracks, growth of which ceases when any one streamer bridges the gap and expands to form the main channel.

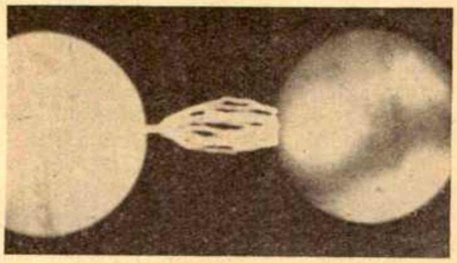

Fig. 1. Photograph of 15 superimposed spark channels. Voltage, 800 kV.; gap spacing, 50 cm.; electrode diameter, 75 cm. Left-hand electrode (anode) contains trigger gap

Similar effects have been observed for untriggered spark gaps[2,3] and for a triggered spark gap[4] at a voltage of the order of 100 kV. By superimposing photographs of several sparks, taken under the same experimental conditions, it is found that the possible spark tracks lie within a well-defined envelope of characteristic shape. A typical photograph, showing this envelope and the straight part of the spark adjacent to the anode, is given in Fig. 1.

In the experiments now in progress[1] an image converter tube is being used as a high-speed optical shutter of adjustable exposure time to measure the temporal progression of luminosity across the spark gap during the breakdown initiation process. Measurements of the current in the gap during the time-interval between the application of a trigger pulse to the system and complete breakdown between the spherical electrodes are also being made. Until these investigations are completed any theory to explain the bend in the spark track can only be speculative. It would appear, however, from the regularity in track shape for a large number of successive shots and the relatively constant length of the straight part of the spark that the bend in the spark track at voltages of about 1 MV. is an inherent consequence of the breakdown mechanism and is not due to the presence of dust or other foreign particles in the gap.

CHEMISTRY

Evidence of the Influence of Defects on the Szilard–Chalmers Process

A variety of observations made in recent years lead to the conclusion that the fate of the fragments generated in crystalline solids by radiative thermal neutron capture is determined, in part, by the density, and possibly the nature, of the defects in the crystals[1]. It has also been suggested that the annealing reactions which can be carried out after the neutron irradiation by heating or photon irradiation also involve these defects[2].

A well-known method of introducing vacancies into simple ionic crystals is by the addition of small concentrations of ions bearing a different charge to the corresponding ions in the host lattice. Thus each calcium ion incorporated into a potassium chloride lattice leads to the simultaneous inclusion of a cation vacancy[3]. We have prepared homogeneous crystals of potassium chromate containing calcium ions from melts. After neutron irradiation we found the retention of chromium-51 as chromate in the contaminated crystals was not very different from the value for pure chromate crystals, but the rate of thermal annealing in the calcium-contaminated crystals is much greater than for the pure crystals.

Table 1

Calcium (per cent)	Initial retention	Retention after 20 hr. at 190° C.
0	75·0	82·0
0·022	76·5	91·5

Thus the behaviour of the calcium-contaminated crystals, with their cation vacancies, is very similar to potassium chromate crystals into which defects have been introduced by crushing or irradiation with γ-rays or energetic electrons[2].

Previous investigations have shown that if a neutron-irradiated salt is thermally annealed at constant temperature until further annealing only takes place very slowly (that is, more than 6 hr. in the case of potassium chromate), and if the thermal annealing is now interrupted by an irradiation of the crystals by ionizing radiation, on continuing the thermal annealing at the same temperature a further stage of rapid annealing takes place[4,5]. We have now shown that an essentially similar result can be produced by crushing the crystals instead of irradiation with ionizing radiation. In Fig. 1 the full line records the retention as a function of time on heating to 230° and the broken line the retention of a portion of the same material that was crushed after 16 hr. heating.

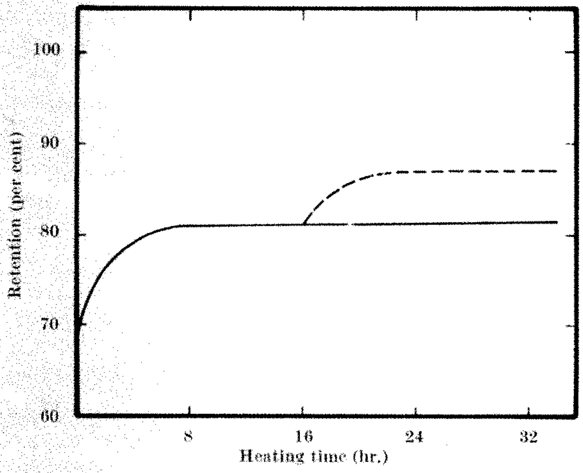

Fig. 1

These observations reinforce the interpretation of such phenomena outlined in our previous work[2].

Determination of Molecular Weights of Gelatin by Scattered Light Measurements

THE clarification of aqueous solutions of polyampholytes, as a preliminary to determination of molecular weight by scattered light, is particularly difficult and is in fact the main trouble with gelatin solutions. Stainsby's enzymatic digestion technique[1] offered an elegant solution to this problem. This method determines the scattering due to the gelatin by the difference between the light scattered by a moderately clarified solution before and after tryptic digestion. Though Stainsby had confined his use of the technique to gelatin fractions, he nevertheless suggested that it should be applicable to a wide range of systems.

The results of the present work on a large number of gelatins have shown that the Stainsby technique is not universally applicable to commercial whole gelatins or to all their fractions. Unsatisfactory behaviour was indicated by impossibly high values for the dissymmetry ratio, Z, and high values of the weight average molecular weight $\overline{M}_w$ with respect 0·5 M saline, used by Stainsby, with 1 M potassium thiocyanate as the dispersing solvent, in potassium thiocyanate as the dispersing solvent, in many cases reduced the excessive values for Z and gave a much better correlation between $\overline{M}_w$ and viscosity.

The anomalous high results occurred with gelatins in which there was indication of the presence of larger amounts of suspended extraneous matter. The residual scattering after tryptic digestion was used as a means of estimating the presence of non-gelatin suspended material. The possibility of rapid settling out of the larger extraneous particles as a result of the removal, by the digestion, of the colloidal protection had been recognized by Stainsby. These would not then be taken into account in the final readings. This, however, is not applicable in the present work as the gelatin solutions were, immediately before the experiment, passed through a membrane filter with an upper pore diameter of 1μ. Calculation of the rate of descent of the largest particles which could be encountered in the digest showed that even the densest mineral material would not have begun to clear the incident beam during the period of the experiment.

It was found that gelatins which normally had low residual scattering and gave reasonable results for both Z and $\overline{M}_w$ could be made to give anomalous results, in spite of the use of Stainsby's technique, by the introduction of small quantities of very fine suspensions of barium sulphate (prepared by sedimentation and membrane filtration). This produced an increase in apparent dissymmetry and 90° scatter with both acid- and alkali-processed gelatins (Fig. 1). This increase in 90° scatter, for the example shown, corresponded to an increase in molecular weight of 20 per cent and 60 per cent for the acid- and alkali-processed gelatins respectively. The large differences in the effect of the added suspensions are probably due to the differences in the molecular weight rather than differences to be expected between gelatin types. Similar results were obtained by the introduction of small amounts of an anionic surface active agent (mixed olefine sulphates commercially known as 'Teepol'). These effects are attributed to the adsorption of gelatin to the particles introduced in one case and to the formation of complexes with the gelatin

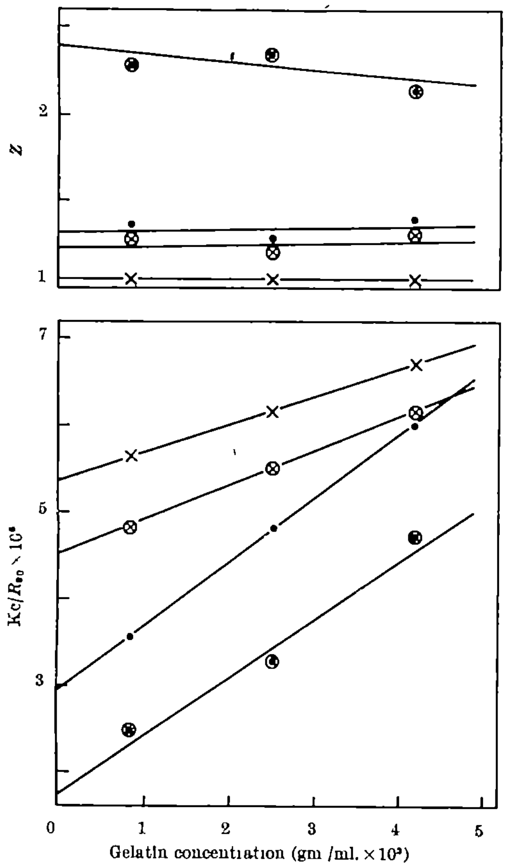

Fig. 1. Effect of addition of small quantities of very fine suspensions of barium sulphate on the dissymmetry and 90° scatter of gelatin solutions, measured by Stainsby's technique. Acid-processed gelatin. ⊗, with suspension, ×, without suspension; alkali-processed gelatin ○, with suspension, ●, without suspension

by the surface active agent in the other. Since both adsorbed layer and complexes are destroyed by enzyme action, their scattering contribution is not fully accounted for by the scattering of the tryptic digest. This general type of behaviour is to be expected if the digestion attacks any component of the initial system other than the simple dispersed gelatin molecules.

It is suggested that this type of mechanism applies in gelatins and fractions having a high residual scatter. This idea is supported by the increase in the number of reasonable results obtained by the use of the disaggregating and desorbing solvent molar potassium thiocyanate. It is also supported by calculations of the number and size of particles required and the amount of gelatin they would have to absorb to produce these effects. In a typical case, the particles had a radius of 0·07μ, were 0·003 per cent of the original material and adsorbed an amount which, expressed as a dry layer, would be 80 Å. thick. The calculations involved simplifying assumptions, but are sufficiently accurate to indicate the reasonableness of the hypothesis.

Lipid and mucopolysaccharide complexes are known to occur in gelatin[2]. Gelatins having appreciable quantities of these materials have a high residual scatter and give a high value for Z. The converse does not necessarily apply. The possibility of small particles of partly denatured collagen was discounted as the residual scatter was not reduced by the enzyme collagenase. Fractionation by alcohol coacervation tends to concentrate extraneous material in the first high molecular-weight fraction and sometimes the last low molecular-weight fraction. This was confirmed by the high residual scatter of these fractions. The middle fractions usually have a low residual scatter and give reasonable results for $\overline{M}_w$ and Z.

It must be concluded that errors can result from the use of Stainsby's technique. They are thought to arise from adsorption on impurities and by complex formation. These errors can be much reduced by the use of molar potassium thiocyanate as the dispersing solvent. Results for gelatins which have a high value for Z and the residual scatter should be rejected in the absence of other evidence. Further work is required to establish the limits of suspended extraneous material which are important.

I thank Dr. E. Pitts of this laboratory for help with the calculations.

Nitro- and Amino-phenylosotriazoles

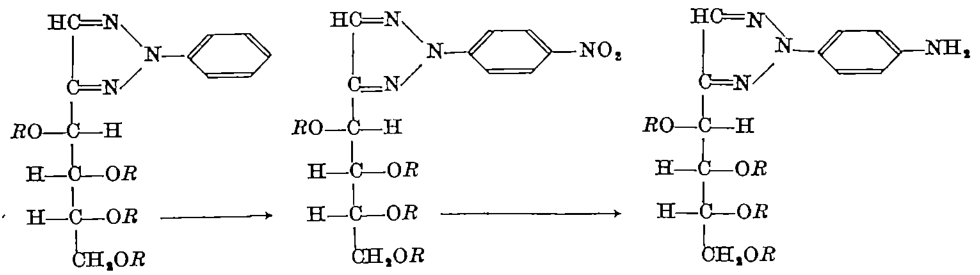
UNLIKE the glycosides, carbohydrate aryl osotriazoles have the sugar residue firmly bound and are unaffected by acids or alkalis. It was therefore interesting to prepare the aminophenylosotriazoles with the view of converting them into sulpha drugs which would acquire added specificity from their stable sugar residues. Alternatively, they could be converted into azo-dyes having affinity towards cellulose fibres.

Aminophenylosazones necessary for the preparation of the aminophenylosotriazoles are difficult to prepare since their hydrazines quickly decompose during osazone formation. Similarly, conversion of nitrophenylosazones into osotriazoles were found to be difficult to achieve[1] and only a small yield of glucose p-nitrophenylosotriazole (II, R = H), m.p. 253°, was obtained when the p-nitrophenylosazone was treated with bromine water.

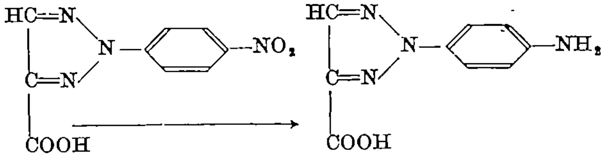
Higher yields of glucose p-nitrophenylosotriazole (II, R = H) were obtained by nitrating glucose phenylosotriazole tetraacetate (I, R = Ac) with fuming nitric acid and sulphuric acid and hydrolysing the resulting p-nitrophenylosotriazole tetraacetate (II, R = Ac) with alkali.

The position of the nitro group was determined by comparison with the p-nitrophenylosotriazole obtained by bromine water and also by oxidizing the osotriazole with potassium permanganate into the known 2-p-nitrophenyl-1,2,3-triazole-4-carboxylic acid (IV), m.p. 237° (refs. 2 and 3). This acid, on catalytic hydrogenation at room temperature using palladium–barium sulphate catalyst, yielded 2-p-aminophenyl-1,2,3-triazole-4-carboxylic acid (V), m.p. 265° (ref. 2), an amino-acid which preliminary experiments showed to possess bacteriostatic activity *in vitro*.

Catalytic hydrogenation of glucose p-nitrophenylosotriazole tetraacetate afforded glucose p-aminophenylosotriazole tetraacetate (III, R = Ac), m.p. 120°, a compound which was converted to a sulphon-



(I) (II) (III)



(IV) (V)

amide and gave a stable azo-dye. Similarly, nitration of glucose *m*-tolyl- and *m*-chloro-phenylosotriazole tetraacetates afforded the 4-nitro derivatives, whereas nitration of *p*-substituted phenylosotriazole tetraacetates such as glucose *p*-tolylosotriazole occurred in the 3-position.

Rhenium Hexachloride

THE preparation of technetium hexachloride by the direct action of chlorine on the metal has been described in a recent communication[1]. As the pentachloride is the highest chloride known for rhenium[2] the unusual situation arose of a second row transition metal showing a higher co-valency than the corresponding third row metal and it was suggested that rhenium hexachloride should exist[1]. This communication describes the preparation and characterization of rhenium hexachloride.

There are reports in the early literature of a volatile higher green chloride of rhenium which was thought to be the heptachloride or the hexachloride, but it was never characterized[3,4]. No more was heard of this supposed green chloride after Geilmann *et al.* announced the preparation of the brown pentachloride in 1933 (ref. 5). Workers who saw the green chloride made their own rhenium by reduction methods and those who obtained the pentachloride used commercial rhenium sponge or powder.

Accordingly, rhenium metal was prepared by the reduction of ammonium perrhenate with hydrogen at 600° C. After flushing the apparatus with purified nitrogen, chlorine was passed over the heated metal at about 600° C. No pentachloride was observed, but a dark solid, melting very readily and giving a green vapour, was obtained. It should be easily distilled in the chlorine stream to a U-tube cooled in an ice–water mixture. Analysis showed the substance to be rhenium hexachloride. Found: Re, 46·0; Cl, 53 4. Required for $ReCl_6$: Re, 46·6; Cl, 53·4. Hydrolysis of the compound in water gave a precipitate of rhenium dioxide and soluble perrhenate ion in the ratio 1 : 2, agreeing with the usual hydrolysis scheme for Re VI compounds:

$$3 \text{ Re (VI)} \rightarrow \text{Re (IV)} + 2 \text{ Re (VII)}$$

Rhenium hexachloride forms very long needles which are dichroic, appearing red-brown by transmitted light and dark green by reflected light. The crystals melt very readily at a few degrees above room temperature to give a dark brownish liquid which volatilizes on very gentle heating to give a green vapour. In contrast to technetium hexachloride[1], the rhenium compound is thermally stable in both chlorine and nitrogen and there is no sign of decomposition to the tetrachloride.

The reaction between chlorine and a rhenium film is thus similar to the action of chlorine on technetium and is in marked contrast to the action of chlorine on rhenium powder. We have also shown, however, that a small amount of the hexachloride is formed from the powder, which had been previously heated in hydrogen to reduce oxide films, particularly in the early stages of the reaction. The hexachloride had been noted before in these circumstances, but it was never characterized[6]. A rough estimate of the yields is 5 per cent hexachloride, 95 per cent pentachloride. It appears that some hexachloride has been present in all preparations of the pentachloride just as it has recently been shown that some rhenium heptafluoride was always present in samples of the hexafluoride[7]. This explains an observation made by me and others (Lock, C. J. L., and Wilkinson, G., private communication) that when the pentachloride is heated in nitrogen to give the trichloride a small proportion of the material melted very readily and could not be decomposed to the trichloride.

As mentioned above, rhenium hexachloride is thermally stable in nitrogen but in some early experiments a black solid was formed on heating the hexachloride in nitrogen. Analysis gave rhenium : chlorine ratio of 1 : 4, but the compound was not the tetrachloride (cf. technetium[1]) as hydrolysis showed it to contain Re VI. It was, in fact, the oxochloride, $ReOCl_4$, formed by traces of oxygen in the nitrogen. When more care was taken to exclude oxygen it was found that the hexachloride was unchanged on heating.

When rhenium hexachloride is warmed in an atmosphere of oxygen, the only product is perrhenyl chloride ReO_3Cl. In the fluoride system all three possible heptavalent oxofluorides are known[8,9], but the only Re (VII) oxochloride is perrhenyl chloride. It was hoped that by gently oxidizing rhenium hexachloride an oxochloride of Re (VII) containing more chlorine could be made, but this was not achieved.

BIOCHEMISTRY

New Fermentation Reactions by *Streptococcus viridans* stimulated by Transformation with Pneumococcal Deoxyribonucleic Acid

TRANSFERENCE of genetic material between related bacterial species was described by Bracco *et al.*, who reported reciprocal transformation reactions to streptomycin resistance involving *Pneumococcus* and two strains of *viridans Streptococci*[1]. The present investigation was undertaken to determine if the fermentative capacities of *Pneumococcus* were similarly transferable to *Streptococcus viridans*.

In this work a type II pneumococcus, II*D*39*S*-*Er*^{r}, served as the source of deoxyribonucleic acid (DNA). This organism is resistant to 150 μgm./ml. of erythromycin on blood agar plates (selected for erythromycin resistance by Dr. Robert Austrian). The receptor strains were the *viridans Streptococci D* and *NBSI*, which had been shown previously to be competent in heterologous transformation to streptomycin resistance[1]. DNA was prepared from *Pneumococcus* by methods previously described[2]. Transformation reactions were carried out by adding pneumococcal DNA extract to the streptococcal cells at the start of their incubation in charcoal-absorbed broth plus preheated pleural fluid[1]. In controls DNA was omitted or crystalline pancreatic deoxyribonuclease was added along with DNA at the start of incubation. Tests for transformation were performed following incubation of the cultures for 24 hr.

The fermentation reactions of *Pneumococcus* II*D*39*S*-*Er*^{r}, *Streptococcus D*, and *Streptococcus NBSI* toward thirteen carbohydrates were determined by inoculating loopfuls of these organisms into undefined semi-solid media of standard composition which contained acid-base indicators and the carbohydrates to be tested in concentrations of 1 per cent[3]. All three strains fermented sucrose, maltose, lactose, salicin and arabinose while they were inert towards glycerol, sorbitol, dulcitol, mannitol and xylose. The strains differed, however, in their reaction to trehalose, raffinose and inulin; these substrates were fermented by the pneumococcus but not by the two streptococcal strains.

Aliquots of cultures of *Streptococcus D* and *Streptococcus NBSI* were tested for their capacity to attack trehalose, raffinose and inulin following exposure of the cultures to DNA from II*D*39*S*-*Er*^{r}. The ability to ferment these three carbohydrates developed each time that transformation of the two streptococcal strains was attempted while controls gave consistently negative results.

Quantitation of the fermentation transformants was based on the observation that the transformed streptococcal cells which had gained the capacity to ferment the chief carbohydrate of the semi-solid medium grew into visible colonies while the untransformed cells grew scantily on secondary energy sources and did not form visible units. This observation was confirmed by the demonstration that colony counts in semi-solid media made from a uniform population of fermenters agreed with those made by the classical pour-plate method in blood agar. The numbers of streptococcal cells with new fermentation properties in fully grown cultures of *D* and *NBSI* which had been incubated with pneumococcal DNA, as determined by colony counts in the fermentation media, are given in Table 1.

Table 1. DEVELOPMENT OF NEW FERMENTATION REACTIONS IN *Streptococcus viridans* FOLLOWING EXPOSURE TO PNEUMOCOCCAL DNA

Carbohydrate	No. of fermenting *Streptococci*/ml. culture			
	Streptococcus D		*Streptococcus NBSI*	
	Exposed to DNA	Control	Exposed to DNA	Control
Trehalose	2,500	0	1,000	0
Raffinose	120	0	10	0
Inulin	15	0	20	0

Population of cultures used in this experiment. *Streptococcus D*, 6 × 10^6/ml. *Streptococcus NSBI*, 3 × 10^6/ml.

The two streptococcal strains were also tested for erythromycin resistance following exposure to DNA from the resistant *Pneumococcus* II*D*39*S*-*Er*^{r}. A proportion of the cells in the treated cultures invariably showed increased resistance to erythromycin while controls retained their original susceptibility.

The number of transformants to higher levels of erythromycin resistance was determined by pour-plating aliquots of a 24-hr. culture exposed to DNA with varying concentrations of erythromycin. Table 2 shows that approximately 1 per cent of a fully grown population of *Streptococcus D* which had been incubated with DNA from II*D*39*S*-*Er*^{r} possessed increased resistance to erythromycin. In contrast, new fermentative capacities were noted in a much smaller proportion of a *Streptococcus D* population treated with DNA, the percentages ranging from $2 \cdot 5 \times 10^{-6}$ to 4×10^{-4} for inulin and trehalose respectively (Table 1). These results suggest that cells exposed to transforming DNA may show great differences in their readiness to accept different genetic markers. The possibility that the fermentation transformants have a large replication lag relative to the transformants to erythromycin resistance or that these cells are at a selective disadvantage has not been ruled out, however.

Pneumococci developing new metabolic properties through transformation have been shown, in certain instances, to have acquired the ability to produce specific enzymes, for example, mannitol-6-phosphate

Table 2. TRANSFORMATION OF *Streptococcus D* TO ERYTHROMYCIN RESISTANCE BY EXPOSURE TO PNEUMOCOCCAL DNA

Erythromycin (μgm./ml.)	No. of surviving organisms/ml. culture		
	Culture exposed to:		
	DNA	No DNA	DNA + DNase
0	3 × 10^8	4 × 10^8	4 × 10^8
0 01	1 8 × 10^8		2 3 × 10^8
0·02	3 × 10^6	0	0
10	4 × 10^1	0	0

dehydrogenase[5] and amylomaltase[6]. In the present work the new metabolic properties of the transformed *Streptococci* have not been thoroughly defined, but one can speculate that they involve the elaboration of enzymes required to split the carbohydrates trehalose, raffinose and inulin into smaller units vulnerable to these organisms.

The work reported here was done in the Department of Microbiology of the New York University College of Medicine in the laboratory of Dr. C. M. MacLeod.

Non-enzymatic Reaction of Fluoro-oxalacetic Acid with Pyridine Nucleotides

β-FLUORO-OXALACETIC acid is a powerful inhibitor of malic dehydrogenase[1] and glutamic-aspartic transaminase[2]. We have recently observed that relatively high concentrations (10 m*M*) of fluoro-oxalacetate also inhibit the reduction of triphosphopyridine nucleotide by L-malate at *p*H 7·4 catalysed by the 'malic enzyme'[3] of chicken liver. The triphosphopyridine nucleotide-dependent decarboxylation of oxalacetate at *p*H 4·5 by this enzyme is inhibited to a greater extent by fluoro-oxalacetate. In the course of this work we found that fluoro-oxalacetate reacts non-enzymatically with di- and tri-phosphopyridine nucleotides, and with some analogues[4] of these coenzymes, to form fluorescent addition compounds. These reactions occur rapidly at 25° in the *p*H-range of 9–10. Oxalacetic acid does not react with diphosphopyridine nucleotide under these conditions. Our experiments suggest that fluoro-oxalacetate reacts at carbon-4 of the pyridine ring of the nucleotides in a manner similar to carbonyl compounds such as acetone and dihydroxyacetone[5]. Fluoro-oxalacetate, unlike oxalacetate, is not appreciably enolized in solution, even at high *p*H[1,6]. The presence of a fluorine atom on the β-carbon of fluoro-oxalacetic acid probably favours the formation of a carbanion in alkaline solution and thus facilitates a nucleophilic attack on carbon-4 of the pyridine ring.

In *tris*(hydroxymethyl)aminomethane buffer (50 m*M*) at *p*H 9·0 and 25°, the reaction of di- and tri-phosphopyridine nucleotides (30 μ*M*) with fluoro-oxalacetate (50 m*M*) is of first order with respect to the nucleotides ($k = 0{\cdot}034$ min.$^{-1}$). Under the same conditions, considerably faster reaction was found with the 3-acetylpyridine and thionicotinamide analogues of diphosphopyridine nucleotide, whereas the corresponding 3-pyridinealdehyde analogue reacted very slowly. Crude preparations of the adducts were prepared by dissolving the nucleotides (30 μmoles) and fluoro-oxalacetic acid (70 μmoles) in 2 ml. of water and then adding 1 *N* potassium hydroxide, with stirring at 25°, in order to keep the *p*H at 10·5–11·5 for 10 min. Ice-cold ethanol (8 ml.) and then diethyl ether (8 ml.) were added. After cooling on ice, the mixtures were centrifuged, and the precipitates washed with ether and desiccated. On paper electrophoresis in ammonium acetate at *p*H 7·5 for 1 hr. at 25° (19 V./cm.; 35 m.amp.), the addition compound of diphosphopyridine nucleotide and fluoro-oxalacetate migrated faster than dihydrodiphosphopyridine nucleotide, and to the same position as dihydrotriphosphopyridine nucleotide. This suggests that at *p*H 7·5 the fluorinated adduct possesses a net charge of -4. The addition compound of fluoro-oxalacetate and triphosphopyridine nucleotide migrated faster than the corresponding diphosphopyridine nucleotide adduct. The addition compounds of the various nucleotides exhibited an absorption maximum at 260 mμ at *p*H 2–9 due to the adenosine moiety. At *p*H 7·4 and 9·0, the adducts of di- and tri-phosphopyridine nucleotide with fluoro-oxalacetate exhibited a second peak at 340 mμ ($\varepsilon = 7{,}900$), while the corresponding addition compound with the 3-acetylpyridine analogue of diphosphopyridine nucleotide possesses a second absorption maximum at 343 mμ ($\varepsilon = 6{,}140$). The absorption maxima of the adducts in the range of 340–350 mμ were abolished by acidification to *p*H 2.

At a concentration of 40 μ*M*, the addition compounds between fluoro-oxalacetic acid and di- and tri-phosphopyridine nucleotides are without influence, at *p*H 7·5, on the action of malic and glucose-6-phosphate dehydrogenases, and of the 'malic enzyme'. Further biochemical properties of these adducts are under investigation. This work was supported by grants C–4681 and C–3211 from the United States Public Health Service, and by a grant of the American Heart Association.

Isolation of Soluble Glucose-6-Phosphatase from Microsomes of Bovine Livers

IN a recent report[1], we described the isolation of soluble glucose-6-phosphatase from bovine liver by treating the microsomes with both sodium deoxycholate and digitonin. The treatment with sodium deoxycholate attacks the microsomes in such a manner that part of the inactive proteins is solubilized. The main part of active proteins is concentrated in the fluffy layer by centrifugation[2]. Using this method, we obtained better results in rendering digitonin soluble.

The present communication describes some improvements regarding the procedure of ultracentrifugation. The homogenization of the bovine liver and the separation of undisrupted cells, the nuclei

Table 1. INCREASE OF ACTIVITY OF GLUCOSE-6-PHOSPHATASE AFTER TREATMENT OF MICROSOMES WITH DIGITONIN

Time of incubation (min.)	Initial activity present in microsomes (μmoles PO_4/ml./hr.)	Activity in solution			Particle-bound activity		
		Absolute activity (μmoles PO_4/ml./hr.)	Total absolute activity of supernatant (μmoles PO_4/hr.)	Initial activity (per cent)	Absolute activity (μmoles PO_4/ml./hr.)	Total absolute activity of residue (μmoles PO_4/hr.)	Initial activity (per cent)
30	109·0	99·0	748·0	682·0	22·0	61·5	56·4
30	218·0	97·0	660·0	302·0	106·0	350·0	160·5
60	109·0	94·0	686·0	630·0	26·0	72·8	66·8
60	218·0	88·0	607·0	279·0	110·0	341·0	156·5
120	109·0	97·0	707·0	648·0	20·0	56·0	51·4
120	218·0	79·0	545·0	250·0	95·0	294·0	135·0

and mitochondria were the same as in our experiments previously reported[1,2]. Determination of the activity of glucose-6-phosphatase was also carried out in the same manner using the method of Freedland and Harper[4]. The samples were incubated with glucose-6-phosphate at 37·5° C. The liberated phosphate was measured by the method of Fiske and Subbarow[5]. The absolute activity was defined as µmoles phosphate/hr. in 1 ml. samples.

The ultracentrifugation of the suspension of microsomes treated with sodium deoxycholate requires 60 min. During this period sodium deoxycholate still affected the microsomes. Therefore, we attempted to reduce the time of its influence. The agglutination of the microsomes at *p*H 5·4 gives particles of such a size that centrifugation at 18,000*g* for 20 min. was sufficient for separation. This agglutination was reached by mixing the suspension of microsomes and an equal volume of 0·1 *M* citrate buffer, *p*H 5·4 (ref. 6). This method was also used for the separation of the microsomes from cytoplasm and for the sedimentation of undissolved residue after treatment with digitonin.

The use of citrate buffer after the treatment of the microsomes with sodium deoxycholate has the disadvantage that a part of the dissolved proteins became insoluble again. A series of experiments with suspensions of microsomes of different contents of protein (25–150 mgm. protein/ml. suspension) showed that always only 6–12 per cent of the protein initially present was dissolved. It is not possible to increase the soluble part of protein using a suspension of microsomes with lower content of proteins. These results were reached only during agglutination with citrate buffer. Under these conditions the dilution of the suspension of microsomes is of no advantage.

The use of citrate buffer has no influence on a possible disintegration of the structure of microsomes. The result of the following treatment of the microsomes with digitonin is the same in applying the method of agglutination or ultracentrifugation.

Treatment with digitonin was always carried out in a way that a final concentration of 1 per cent of digitonin was reached. Even after standing for a few days the digitonin-treated microsomes do not lose their activity of glucose-6-phosphatase. Relatively smaller amounts of enzyme were dissolved by concentrations lower than 1 per cent. For this reason we recommend the concentration of 1 per cent. The complete removal of digitonin from the microsomal preparations necessary for biochemical experiments is extremely difficult. Therefore we did not investigate its influence at concentrations higher than 1 per cent. A time of incubation, longer than 60 min., has no essential advantage. The results are presented in Table 1.

From Table 1 it can also be seen that the total activity of the supernatant of the suspension of microsomes treated with digitonin was much higher than the total activity of the suspended residue of the sodium deoxycholate treatment. This effect is remarkable because the inhibition of the substrate (glucose-6-phosphate) on more dilute enzymatic solutions would be expected to be stronger in consequence of feed-back mechanism. We explain this effect as a result of a 'demascation' of the enzyme in consequence of a possible protein splitting by treatment with digitonin. A suggested regulation of the enzymatic activity by mascating substances is described by Langdon and Weakley[7]. The authors suppose a partial mascation of the glucose-6-phosphatase in livers of normal animals and total activation in livers of diabetic animals.

Formation of Pyrroline and Propane Diamine from Spermidine by Extracts of *Serratia marcescens*

THE oxidation of the natural polyamines, spermine and spermidine, by washed cell suspensions of various bacteria has already been described[1–4]. Propane-1 : 3-diamine is formed from spermidine by extracts of *Neisseria perflava*[5] and by washed cells of *Pseudomonas aeruginosa*[4], *Serratia marcescens*[4] and *Mycobacterium smegmatis*[6]. It has been assumed that during this oxidation the four carbon moiety of spermidine is converted to γ-aminobutyraldehyde[4,5] or to pyrroline[5]; however, these compounds have never been isolated. This communication deals with a partially purified enzyme from *Serratia marcescens* which oxidizes spermidine. The oxidation products, which are formed in stoichiometric amounts, have been shown to be propane-1 : 3-diamine and pyrroline.

S. marcescens was grown in a yeast extract medium[4] containing 0·01 per cent spermidine for 20 hr. at 30° C. An enzyme preparation purified 20–30-fold was obtained by protamine precipitation, ammonium sulphate fractionation, hydroxyl-apatite adsorption and DEAE cellulose chromatography.

This partially purified preparation, as well as crude bacterial extracts or an acetone powder suspension, oxidized spermidine to yield a compound which gave a yellow complex on incubation with *o*-aminobenzaldehyde. This reaction is characteristic for pyrroline or piperideine[7]. The yellow complex migrated on paper (R_F 0·79 in butanol/acetic acid/water 2 : 1 : 1) like 2 : 3-trimethylene-1 : 2-dihydroquinazolinium obtained by incubating synthetic pyrroline[8] with *o*-amino-benzaldehyde. The yellow complex had a maximal absorption at 430 mμ as did the complex obtained with authentic pyrroline[9]. The compound was catalytically reduced by platinum oxide and oxidized to γ-aminobutyric acid in the presence of diphosphopyridine nucleotide by a specific enzyme[8]. It was eluted from a 'Dowex 50' column exactly like synthetic pyrroline.

The other product of the oxidation was characterized as propane-1 : 3-diamine by ion exchange chromatography[10] and by paper chromatography[4].

Spermidine, labelled with carbon-14 (in the C_4 moiety[11]), gave rise to labelled pyrroline whereas the propane-1 : 3-diamine formed was not radioactive. The specific activity of the pyrroline formed was similar to that of the added spermidine. Spermidine labelled in the C_3 moiety yielded labelled propane-1 : 3-diamine; the pyrroline formed was not radioactive.

Table 1 shows that 1 μmole each of propane-1 : 3-diamine and pyrroline were formed per μmole of spermidine oxidized. In the presence of catalase 0·5 μmole of oxygen was taken up during this reaction. If no catalase was added to the preparation, the oxygen uptake was about 50 per cent higher. No ammonia was formed during this oxidation. The same preparation did not produce pyrroline from putrescine or spermine.

Table 1. OXIDATION OF SPERMIDINE BY *S. marcescens* ENZYME

Spermidine oxidized*	4·00 μmoles
Propane-1 . 3-diamine formed*	4·03
Pyrroline-formed†	3·90
Oxygen consumed‡	4 01 μatoms
Ammonia formed§	0

Reaction mixture contained 100 μmoles sodium phosphate buffer *p*H 7·0; 0·3 μmole mercaptoethanol, 4·0 μmoles spermidine, 15,000 units catalase; enzyme (equivalent of 1 1 mgm. protein). Total volume, 3 0 ml. Incubated at 30° C. for 120 min.

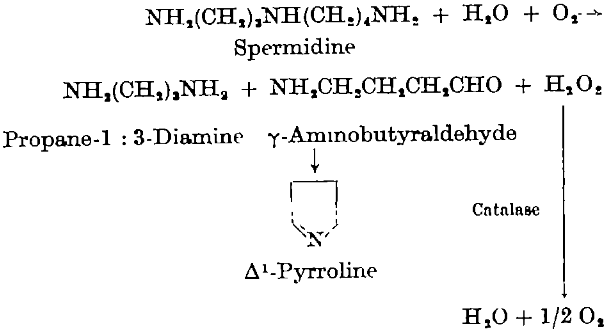
* Estimated by the dinitrofluorobenzene method after separation on 'Dowex 50' column (ref. 10).

† Estimated by the *o*-amino-benzaldehyde method (ref 9).

‡ Estimated by the Warburg manometric technique.

§ Estimated by micro-diffusion and nesslerization (ref. 17) after trapping the pyrroline with *o*-amino-benzaldehyde.

These results indicate that the initial steps in the oxidation of spermidine by *S. marcescens* are as follows:



$NH_2(CH_2)_3NH(CH_2)_4NH_2 + H_2O + O_2 \rightarrow$
Spermidine
$NH_2(CH_2)_3NH_2 + NH_2CH_2CH_2CH_2CHO + H_2O_2$
Propane-1 : 3-Diamine
γ-Aminobutyraldehyde
N
Δ¹-Pyrroline
Catalase
$H_2O + 1/2\ O_2$

γ-Aminobutyraldehyde formed during this oxidation cyclizes to pyrroline spontaneously[7]. A similar process occurs during the oxidation of putrescine by various enzymes[8,12,13]. Spermidine oxidase obtained from *S. marcescens* thus differs from the plasma amine oxidase studied by Tabor *et al.*[14] in that the latter oxidizes spermine and spermidine[14,15], and does not produce pyrroline or propane-1 : 3-diamine[16].

Removal of Calcium and Relaxation in Actomyosin Systems

EXPERIMENTS described in previous papers[1-4] show that the removal of the essential calcium from actomyosin accounts for the mechanism of relaxing action of the natural relaxing factor[5] as well as that of ethylenediamine tetraacetic acid (EDTA)[6,7]. The difficulty in accepting this view, however, might be that such a large particle as the relaxing factor, about 0·1μ or more in diameter, would produce an action by the same mechanism as that of a small soluble molecule, EDTA.

Recently we found that a chelating resin 'Dowex *A*-I' (Dow Chemical Co.), of which the active site is iminodiacetic acid attached to the styrene-divinylbenzene co-polymer matrix, was capable of relaxing actomyosin systems. As noted in the preceding papers[1,2], the relaxing capacity of a chelating substance is determined by its actual calcium-binding activity under the experimental conditions; the relaxation experiments being performed in the presence of excess magnesium, the effective calcium-binding depends not only on the stability constant for calcium but also on the difference between those for calcium and magnesium. Since the stability constant of the resin for calcium is rather small, that is, 3 × 10^3 at *p*H 6·8, and is about three times that for magnesium, the relaxing action of the resin had been expected to be not so strong; rough calculations based on these figures indicated that, if the relaxation experiments with glycerinated muscle fibres were carried out following the method of Ebashi *et al.*[8], the relaxing activity of the resin would be one-fiftieth to one-hundredth that of EDTA on the basis of molar concentration of chelating sites. Indeed, it was revealed that the relaxing activity of resin suspensions containing 20 m*M* chelating sites approximately corresponded to that of 0·2 ± 0·06 m*M* EDTA in good agreement with the results expected. The super-precipitation of extracted actomyosin was also inhibited by the resin suspension; the activity of the latter was shown to be about one-sixtieth that of EDTA. The size of the resin particle did not significantly influence its relaxing activity in the range of diameter 1–50μ. No relaxing activity of the resin was lost by repeated washings and no soluble substance capable of relaxing came out of the resin, indicating that the resin particle itself was the effective substance.

As has already been noted[1-3], the calcium-binding activity of the physiological relaxing factor is not less than that of EDTA, but exceeds the latter under physiological conditions. It is shown in this communication that a much larger particle than the relaxing factor has a relaxing activity to the extent expected from its calcium-binding capacity. Now it is very probable that the relaxing factor produces the relaxation of the actomyosin systems by a common mechanism with EDTA.

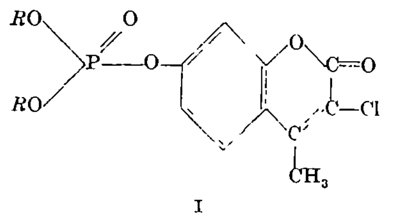
A New Class of Compounds showing Anthelmintic Properties

We wish to report anthelmintic activity of a novel class of chemical compounds (patent pending) for which compound I, (R = ClC_2H_4–), will serve as an example. This compound, bearing our code number 96*H*60, is *O*, *O* di-(2-chlorethyl) *O*-(3-chloro-4-methylcoumarin-7-yl) phosphate, for which the common name 'Haloxon' is suggested.



I

Oral doses of 'Haloxon' given to sheep and cattle have a very high efficiency against adult worms of the genera *Haemonchus*, *Ostertagia*, *Trichostrongylus*, *Cooperia* and *Strongyloides* and a high level of efficiency against *Nematodirus* and *Bunostomum*. Immature stages of some of these parasites are destroyed. The recommended dose for sheep and cattle is in the range 35–50 mgm./kgm.; but much lower doses are effective against *Haemonchus* spp. and *Cooperia* spp. 'Haloxon' has a marked anthelmintic effect against *Capillaria obsignata* in poultry, oxyurids, *Nematospiroides dubius* and *Strongyloides ratti* in rodents and against ancylostomes and ascarids in carnivores.

'Haloxon' is much less toxic than the related compound 'Coroxon', (I, R = C_2H_5–), the substitution of a chlorine atom in the ethyl groups of 'Coroxon' having a very profound effect on anticholinesterase activity. 'Coroxon' in glycerol formal shows an acute oral LD_{50} to rats of 12 mgm./kgm., but for 'Haloxon' in a similar formulation the figure is increased to 900 mgm./kgm. Lambs and yearling sheep have tolerated four to six times the anthelmintic dose. Others have received twenty consecutive weekly doses of 100 mgm./kgm. of 'Haloxon' and have shown no ill-effects. A single oral dose of 250 mgm./kgm. 'Haloxon' to sheep results in a slight depression of red cell cholinesterase activity (which returns to normal within one week of dosing), whereas an oral dose of 10 mgm./kgm. 'Coroxon' results in a 95 per cent depression in red cell cholinesterase activity.

Changes in Absorption during Photosynthesis in the Ultra-violet Spectrum

Seven different types of changes in absorption between 400 and 800 mμ and with lifetimes between 10^{-5} and 10^{-2} sec. have been found in connexion with photosynthesis of green plants. These changes are caused by the formation of the π-π*— triplet states of chlorophyll a_0, resp. b_0 (ref. 1), by probably metastable states of chlorophyll a_1 (ref. 2), by the photo-oxidation of chlorophyll *a* (refs. 3 and 4), by the oxidation of cytochrome[4,5] and by the reduction of added Hill reagents[6]. Changes in absorption at 475 and 515 mμ[7,8] are caused by the reduction of a substance *X* (ref. 6). Changes at 420 mμ are caused by the reaction of an unknown compound. The relations between chlorophyll *a*, cytochrome, *X* and Hill reagents lead to a reaction pattern of photosynthesis as presented in refs. 4 and 5. This report presents evidence for an eighth type of change in absorption.

Bishop[9] has shown that plastoquinone is somewhere involved in transport of electrons during photosynthesis because after extraction of plastoquinone the

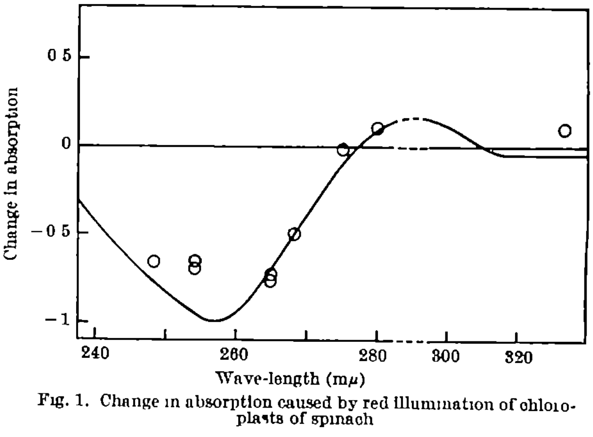

Fig. 1. Change in absorption caused by red illumination of chloroplasts of spinach

photolysis of water stops but is fully restored by recondensation of plastoquinone.

To obtain more information about the function of plastoquinone we looked for changes in absorption in the ultra-violet spectrum. Preliminary measurements are shown in Fig. 1. Changes in absorption were measured with reference to 280 mμ. The magnitude of the observed changes is about 1 per cent. They take place in the region of the absorption bands of plastoquinone and the short wave band of triphosphopyridine nucleotide (TPN). Changes in absorption due to TPN could be eliminated because chloroplasts free of mitochondria show practically no changes at the long wave-band of TPN at 340 mμ. Therefore, we tend to assume that the changes are caused by the reduction of plastoquinone. For comparison we have depicted in Fig. 1 as a solid line the changes in absorption produced by plastoquinone reduction *in vitro* (derived from measurements of Crane[10] and Bishop[9]). The curve is standardized with the measurement at 268 mμ. The light-induced plastoquinone reduction is fast, compared with the slow re-oxidation (several seconds). Addition of ferricyanide has strong influence on the re-oxidation. Probably plastoquinone is at least engaged in a reaction with the reductant Z⁻ (see Fig. 2 in ref. 4) and can be re-oxidized by ferricyanide. We hope that the kinetic analysis of these new changes in absorption lead to an understanding of the role of plastoquinone in the mechanism of photosynthesis.

PHYSIOLOGY

Activation of Histidine Decarboxylase in Tumour Cells in Mice

IT has been shown in this laboratory that activation of histidine decarboxylase occurs as part of various types of normal and malignant rapid tissue growth, and that such growth can be arrested by inhibition of histamine formation. This applies to the embryo[1] and granulation tissue of healing wounds[2] in rats where histidine decarboxylase activity reaches exceedingly high levels. Elevation of the enzyme activity by artificial means will accelerate the rate of wound healing[2] and increase the collagen content of granulation tissue[3], whereas inhibition of histamine formation has the reverse effect. Tumour tissue obtained from female albino rats bearing subcutaneous transplants of the Walker rat mammary carcinoma produced histamine at considerable rates *in vitro* whereas in normal rat mammary tissue the rate of formation was too low to be measured[4]. A similar finding was made in rats bearing an implanted hepatoma[5]. In these previous investigations it was not possible to define the phase of growth as regards frequency of mitosis.

The results reported here were obtained with the Landschütz I tumour growing in the mouse peritoneal cavity as single free cells where it was possible to determine: (*a*) the total number of cells contained in the tumour; (*b*) the phase of growth expressed as the frequency of tumour cells in mitosis at different intervals after inoculation of the tumour. In the following *T*-cells will be used for tumour cells, mitoses for *T*-cells in mitosis and c.p.m. for radioactivity of histamine labelled with carbon-14 formed during a 3-hr. incubation of the tumour cells with ^{14}C-histidine.

In each set of experiments tumour cells from four mice were pooled. The mice were anæsthetized with ether and bled to death through the carotid arteries. A small incision was made through the abdominal wall; the peritoneal cavity rinsed six times with 2-ml. portions of saline to which a few drops of a 20 per cent potassium oxalate solution were added to prevent coagulation. The rinsings from the four mice were mixed, centrifuged for 15 min., the clear cell-free supernatant discarded and the cells re-suspended in saline. This cell suspension was used for the actual investigation.

The rate of ^{14}C-histamine formation from ^{14}C-histidine was determined *in vitro* in one aliquot by Schayer's isotope dilution method as described by White[6], and the total number of cells estimated

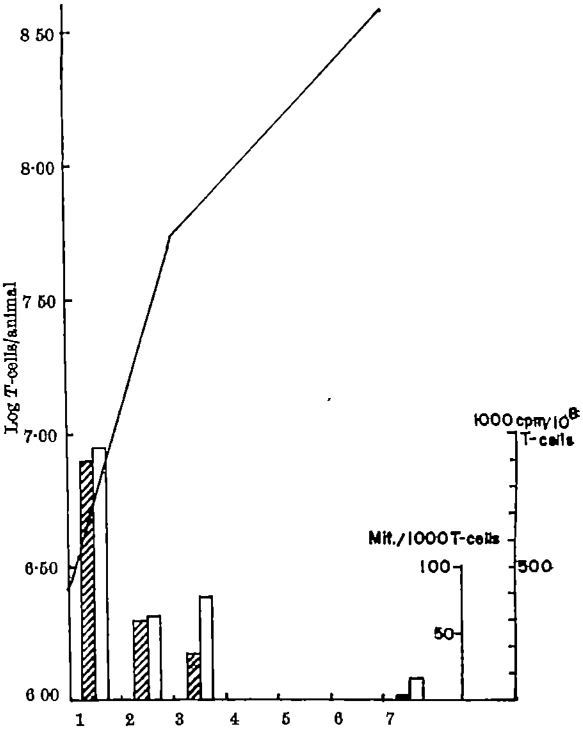

Fig. 1. Measurements in 16 mice simultaneously inoculated with Landschutz I ascites tumour cells. The continuous line represents growth in terms of total number of tumour cells per mouse. The hatched columns stand for amount of ^{14}C-histamine formed and the unhatched for frequency of tumour cell mitosis at 1, 2, 3 and 7 days after inoculation. Hatched, c.p.m./10^8 *T*-cells; white, mitoses/1,000 *T*-cells

according to Klein and Révész[7] in another aliquot. A differential cell count was made on a sample of the suspension by staining with a 2 per cent 'Orcein' solution, placing a drop on a slide and examining the cells under the microscope. It was hereby possible to count differentially the number of T-cells, mitoses and non-T-cells.

The results from one typical experiment are given in Fig. 1. This shows first that at the onset of tumour growth the histidine decarboxylase activity is correlated with the frequency of tumour cell mitosis and, further, the lack of correlation between enzyme-level and total number of tumour cells. These results display striking resemblance to the situation in healing wound tissue where histidine decarboxylase is activated to peak-level on the first day after wounding[2].

These experiments strongly support the idea of histidine decarboxylase activation as part of certain types of rapid tissue growth[8]. This concept is now further strengthened by the clear correlation between mitosis frequency and enzyme activity in the initial stages of tumour growth.

Attempts at arresting tumour growth by enzyme inhibition are in progress.

Orientation of Spermatozoa in Mucus of the Cervix Uteri

Bovine cervical mucus has been shown to contain a mucoid which behaves as though its molecules were long, flexible and thread-like[1]. The elastic properties and the Weissenberg effect shown by native mucus (at œstrus) are traceable to this molecular form[2]. Native mucus may be drawn out into thick threads in which the mucus is anisotropic due to the uncoiling and alignment of the molecules along the lines of strain. It is probable that mucus secreted by the cervix uteri and expressed into the vagina is in this condition, the lines of strain running along the path the spermatozoa should follow.

It has been suggested that spermatozoa in cervical mucus would swim preferentially in the direction in which molecules were aligned. To test this possibility, threads of bovine œstrous mucus were drawn out with platinum hooks on to the central part of slides with parallel grooves of the type described by Harvey and Jackson[3]. A drop of bull semen was pipetted on to one end of each strip of mucus. The slides were then incubated for approximately 15 min. at room temperature in Petri dishes lined with filter paper damped with saline. For control purposes semen was also added to one end of a comparable streak of 0·9 per cent sodium chloride solution (saline) on a similar slide.

After incubation the mucus (or saline) was examined under a microscope. In fields very close to the semen drop, the sperm were so numerous that scoring would have been impossible. A number of fields were therefore chosen at a distance of about 2 or 3 cm. from the semen source. All the sperm in a given field were scored according to the direction in which they were travelling, as judged by eye in relation to the grooves in the slide (parallel to the direction in which the mucus had been stretched) and the cross-markings at right-angles to the grooves.

Table 1 shows the results of nine experiments in which two different samples of mucus and three samples of semen were used.

Table 1. ORIENTATION OF SPERMATOZOA IN A THREAD OF MUCUS. MEAN PERCENTAGES WITH STANDARD ERRORS (RANGE IN BRACKETS)

Direction of sperm movement	Mucus (9 exp.)	Saline (3 exp.)
Along the axis of orientation	70 ± 4 (59–91)	33 ± 1 (31–36)
At right-angles to the axis	20 ± 3 (4–35)	37 ± 1 (35–39)
Diagonally	8 ± 2 (0–18)	17 ± 1 (15–19)
Pivoting and circling	3 ± 1 (0–7)	12 ± 1 (10–14)
Proportion of those orientated along the axis going away from the semen source	65 ± 7%	65 ± 6%
Total No. of sperm counted	708	701

Orientation could not have been induced by flowing of the mucus along the slide because, in the first place, epithelial cells in the mucus were stationary, and, in the second place, there was little difference between the swimming-rates of sperm in the two directions, away from and towards the semen source.

Since the technique allows for unconscious selection of sperms for scoring, it was arranged for a further two experiments to be carried out by another observer who did not know the 'expected' result. Both sets of results from these experiments showed the same trend as those in Table 1, but to an even greater extent; in the first 84 per cent and in the second 95 per cent of the sperm were orientated along the strip of mucus. Of these spermatozoa 85 per cent and 97 per cent respectively were orientated away from the semen source. In the first none, and in the second only 1 per cent, of the sperm was circling.

Similar experiments were carried out with preparations of purified mucopolysaccharides dissolved in saline. These solutions did not have a prolonged relaxation time and the molecules, though similar to those in native mucus, were therefore randomly orientated. The results for two experiments with each of two such preparations were very similar to those obtained with pure saline. Of 1,092 sperm scored, 30 per cent were orientated along the streak, 34 per cent at right-angles.

It appears, therefore, that spermatozoa travelling in a thread of mucus are preferentially orientated in the direction in which the thread has been drawn out.

This work forms part of a programme of research on cervical mucus supported by the Population Council, Inc., Rockefeller Institute, New York.

Sodium Transport and Phosphoproteins

In previous work[1] we have shown that liver slices suspended in a medium free of sodium ions show a depressed turn-over of phosphoprotein phosphorus. This effect is reversed by addition of sodium. In these and the experiments shown here, the phosphoproteins have been identified by isolation of radioactive phosphorylserine from acid hydrolysates of the crude proteins. We have found that the phosphoproteins sensitive to Na^+ are non-mitochondrial[1], the mitochondrial phosphoproteins appearing to have different properties[2].

We now find that the effect of Na^+ on phosphoprotein turn-over is strongly influenced by the concentration of externally added Ca^{2+} ions. In Table 1, we show that Ca^{2+} ions tend to inhibit phosphoprotein turn-over as well as that of adenosine triphosphate. Na^+ reverses this effect, but it is clear that as the Ca^{2+} level is reduced the inhibition of uptake of phosphorus-32 falls away, while the system still requires Na^+ for full activity.

Table 1. Effect of Na^+ and Li^+ Ions at Two Ca^{2+} Concentrations

Ca^{2+} level m*M*	2·8			0·93		
Addition	Choline	Na^+	Li^+	Choline	Na^+	Li^+
ATP, sp.a.	97,000	147,000	150,000	155,000	228,000	172,000
Phosphoprotein P, sp.a.	11,700	18,000	12,000	18,400	39,000	17,200

Slices of about 200 mgm. wet weight were suspended in Ringer solution containing choline-chloride instead of sodium chloride. *p*H 7·2 was maintained with sodium bicarbonate, gas phase was 95 per cent oxygen – 5 per cent carbon dioxide. Temperature, 38°. After 10 min. incubation in the medium, which contained phosphorus-32 of specific activity 3×10^6 c.p.m./μmole, Na^+ choline or Li^+ was added to a final concentration of 0·039 *M*. 15 min. later, trichloroacetic acid (final concentration, 5 per cent) was run into the flasks and the contents homogenized rapidly and chilled.

The effect of Li^+ ions is also shown in Table 1. At high levels of Ca^{2+}, Li^+ causes a marked stimulation of ATP, but has no such effect on phosphoproteins. This experiment is further evidence that the action of Na^+ on the latter compounds is specific.

Cosmos and Harris[3] have shown that calcium ions are gained by frog skeletal muscle on reduction of the external Na^+, and expelled on further addition of Na^+; and have postulated that Na^+ and Ca^{2+} ions compete for a common site (see also Niedergerke and Harris[4]).

The present results strongly support the idea that phosphoproteins are involved in Na^+ transport, and are in keeping with previous suggestions to that effect[5,7].

The evidence for this can be summarized as follows:

(1) Systems deficient in Na^+ show reduced turn-over of phosphoprotein phosphorus;

(2) The addition of Na^+, but not of Li^+, K^+ or of choline reverses this effect;

(3) The level of Ca^{2+} greatly influences the rate of turn-over of phosphoprotein phosphorus and supports the idea of a competition between Na^+ and Ca^{2+} for a common site.

(4) Li^+ ions can be shown to stimulate adenosine triphosphate turn-over while having no effect on phosphoprotein turn-over.

(5) Drugs such as strophanthin which inhibit Na^+ transport prevent the effect of Na^+ on phosphoprotein turn-over while having no action on adenosine triphosphate (Table 2).

Table 2. Effect of Strophanthin on Phosphoprotein Turn-over

		Specific activity, c.p.m./μmole phosphorus of			
Addition	3×10^{-4} *M* strophanthin	Phosphoprotein as phosphoserine-P	Increase (per cent)	ATP	Increase (per cent)
Choline	–	479	—	306×10^3	—
Na^+	–	700	46	483×10^3	58
Na^+	+	520	9	460×10^3	51

The conditions were as in Table 1 with 2·8 m*M* Ca^{2+}. The phosphoproteins were subjected to acid hydrolysis and chromatography to give the activity of phosphorylserine derived from them. Carrier phosphorylserine, 10 μmoles, was added before acid hydrolysis.

Gamma-Aminobutyric Acid and Other Blocking Substances extracted from Crab Muscle

As part of an attempt to identify the transmitter agent released by inhibitory nerves in crustacean muscle we have extracted and purified heat-stable 'inhibitory' substances of a crab muscle and its associated nerve supply. The fibres of the extensor muscle (opener) of the dactyl of the walking leg of *Cancer borealis* are densely innervated by two inhibitory nerve fibres, and by extracting the whole muscle, although adding non-neural elements, we were assured of obtaining the materials stored within the nerve endings. The extracts were assayed on the extensor muscle of the dactyl in the crayfish, *Orconectes virilis*. Only those extracts which imitated the effect produced by neural inhibitory activity (reduction of the excitatory junctional potentials without shifting the resting potential by more than 5 mV.) were considered 'inhibitory' and were further purified.

Fifty-five extensor muscles were dissected free from hypodermis and from the larger bundles of sensory nerves. The muscles were frozen on dry ice, ground to a powder and lyophilized. The resulting powder (1·4 gm.) was extracted three times with 30 ml. of boiling distilled water. The pooled extracts were concentrated by freeze-drying and dialysed against three changes of 100 ml. of distilled water at 4° C. for 32 hr. The physiological activity was confined to the dialysate, which was taken to dryness. 215 mgm. (a half) of this material was dissolved in 0·5 *M* acetic acid (*p*H 2·5) and fractionated on an Elphor continuous electrophoresis apparatus at 4° C. The extract was applied to the paper at the rate of 1 mgm. of starting material per hour, and the voltage was adjusted so that potassium appeared at one border of the paper and inorganic phosphate near the other. All the fractions were lyophilized, and a portion of each was then dissolved in van Harreveld's solution for assay.

Each active fraction was further purified by ascending paper chromatography as follows. A large amount of the fraction was applied in a long line, near the bottom of a sheet of washed Whatman No. 1 filter paper. After developing with a suitable solvent the paper was dried for a day. Narrow vertical strips were stained with ninhydrin or other colour reagents, and, using these strips as guides, the entire paper was

† Proline was tested only on crayfish muscle.

divided into horizontal sections which were separately eluted with water. A fraction of each of these eluates was dried, dissolved in saline and assayed. The remaining portions of the active eluates were chromatographed again in a series of solvents to determine their purity and to establish their identity.

Five blocking substances (Table 1) were identified by comparing their chromatographic and electrophoretic behaviour with that of authentic samples. Gamma-aminobutyric acid (GABA) was further identified by a micro-adaptation of the highly specific enzymatic assay of Jakoby and Scott[1]. The amounts of GABA determined by the enzymatic assay and by the biological assay were in good agreement. The 'unidentified compound' of Table 1 was present in very large amounts, and must have a very low physiological activity relative to GABA. Taurine and alanine were present in such large amounts that they accounted for about one-half and one-tenth respectively of the total blocking activity of the original hot-water extract in spite of their low physiological activities compared to GABA. GABA contributed about 20 per cent of the total blocking activity and β-alanine and proline together less than 5 per cent. Blocking activity was found in fractions which contained large amounts of inorganic phosphate, calcium or magnesium. The purification and assay procedures were such that a compound which contributed less than 3 per cent of the total blocking activity of the extract might have been overlooked. The unidentified compound shared with citrulline the following properties: (*a*) very similar R_F values in solvents 1, 2, 4 and 6 (but not in solvent 5); (*b*) white fluorescence under ultra-violet illumination (2537 Å.); (*c*) similar colour reactions to ninhydrin, the Sakaguchi reagent and Ehrlich's reagent. Presumably, it is a carbamyl compound. It was accompanied by very large amounts of an unidentified and inactive guanido compound which also stains with ninhydrin and is not arginine or lombricine.

Using similar techniques, GABA has also been found in peripheral nerves of crabs (10–12 μgm. GABA per 100 mgm. dry weight of nerve) and in the lobster central nervous system (about 60 μgm. GABA per 100 mgm. dry weight of ganglia (to be published)). GABA is of considerable interest because it is the most active of the stable blocking compounds found by these methods in the crustacean nervous system or muscle, and because it closely imitates the actions of the natural transmitter at inhibitory junctions in crayfish[2-6] and lobster[7]. D. Hamilton and R. S. Eisenberg (unpublished results) have found in preliminary experiments that it reduced the size of the excitatory junctional potential and increased the membrane conductance in extensor muscles of *Cancer borealis*. Crab and crayfish muscles have similar sensitivities to GABA; strong blocking effects are seen with concentrations of 1–3 μgm./ml. On the other hand, our chemical extraction methods would have destroyed active heat-labile compounds. Florey and Chapman[8] reported that they found in methanol extracts of crab nerve a compound which they believe is more active than GABA.

HÆMATOLOGY

Starch-Gel Electrophoresis of Mouse Hæmoglobins

The hæmoglobins of mice were first shown to exist in two different inherited forms by Ranney and Gluecksohn-Waelsch[1,2] using paper electrophoresis. Their work was confirmed and extended by Russell and Gerald[3], who found only two hæmoglobin types, diffuse and single, among twenty inbred lines of mice, using the starch-block technique. Starch-gel electrophoresis gives a better resolution of proteins than either of these techniques, and there have been three accounts[4-6] of the detection of slow-moving bands in the diffuse hæmoglobin using starch gel with continuous borate buffer. Popp and St. Amand[4] noted these bands and also two peaks in the ultracentrifuge analysis of diffuse hæmoglobin. Ranney, Marlowe-Smith and Gluecksohn-Waelsch[5] observed that both the slowest band of the electrophoretic pattern and the faster peak of the ultracentrifuge pattern increased when the hæmoglobin solution was stored for 4 weeks at 4° C. Rosa *et al.*[6] tested six inbred lines, five of which were among those used by Russell and Gerald[3], and claimed that they could be further sub-divided into at least four hæmoglobin types, when these bands were taken into account.

In the present investigation, in order to type with certainty the slower bands, very strong solutions of carbon-monoxy-hæmoglobin (10–15 per cent) were used within 48 hr. of the bleeding of the mice, and a variety of buffers tried. The discontinuous buffers of Poulik[7] and Aronsson and Grönwall[8] gave good results, but the best were obtained with a system using *tris*(2-amino-2(hydroxy-methyl)-1 : 3-propanediol), EDTA (disodium ethylene-diamine-tetra-acetate dihydrate) and citric acid in the gram-molecular concentrations 0·0385, 0·0009 and 0·0035 respectively in the gels, and veronal buffer of *p*H 8·6 and ionic strength 0·05 in the troughs.

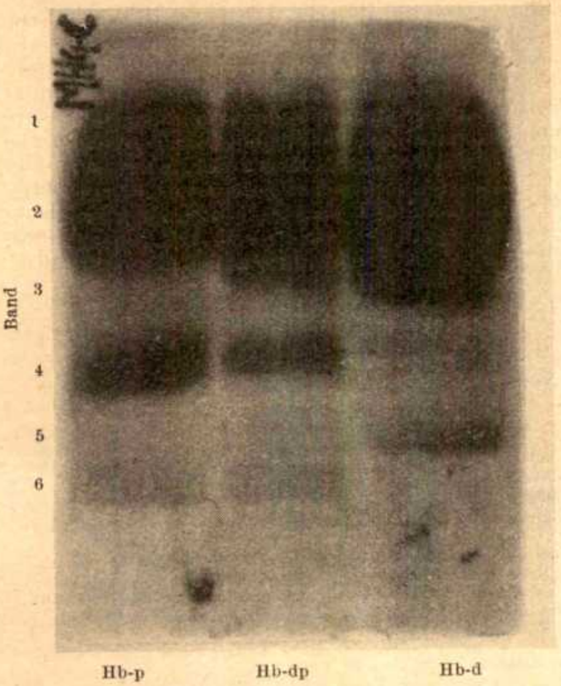

Fig. 1. The pattern after starch gel electrophoresis of three hæmoglobin types, all from the polydactylous line

With this technique the diffuse hæmoglobins consistently gave five bands (Fig. 1, Hb-d). Numbered in order of their mobilities, the strongest is 2 and coincides with the single hæmoglobin type, 5 is weak and 4 very weak. Standard strains tested were *C57BL/6* and *C57BR/cd* of the single type, and *CBA/Fa*, *A/He*, *DBA/2*, C_3H and *AKR* of the diffuse type. No differences within these types were observed, supporting the classification of Russell and Gerald[3], as opposed to that of Rosa *et al.*[6]. (B. L. Cohen (personal communication) classified these lines similarly, using Poulik discontinuous buffer in starch gel.[7])

However, in the non-inbred strain developed by Fisher and Holt for the expression of polydactyly[9], two variants of the normal diffuse pattern were observed in low frequency (Fig. 1). In one form, of which only three examples were found, band 3 is absent and 4 greatly increased, and 5 is replaced by a new slower band 6. The other form shows all six bands simultaneously. Both forms give the same ultracentrifuge pattern as diffuse hæmoglobin. The polydactylous strain was nearly extinct, so that few breeding data exist for these variants. What there is suggests that they are the heterozygous and homozygous products of a gene allelic with those of single and diffuse. They are therefore provisionally called Hb-p and Hb-dp respectively. The results of matings of mice of types Hb-p and Hb-dp with those of type Hb-d (diffuse) are summarized in Table 1. An outcross of an Hb-dp female to an Hb-s male of the *C57BL/6* line produced 2 offspring classifiable as Hb-ds and 4 undistinguishable from Hb-p, but presumably of the fifth genotype Hb^p/Hb^s. A mating between two such mice has yielded 6 apparent Hb-p to 1 Hb-s young.

Table 1

Mating type		No. of matings	Offspring		
♂	♀		Hb-d	Hb-dp	Hb-p
Hb-d	Hb-dp	3	8	9	0
Hb-dp	Hb-d	1	4	3	0
Hb-p	Hb-d	2	0	10	0

Mice from line C_3H were supplied by the Department of Radiotherapeutics, Cambridge, and from lines *C57BL/6*, *C57BR/cd* and *DBA/2* by the Medical Research Council Laboratory Animals Centre, Carshalton.

Interspecific Hybridization of Hæmoglobin

Formation of hybrids between hæmoglobin of different species (human and canine) have been described[1]. It is the result of a complete dissociation of the two hæmoglobins into chains with subsequent re-association in equal proportion; the two new molecules of hybrids become apparent; 50 per cent of the canine hæmoglobin participates in the formation of hybrids.

In other cases hybridization between hæmoglobins of different species has been impossible[2]. We present here: (1) an example of incomplete hybridization in which less than 50 per cent of animal hæmoglobin is involved; (2) conditions under which 100 per cent of animal hæmoglobin is involved.

The hæmoglobins were prepared as described in ref. 3. The dissociation occurred after a dialysis against acetate buffer 0·2 *M*, *p*H 4, 7 (ref. 4). Control was obtained by starch-block electrophoresis accord-

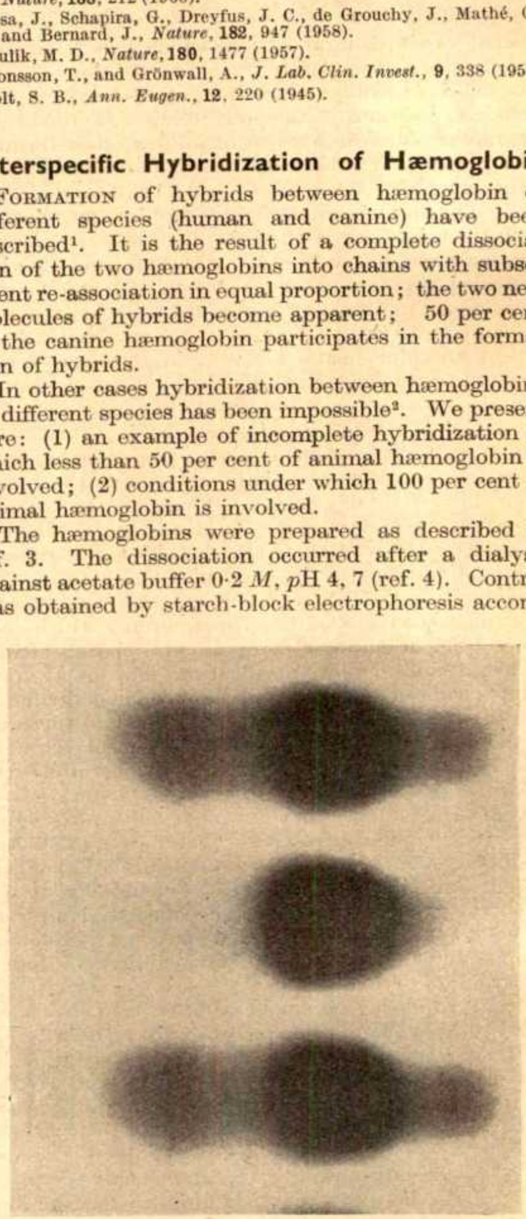

Fig. 1. Incomplete hybridization between human and rabbit hæmoglobins. Top, hybrid; middle, extemporaneous mixture; bottom, hybrid

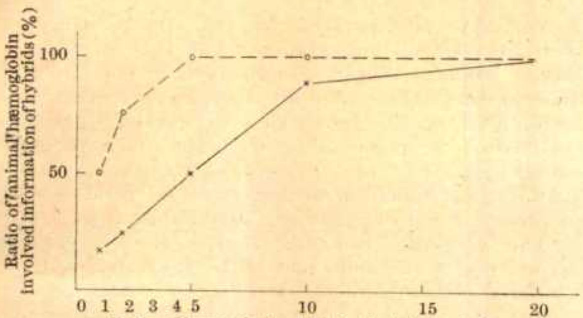

Fig. 2. Variation of the fraction of animal hæmoglobin involved in hybrids with the ratio of the initial mixture. ×, Rabbit; ○, dog

ing to the method described in ref. 5. The spots were eluted and hæmoglobin estimated[6].

Hybridization of human and rabbit hæmoglobins in equal proportions gave rise to two hybrids; but the ratios of each never reached 25 per cent of the initial mixture. Several conditions as temperature, concentration, *p*H, time, gave the same results (Fig. 1). The interpretation of this incomplete hybridization has to be discussed.

(1) An ultracentrifugation control (a single component of $S_1 = 2{\cdot}65$ of acidic *p*H instead of 3·6 at *p*H 7) allows the exclusion of incomplete dissociation of rabbit hæmoglobin.

(2) We can exclude the hypothesis of a hybridization of a minor fraction of rabbit hæmoglobin because after a first hybridization, the hybrids can be eliminated, and the hybridization on the remaining human and rabbit fractions repeated; the same quantities of hybrids reappear.

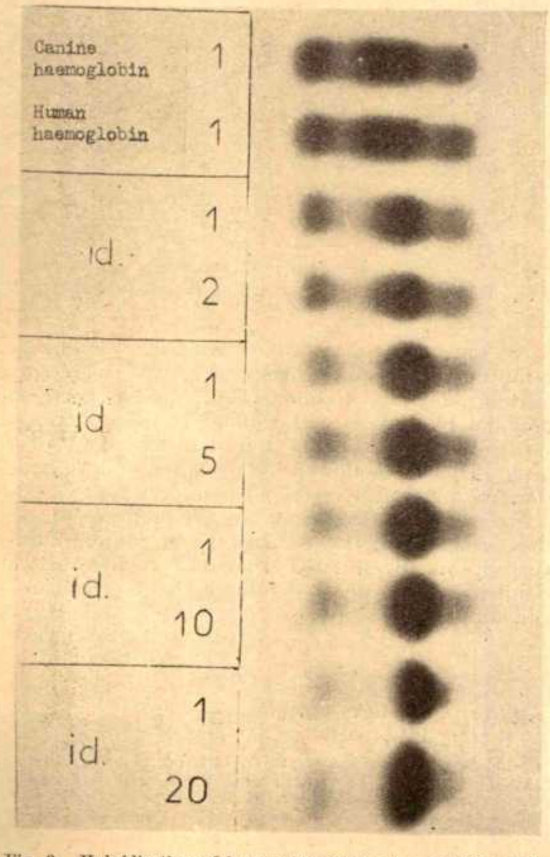

Fig. 3. Hybridization of human and canine hæmoglobin with change in the ratio of the two hæmoglobins

(3) The final hypothesis is that the affinity of one rabbit chain toward the other is stronger than that of a rabbit chain toward the corresponding human chain.

To test these hypotheses we changed the ratio of the two hæmoglobins in order to displace the equilibrium. Fig. 2 shows that the proportion of rabbit hæmoglobin which is involved in hybrids is 16 per cent when the initial mixture of human and rabbit hæmoglobin is 1 : 1 and more than 50 per cent when the ratio is 5 : 1.

The same experiment was performed with human and canine hæmoglobin (Fig. 3). When the ratio is 1 : 1, 50 per cent of canine hæmoglobin is involved in formation of hybrids; when the ratio is 5 : 1, 100 per cent of canine hæmoglobin is involved (Fig. 2).

Perhaps the application of systematic variations of ratio during hybridization of normal and abnormal hæmoglobin will allow the detection of abnormalities otherwise undetectable.

Absorption-Elution Grouping of Modifications and Development of Bloodstains

THE ABO grouping of dried blood smears by the absorption-elution method has already been described[1]. That a similar technique can be applied to bloodstains on fabric is also known[2]. This communication is intended to describe the modifications and development which have followed subsequent to the introduction of the absorption-elution method to this laboratory as a routine test and how the procedure has been made even more simple and its application even more effective.

In the grouping of smears, one of the difficulties encountered was to ensure that the cavities produced by the application of gum–dammar–beeswax mixture remained intact. Not infrequently the wax was found to have become lifted from the slide while in the elution chamber and inadvertent mixture of the cell suspensions to have taken place. This can be avoided by the use of three-cavity 3 in. × 1 in. glass slides (12 mm. diam. wells). For practical purposes, only anti-A, anti-B and anti-H antisera are generally used, and the three cavities are adequate for routine work.

In the grouping of bloodstains on fabrics, group specific substances present in some fabrics are known to interfere with bloodstain grouping. Furthermore, the cutting of a garment may not be desirable. Extracts of the bloodstain can be made either by soaking a piece of bloodstained fabric in water or by the application of water to the uncut garment and scraping with a scalpel. Minimum quantities of water should be used (6–12 drops). Similar treatment to a control area as near as possible to the stain is essential. Saline extracts are not satisfactory due to the formation of salt crystals on drying. The procedure is as follows: (1) Prepare the slides by placing one or two drops of extract in each of the three cavities. With a glass rod, cover the whole of the cavity with extract. Control A, B and O stains may be made from 1/10 solutions of A, B and O cells in water. Extracts from control areas of fabrics will not adhere to the slide unless protein is added. For this purpose, to fabric controls, add one drop of 1/10 O serum in water to each cavity. (2) Dry in air or on a hot plate at 40–45° C. (3) Fix in McIlvaine buffer at 99° C. for 1 min. (For large-scale grouping the use of stainless steel racks is recommended). (4) Blot dry. (5) Dispense one or two drops of anti-A, anti-B and anti-H antisera to the three cavities, ensuring that all the stain is covered. (6) Place in a moist chamber and leave for 3 hr. to absorb. (A plastic refrigerator box approx. 9 in. × 4 in. is a suitable chamber. Three or four layers of filter paper should be moistened with water and forced into the bottom of the box. Invert the box, and use the lid as a slide tray.) (7) Place in refrigerator at 4° C. for ½ hr. to increase agglutination intensities. (8) Wash off excess antibody with cold saline. Place slides in stainless steel rack and wash by alternate raising and lowering in each of two beakers of cold saline, ten or fifteen times in each beaker. (9) Blot dry. (10) Dispense one or two drops of A, B and O cells 2 per cent v/v to the relevant cavities. (11) Elute at 50°–55° C. for 10 min., in a moist chamber. (12) Remove from oven, rotate, leave for 15 min., read.

All bloodstain grouping tests in this laboratory are performed in duplicate. Known A, B and O controls are run at the same time, together with a 1/10 O serum blank. Slides may be marked for purposes of identification with a lead pencil if one end of the slide is finely ground into an opaque surface. Sensitivity tests have shown that the minimum quantities of dried whole blood necessary to produce good macroscopic results are approximately 10 μgm. when testing for A or B antigens and 200 μgm. when testing for H antigen.

I thank Mr. S. S. Kind for helpful discussions.

PHARMACOLOGY

Hæmatological Effect of a Derivative of the Monocarboxylic Acid of Vitamin B_{12} in Primary Polycythæmia

AN increasing number of derivatives of the monocarboxylic acid of vitamin B_{12} is known to antagonize the growth-promoting effect of vitamin B_{12} in various microbiological cultures (*Escherichia coli, Euglena, Ochromonas*, etc.) in the chick embryo and the rat[1–3].

Very few papers have, however, appeared dealing with the clinical indications of the B_{12} antagonists. Beard[4] reports that if administered in combination with 5,000γ of anti-vitamin B_{12}, 5γ of vitamin B_{12} will not be followed by a reticulocyte crisis in patients with pernicious anæmia. Smith[5] found that in patients suffering from chronic myeloid leukæmia, anti-vitamin B_{12} failed to improve general condition or depress the high level of serum vitamin B_{12}.

The present communication describes clinical experience gained with one of the B_{12} antagonists in primary polycythæmia. It is true that the number of patients involved is very low, and 6 months only have passed since the trials were begun, yet the results already observable are thought remarkable enough to merit preliminary communication.

The B_{12} antagonist used was the homogeneous monocarboxylic acid of vitamin B_{12} prepared by Kelemen[6]. It was administered to four patients in intramuscular daily doses of 1–3 mgm. Fig. 1 demonstrates the substantial reduction in the number of red cells in circulation after a total dosage of 20–30 mgm. in three cases, and of 90 mgm. in the fourth. The white cell count and the qualitative blood picture remained in all patients practically unchanged, nor was there any deterioration in the platelet count. Marrow puncture showed the erythroid–myeloid ratio to have come within the normal range in one case, and to have improved markedly in two, and moderately in one, patient. The hæmatocrit decreased and the sedimentation-rate increased. The spleen remained unchanged in size.

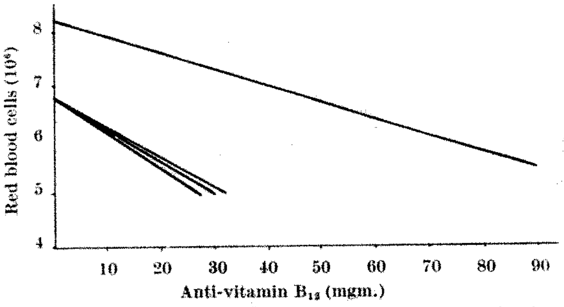

Fig. 1. Effect of anti-vitamin B_{12} on red blood cells of polycythæmic patients

All four patients showed alleviation in subjective symptoms. In three cases this was followed by lasting remission. In one patient who had been given previous treatments with radioactive phosphorus, the slow remissive response required 93 mgm. of the drug. This was followed by a relapse, and renewal of the treatment proved of no avail.

Extended investigations are in progress to see if the reduction in the red blood cell count following anti-vitamin B_{12} in polycythæmia vera is statistically significant, and to understand the mechanism involved.

Myocardial Catechol-O-Methyl Transferase Activity after Chronic Cardiac Denervation

In a recent study of the denervated dog heart[1], we noted a marked increase in cardiac sensitivity to norepinephrine, a finding anticipated from previous investigations of denervated organs[2]. Catechol-*O*-methyl transferase activity was measured in these denervated hearts to determine whether this pharmacological supersensitivity might be accompanied by a decreased ability of the myocardium to *O*-methylate norepinephrine. The results showed that cardiac denervation produces a decrease in the catechol-*O*-methyl transferase activity of the myocardium; whether this decrease is related to the phenomenon of supersensitivity, however, is open to considerable doubt.

Six dogs were subjected to cardiac denervation by regional neural ablation[1]. After 7–84 days the response of the cardiac contractile force[3] to several sympathomimetic amines and to cervical sympathetic and vagal nerve stimulation was measured. Portions of the left ventricular myocardium were then removed and frozen for subsequent determination of catechol-*O*-methyl transferase activity[4] and catecholamine content[5]. Control tissue was obtained in a similar manner from normal dogs. Nerve stimulation failed to produce a cardiac response in the denervated dogs, as did the injection of tyramine; in addition, catecholamines could not be detected in the denervated myocardium (Table 1). When compared with normal dogs, the cardiac-denervated animals showed nearly a ten-fold decrease in the threshold dose of L-norepinephrine required to give a detectable response in cardiac contractile force; there was also a three-fold increase in the cardiac response to a standard dose of 0·25 μgm./kgm. L-norepinephrine. These findings confirmed the adequacy of the denervation and the presence of marked supersensitivity to injected L-norepinephrine. Catechol-*O*-methyl transferase activity in the denervated myocardium was significantly less than in normal dogs, the mean value after denervation being 58 per cent of control (Table 1).

Table 1. EFFECT OF CHRONIC CARDIAC DENERVATION ON THE CATECHOL-*O*-METHYL TRANSFERASE ACTIVITY AND CATECHOL AMINE CONTENT OF THE LEFT VENTRICLE OF THE DOG

	Innervated	Denervated
No. of dogs	7	6
Catecholamine content:		
Mean ± *S.D.*	0·77 ± 0·148 μgm./gm.	< 0·03 μgm./gm. †
Range	0·57–0·98 μgm./gm.	< 0·03 μgm./gm.
Catechol-*O*-methyl transferase activity:		
Mean ± *S.D.*	0·12 ± 0·024 units *	0·07 ± 0·021 units †
Range	0·07–0·14 units	0·03–0·09 units

* 1 unit = 1 μmole L-norepinephrine metabolized/gm. tissue/hr.
† Significantly different from innervated ($P < 0·01$).

In other studies we have shown that the complete inhibition of catechol-*O*-methyl transferase by pyrogallol produces no potentiation and only moderate prolongation of the cardiac response to injected norepinephrine in the dog[6]. It therefore seems unlikely that a 42 per cent decrease in myocardial catechol-*O*-methyl transferase activity could account for the several-fold increase in cardiac sensitivity produced by denervation. Norepinephrine may also be metabolized by monoamine oxidase, but Burn *et al.*[7] have shown that this enzyme remains intact in the denervated foreleg arteries and iris of the cat. These investigations taken together, suggest that the supersensitivity of denervated organs to norepinephrine cannot be attributed to a marked loss of catecholamine-metabolizing enzymes from denervated tissue.

Interference of Chlorpromazine with the Metabolism of Aromatic Amino-acids in Rat Brain

CHLORPROMAZINE (2-chloro-10-(3-dimethylamino-propyl)-phenothiazine, 'Largactil^R') and chlorprothixene (2-chloro-9-(ω-dimethylamino-propyliden)-thioxanthene, 'Taractan^R') counteract the changes in the monoamine content of rat brain induced by monoamine oxidase inhibitors, reserpine and 5-hydroxytryptophan[1]. It has been suggested that this might be due to reduction of the permeability of storage organelles for aromatic monoamines[1]. However, investigations have not yet been undertaken to determine whether chlorpromazine interferes also with the penetration of monoamine precursors (for example, aromatic amino-acids) into the brain. In this communication we will show that chlorpromazine interferes with the metabolism of 3,4-dihydroxyphenylalanine (dopa) and of 5-hydroxytryptophan in rat brain.

After fasting for 14–16 hr. Wistar rats weighing 70–130 gm. received chlorpromazine intraperitoneally and 30 min. later either 20 mgm./kgm. D,L-dopa-2-^{14}C or 75 mgm./kgm. unlabelled D,L-5-hydroxytryptophan subcutaneously. In the experiments with dopa, whole blood and brain were assayed for dopa-^{14}C, for catecholamine-^{14}C, as well as for carbon-14 in the remaining fraction, containing presumably phenylcarbonic acids, phenylglycols, glycine conjugates. This procedure (to be described elsewhere in detail) included hydrolysis of $HClO_4$-extracts by 'glusulase' (enzyme mixture containing glucuronidase, sulphatase; Endo Laboratories), fractionation on 2 micro-columns of 'Dowex' 50 × -4 ($pH = 6·5$ and H$^+$-form, respectively) and use of a Packard liquid scintillation counter. With this fractionation procedure the recovery of dopa-^{14}C and norepinephrine-2-^{14}C added to $HClO_4$-extracts was 95–100 per cent. The radioactivity found in 1 gm. (fresh weight) of brain or 1 ml. of blood was calculated for each fraction in per cent of the radioactivity administered per gm. of body-weight. After injection of 5-hydroxytryptophan the following procedures were carried out simultaneously: (*a*) immediate homogenization of the brains and spectrophotofluorometric assay of 5-hydroxytryptamine[2] (5-hydroxytryptamine rise *in vivo*); (*b*) anaerobic incubation of the intact isolated brains in wet chambers for 2 hr. at 37° C. before homogenization and determination of the 5-hydroxytryptamine rise occurring post mortem[3].

Experiments with dopa-2-^{14}C: In rats treated with 20 mgm./kgm. chlorpromazine 30 min. before administration of dopa-^{14}C the blood concentration of dopa-^{14}C was found to be remarkably higher than in control animals. Thus, in total blood the quotient dopa-^{14}C content of chlorpromazine-treated animals/dopa-^{14}C content of controls showed the following increase: 30 min. after injection of the amino-acid, 1·09; 60 min., 1·43; 90 min., 1·79; 120 min., 1·96. The effect of chlorpromazine was dependent on the dose of the drug (Fig. 1, above). In brain no significant change of dopa-^{14}C occurred after chlorpromazine within the intervals mentioned above and at different doses (Fig. 1, above). In consequence, there was a fall in the brain/blood ratio of dopa-^{14}C, indicating that dopa-^{14}C within the brain cells was relatively decreased by chlorpromazine. Even in doses as low as 2 mgm./kgm. chlorpromazine had a significant effect ($P < 0{\cdot}05$; *t*-test) (Fig. 1, below). Chlorpromazine did not decrease the brain/blood ratio of other carbon-14 labelled fractions significantly. The results with dopa-^{14}C suggest that chlorpromazine either reduces the uptake of this amino-acid by brain or increases its cerebral turn-over.

Preliminary experiments with 5-hydroxytryptophan-2-^{14}C gave results similar to those obtained with dopa-2-^{14}C.

Experiments with unlabelled 5-hydroxytryptophan: In rats treated with 5-hydroxytryptophan the brain 5-hydroxytryptamine increases *in vivo* as well as for several hours after death[3], probably due to continuing decarboxylation of 5-hydroxytryptophan. Chlorpromazine in doses of 5–20 mgm./kgm. injected prior to 5-hydroxytryptophan caused an inhibition of the 5-hydroxytryptamine rise in the brain *in vivo* as well as post mortem (Fig. 2). Since 5-hydroxytryptophan decarboxylase was found unaffected[4] in the brain of chlorpromazine-treated rats, this action of chlorpromazine might be explained by decreased penetration of 5-hydroxytryptophan to the cellular site where decarboxylation into 5-hydroxytryptamine occurs.

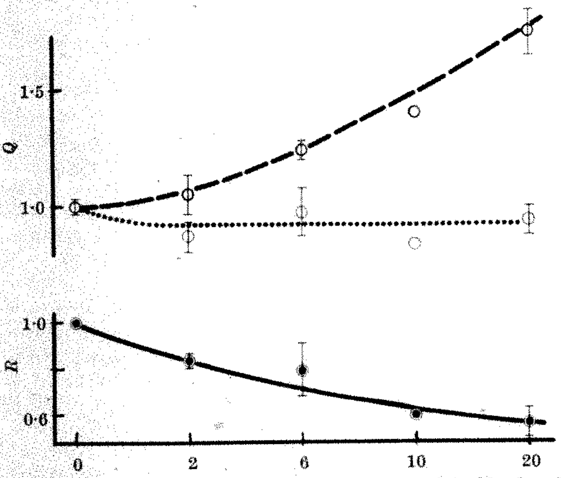

Fig. 1. Influence of chlorpromazine on dopa-^{14}C in blood and brain of rats. Abscissa: doses of chlorpromazine in mgm./kgm. Ordinate, above, Q indicates the following quotient:

$$\frac{\text{Dopa-}^{14}\text{C-content in chlorpromazine-treated rats}}{\text{Dopa-}^{14}\text{C-content in controls}}$$

– – – ○ – – –, blood; · · · ○ · · ·, brain

below: R means the ratio $Q_{\text{brain}}/Q_{\text{blood}}$. Chlorpromazine was injected intraperitoneally 30 min. prior to 20 mgm./kgm. D,L-dopa-2-^{14}C (specific activity 0·67–3·33 μc./μmol.) The animals were decapitated 1 hr. after subcutaneous administration of dopa-^{14}C. For the quotient Q chlorpromazine-treated animals were related to controls killed simultaneously. The ratio R was calculated for each individual experiment. The points (except that for 10 mgm./kgm.) represent means ± standard errors of three experiments, each experiment was carried out with pools of brain and blood respectively from three animals. Control values in percentage of dopa-^{14}C administered per gm. of body-weight; brain, 3·06 ± 0·24/gm. fresh tissue; blood, 8·00 ± 0·63/ml.

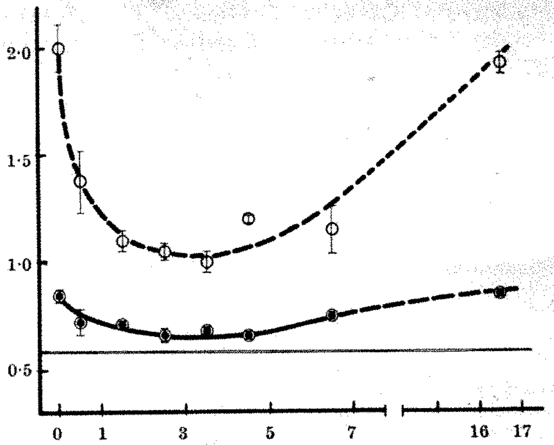

Fig. 2. Inhibition by chlorpromazine of the 5-hydroxytryptophan-induced rise of 5-hydroxytryptamine in rat brain *in vivo* and post mortem. Abscissa: Interval in hr. between intraperitoneal injection of 20 mgm./kgm. chlorpromazine and decapitation. Ordinate: 5-Hydroxytryptamine in μgm./gm. fresh brain. 75 mgm./kgm. of D,L-5-hydroxytryptophan were given subcutaneously 30 min. prior to decapitation. Time 0 represents animals receiving 5-hydroxytryptophan only. The points represent mean values ± standard error of 2–8 estimations of 5-hydroxytryptamine (each with pools of 2 brains). —⊙—, Brain homogenized immediately after decapitation; - - - ○ - - -, intact brains incubated at 37° C. for 2 hr. after death; =, untreated controls, brain homogenized immediately after decapitation

Inhibition of dopa- and 5-hydroxytryptophan-uptake by brain could partly explain earlier findings that chlorpromazine reduces the *in vivo* accumulation of cerebral monoamines due to administration of monoamine oxidase inhibitors or of 5-hydroxytryptophan[1]. There remain, however, other effects of chlorpromazine on monoamine metabolism which are probably due to interference with the permeation of monoamines, for example, inhibition *in vivo* of the reserpine-induced monoamine depletion of the brain[1], decrease in the uptake of epinephrine-^{14}C by several tissues[5,6], acceleration of the epinephrine-^{14}C-turnover in intact animals[7]. Thus, it may be concluded that chlorpromazine reduces *in vivo* the permeability of membranes responsible for the uptake of aromatic monoamines and possibly also that of aromatic amino-acids.

Interference of chlorpromazine with biological membranes has already been described for other substances *in vitro* and *in vivo*. Thus, *in vitro* the drug diminishes the uptake of 5-hydroxytryptamine by blood platelets[8], the water imbibition of mitochondria by thyroxine and other swelling agents[9], the uptake of glycine by brain slices[10], the binding of *N*-ethyl-3-piperidyl benzylate to mitochondrial granules[11] and the release of acetylcholine from storage organelles[12]. Chlorpromazine reduces *in vivo* the diffusion of trypan blue[13], the intestinal absorption of lipids[14,15] and sugars[16], dextran-induced œdema[17,18], the increase of permeability due to hyaluronidase[19], etc. Recent[1] and present findings support the idea that chlorpromazine might primarily affect the permeability of the membrane[9]. They show, furthermore, that this action of the psychotropic drug affects *in vivo* the metabolism of aromatic amino compounds that have been considered of special importance for brain functions.

It is unlikely that the interference of chlorpromazine with the penetration of aromatic amines and amino-acids is a consequence of hypothermia produced by the drug. The finding that chlorpromazine acts in the brain (kept at constant temperature) post mortem as well as *in vivo*, and the experiments *in vitro* mentioned here, do not support such an assumption.

We thank Mr. E. Bühler for skilful technical assistance and valuable contributions to the analytical procedure.

HISTOCHEMISTRY

Starch-Gel Electrophoresis of Alkaline Phosphatases using a Histochemical Method

We have recently reported a technique for the demonstration by a histochemical method of phosphatase bands following starch-gel electrophoresis[1,2].

Examination of phosphatases of various organs have demonstrated the following: (1) That rat liver cells contain six separate glycerophosphatases. (2) That there are phosphatase bands which hydrolyse glycerophosphate, adenosine triphosphate and adenosine monophosphate, and there are other bands which are specific for either adenosine monophosphate or adenosine triphosphate. (3) Specific phosphatase bands were also found for diphosphopyridine nucleotide, triphosphopyridine nucleotide, glucose-6-phosphate, fructose-6-phosphate and hexose-diphosphate with, however, some overlapping of some of the bands.

In order to determine the spectrum of activity of a single glycerophosphatase a commercial preparation of calf intestinal alkaline glycerophosphatase (obtained from California Biochemicals) was subjected to starch-gel electrophoresis according to the foregoing technique[1,2]; and the preparation was given the opportunity to hydrolyse each of eleven separate phosphate esters (adenosine monophosphate, adenosine diphosphate, adenosine triphosphate, diphosphopyridine nucleotide, triphosphopyridine nucleotide, creatine phosphate, sodium β-glycerophosphate, glucose-6-phosphate, fructose-6-phosphate, glucose-1-phosphate and acetyl phosphate). The electrophoresis of this purified phosphatase demonstrated only one band of phosphatase activity which was active in hydrolysing all the substrates studied. At first we believed that this contradicted our findings on specific phosphatases or at least that intestinal phosphatase was different from other phosphatases. This was a distinct possibility, since Brandes *et al.*[3,4] had demonstrated that the brush border phosphatase of the intestinal cells lay between the microvilli outside the cell membrane. It was thus an extracellular enzyme and also, in view of its site, might be expected to be non-specific in its activity and to differ from the intra-cellular enzymes which are concerned with metabolic processes. However, Ahmed and King[5] in their discussion of placental phosphatases make the point that all the purified alkaline phosphatases studied to date (from kidney, intestine and placenta) hydrolyse all monophosphate esters non-specifically, but that polyphosphates and metaphosphates are not hydrolysed. On the other hand, Schmidt *et al.*[6] state that purified intestinal and kidney alkaline phosphatases hydrolyse all the phosphate esters studied (including poly- and meta-phosphates). Our results have shown that the single band of calf intestinal phosphatase in our starch-gel preparations actively dephosphorylates adenosine diphosphate and adenosine triphosphate as effectively within the limitations of the technique as it does adenosine monophosphate or glycerophosphate, or indeed as effectively as it hydrolyses any of the other phosphate esters.

Although we have not carried out investigations on homogenates of intestine to date, work on kidney homogenates has demonstrated specific phosphatase bands after starch-gel electrophoresis for certain phosphate esters. We did not find a single band which would hydrolyse all the esters presented to it. It seems possible, therefore, that the act of extraction and purification of a phosphatase may have altered the active centre of the enzyme in such a way as to

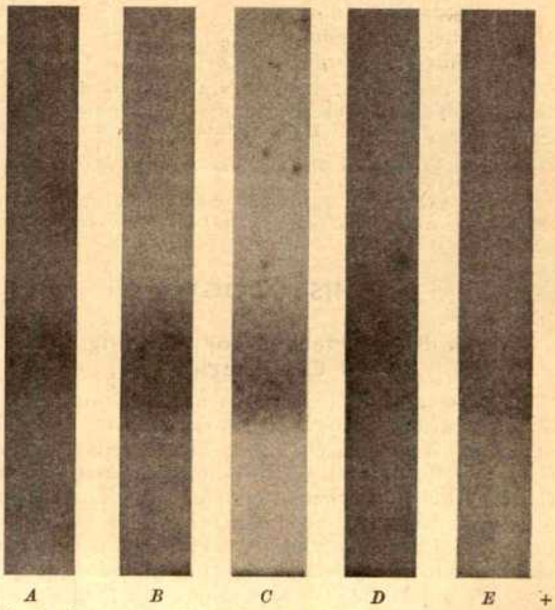

Fig. 1. Zymograms obtained with a purified calf alkaline phosphatase preparation. Note the same enzyme hydrolyses all the substrates. *A*, Incubated with fructose-6-phosphate as a substrate; *B*, incubated with glucose-6-phosphate as a substrate; *C*, incubated with creatine phosphate as a substrate; *D*, incubated with adenosine triphosphate as a substrate; *E*, incubated with adenosine diphosphate as a substrate

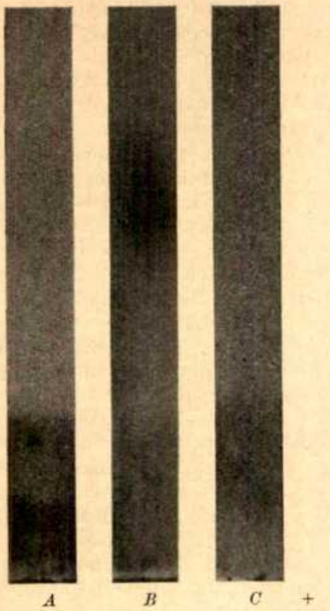

Fig. 2. Zymograms obtained with a rat kidney homogenate. Note the bands of enzymatic activity are different for each substrate. *A*, Incubated with sodium β-glycerophosphate as a substrate; *B*, incubated with adenosine triphosphate as a substrate; *C*, incubated with adenosine monophosphate as a substrate

render it non-specific. We believe this possibility should be allowed for in future investigation with purified enzyme preparations and underlines the fact that experiments conducted in test tubes on starch gel or any *in vitro* method should not necessarily be assumed to bear any relation to what goes on *in vivo*.

HISTOLOGY

Sudan Black Method for Staining Sites of Calcification

IN 1958[1] a method was described for staining sites of calcification at the 'calcification front'—the edge of the preosseous matrix in bone, the cartilage around the hypertrophic cells of the epiphyseal cartilage and the junction of predentin and dentin. The method consisted, after fixation, in extracting the tissue with hot pyridine, decalcifying, embedding in gelatin, and staining with an alcoholic solution of sudan black *B* after sectioning on a freezing microtome. The sections were mounted in glycerine jelly. A fuller account of the method was published later[2].

This method has been used with success by Ponlot[3] and by Johnson (private communication). However, I have since found that the results after pyridine extraction may be somewhat erratic. At present the reason is not known; it may be due to differences in the quality of the various batches of pyridine used. Recent work[4] suggests that the sudanophil material may be lipid in nature, and that prolonged extraction with pyridine may remove it completely, partial extraction unmasking it and making it sudanophil.

A reliable method is to place the tissue, after fixation, in absolute alcohol for one day and then into benzene at 60° C. for 24 hr., after which it is again transferred to absolute alcohol. Then, after washing, decalcification and embedding are carried out. The sudanophil material is apparently not removed by this procedure.

PATHOLOGY

Seromucoid-Levels in Osteolathyrism in the Rat

SCHWARTZ[1] has recently reported significant increases in mean levels of serum mucoproteins in lathyric rabbits, and has interpreted these as reflecting an increased depolymerization of ground substance. Grant, Hathorn and Gillman[2] have reported increased levels of serum mucoproteins in rats made lathyric by feeding sweet pea diets. They have suggested the occurrence in these animals of an increased synthesis and discharge of mucoproteins by the liver, associated with a decreased rate of utilization of mucopolysaccharide by the aorta and other connective tissues during synthesis of new fibrillar components. Our own unpublished observations of seromucoid-levels made over a period of years in a number of series of rats in which osteolathyrism had been produced by feeding β-aminopropionitrile are not in agreement with these reports.

Our findings have indicated that changes in seromucoid-level do not uniformly occur in osteolathyrism and, when present, are transitory and seem to result from a re-enforcement by the lathyrogenic agent of a stressful situation to which the animals were subjected—such as might result from a change in living quarters—rather than being a specific effect of the disease itself. It has previously been suggested that elevated serum glycoproteins may represent a response to non-specific stress[3].

All rats in our work were males of the Holtzman Sprague–Dawley strain and varied in age from 21 days in some experiments to 3 months in others. Experimental diets consisted of finely ground Rockland rat stock diet with additions of β-aminopropionitrile fumarate varying in amounts corresponding to 0·175–0·8 per cent of the diet, levels which are markedly to severely lathyrogenic when fed to rats. Control animals were fed unsupplemented stock diet. In the earlier experiments seromucoid was determined by the original method of Winzler *et al.*[4]. In recent determinations the modification of Weimer and Moshin was used[5]. Tyrosine content was used as a measure of seromucoid in all determinations.

Results obtained with older rats paralleled those from weanling rats. When the rats were caged in

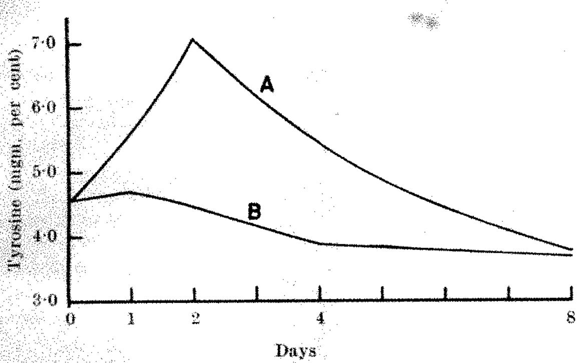

Fig. 1. Seromucoid-levels. Rats, 30 days of age on arrival, were placed six in a cage and fed stock diet. After 3 days they were placed into different individual cages (day 0, on chart). Curve *A*, rats receiving 0·4 per cent β-aminopropionitrile fumarate from day 0. Curve *B*, rats receiving normal diet. Curves were plotted from means of values obtained from individual sera of 5 or 6 rats per group (blood obtained by heart puncture under ether anæsthesia, each rat used only once)

groups of 3–6 after their arrival from the supplier, then distributed to different individual cages at the beginning of the experimental period, transitory rises in seromucoid-levels occurred in the groups receiving the diets containing β-aminopropionitrile, reaching a maximum after 2 days and declining gradually to coincide with control-levels at 8–15 days after the beginning of the experiment (Fig. 1). Individually caged rats which were accustomed to their individual quarters before being changed to the experimental diets showed no such elevations in seromucoid-levels. In fact, when young rats were placed in their experimental cages in pairs immediately on arrival from the supplier, then started on experiment on the following day without a change in quarters, the added 'security' afforded by the cage-mate apparently prevented even a transitory rise in seromucoid-level even though the period of acclimatization was minimal (see Table 1). Acclimatized rats showed no significant differences from normals for periods up to 28 days, our longest experimental period.

The explanation for the sustained elevation in the serum mucoprotein fractions in experimental lathyrism reported by others[1,2] is not apparent. Their 'mucoprotein' fractions appear to represent the same perchloric acid-soluble and phosphotungstic acid-insoluble fraction as our 'seromucoid'. Species or strain differences might conceivably be at least a partial explanation for the differences in results. It may also be pertinent to point out that the experimental diet used by Grant *et al.*[2] differed appreciably from their control diet in other aspects besides lathyrogenicity. It has been shown that the levels of certain blood constituents may be more dependent on other variables in the diet than they are on lathyrogenic activity[6]. Even the symptomatology of osteolathyrism can be affected by dietary changes not involving changes in the level of the lathyrogen[7–10]. Whatever the explanation for the differences between our results and those of others may be, it seems apparent that elevated seromucoid-levels are not a necessary concomitant of osteo-lathyrism in the rat. This finding does not necessarily imply, however, that mucopolysaccharide metabolism is not affected in osteolathyrism.

Table 1. Seromucoid-Levels in 30-day-old Rats placed Two in a Cage on Arrival and started on Experiment the Following Day (Day 0) without changing Cages

Day	Seromucoid in mgm. per cent tyrosine*	
	Experimental†	Normal
0	—	4·66
1	4·98	5·49
2	4·07	3·38
4	3·46	3·33
7	10·55‡	9·20‡
14	4·72	4·78

* Each value was determined in quadruplicate on the pooled sera from 6 rats (blood obtained by decapitation).

† The experimental diet contained 0·25 β-aminopropionitrile fumarate.

‡ The reason for the high values in both groups on day 7 is not known. The same factors, whether analytical or environmental, apparently affected both results. The rats were housed in a room that was used by several groups of investigators and contained also other species of small animals.

This work was supported by grant *A*-1427 from the U.S. Public Health Service. We are grateful to Abbott Laboratories, North Chicago, Ill., for generous gifts of β-aminopropionitrile fumarate.

Antibrain Antibodies of the 19*S* γ-Globulin Type in Rats with Allergic Encephalomyelitis

It is known that complement-fixing antibrain antibodies can be detected in rats and other animals with allergic encephalomyelitis following sensitization to nervous tissue plus Freund's adjuvant[1]. Although these complement-fixing antibrain antibodies fix complement with autologous brain antigen[2], failure to transfer passively allergic encephalomyelitis with immune serum and the lack of correlation between antibody titre and occurrence of disease in individual animals have left the role of such antibodies undefined[1,3]. This communication summarizes additional studies which indicate that complement-fixing antibrain antibodies in rats appear to belong to 19*S*-type γ-globulins and are incapable of giving passive cutaneous anaphylaxis.

Attempts to elicit passive cutaneous anaphylaxis were made using the technique of Ovary[4]. Rat sera tested for passive cutaneous anaphylaxis were from animals sensitized to guinea pig spinal cord-adjuvant and had been assayed previously for antibrain antibody by the quantitative complement fixation technique described in detail elsewhere[5]. Test sera (undiluted or diluted) were injected intracutaneously in 0·1-ml. amounts over the back of normal albino rats each weighing approximately 200 gm. These test rats were challenged intravenously 1–3 hr. later with rat brain antigen and Evans blue dye. The type of brain antigen used for challenge consisted of either 'detergent solubilized' lyophilized rat brain in physiological saline or a 20 per cent rat brain homogenate in saline (clarified by low-speed centrifugation and heated at 80° C. for 30 min. to eliminate thrombo-

plastin activity). Each test rat received 6–113 mgm. of brain (dry weight) for challenge. Serum test sites were inspected for blue staining (positive passive cutaneous anaphylaxis reaction) 1–2 hr. after intravenous injection of brain antigen and dye. Several passive cutaneous anaphylaxis experiments are shown in Table 1. Each of the 10 sera tested contained antibrain antibody, fixing between 16 and 44 units of complement *in vitro* with brain antigen. All 10 sera gave negative passive cutaneous anaphylaxis reactions when tested either undiluted or diluted 1 : 10; or 1 : 100. Similar attempts to elicit passive cutaneous anaphylaxis in guinea pigs, a more sensitive test animal, were carried out using 14 test sera from guinea pigs or rats sensitized to homologous spinal cord-adjuvant, respectively. None of these 14 sera gave positive passive cutaneous anaphylaxis reaction.

From the work of Ovary *et al.*[6] it seemed likely that our inability to elicit passive cutaneous anaphylaxis with rat immune sera might be explained, at least in part, if the antibrain antibodies in question were of the 19*S* γ-globulin variety. In order to clarify this point, immune rat sera known to contain antibrain antibody were treated with 2-mercaptoethanol, a procedure reported to inactivate 19*S*-type antibodies[7–9]. Immune sera were mixed with an equal volume of 0·2 *M* 2-mercaptoethanol, or dialysed against 0·1 *M* 2-mercaptoethanol, at 4° C. for 1–4 days. The treated sera were then dialysed against physiological saline for 3 days and reassayed for their capacity to fix complement with brain antigen. Representative results are shown in Table 2. Before 2-mercaptoethanol treatment, the 11 rat serum samples and the immune serum pool fixed from 14 to more than 67 units of complement with rat brain antigen. The capacity of all sera to fix complement with rat brain was regularly abolished by 2-mercaptoethanol treatment. This striking effect of 2-mercaptoethanol was noted with 6 additional rat immune serum pools as well as with 13 other individual rat sera. Since 19*S*-type antibody has been reported by Ovary *et al.*[6] to prevent detection of 7*S*-type antibody in passive cutaneous anaphylaxis, 6 immune rat sera were tested for their capacity to elicit passive cutaneous anaphylaxis after mercaptoethanol treatment. All 6 sera failed to give passive cutaneous anaphylaxis reactions, suggesting that they contained little, if any, 7*S*-type antibrain antibodies.

* Individual serum samples obtained from rats 17–21 days after sensitization to guinea pig spinal cord plus Freund's adjuvant; serum pool prepared from sera obtained from rats 7–41 days after sensitization.

† Maximum number 50 per cent hæmolytic units of complement ($C'H_{50}$) fixed, of exactly 100 $C'H_{50}$ available, by 0·25 ml. serum and rat brain antigen diluted 1 : 250.

Direct evidence for the high molecular weight nature of the complement-fixing antibrain antibodies under study was obtained by density gradient ultracentrifugation of one immune rat serum known to fix 80 units of complement with rat brain antigen. Following ultracentrifugation the fractions which contained less than 20 per cent of the total protein and all the 19*S*-type molecules fixed 84 units of complement. No significant fixation of complement could be detected by the fractions containing the remaining slower sedimenting molecules of the 7*S* variety.

Our data indicate that complement-fixing antibrain antibodies, produced by rats sensitized to guinea pig spinal cord and adjuvant, are high molecular weight γ-globulins. This finding accounts, at least in part, for failure of such antibodies to give passive cutaneous anaphylaxis. The observations reported here are of particular interest in view of work by others showing that positive passive cutaneous anaphylaxis reactions can be obtained with sera from animals with auto-immune thyroiditis or with human thyroiditis sera containing antithyroid antibodies of the 7*S*-type[6,10]. Our interest in the nature of the complement-fixing antibrain antibodies in rats, described in this communication, has been heightened by our recent finding that passively administered rat immune serum containing high-titre complement-fixing antibrain antibodies exerts a striking suppressive effect on development of allergic encephalomyelitis in actively sensitized recipients[11].

We thank Dr. E. C. Franklin for carrying out the density gradient analysis. This work was supported by U.S. Public Health Service grants *B*–1127 and *B*–3104.

RADIOBIOLOGY

Chromosomes of Two Cases of Human Chronic Myeloid Leukæmia

THREE reports have described an abnormally small chromosome (Ph^1) replacing one of the four smallest, acrocentric autosomes in the chromosome complement of cells from patients with chronic myeloid leukæmia[1-3]. The Ph^1 chromosome has been found in cultured peripheral blood or bone marrow cells from twenty patients with chronic myeloid leukæmia, ranging from untreated cases to those in terminal, acute stages, and a causal relationship between the chromosome abnormality and the disease has been suggested. Tough *et al.*[3] failed to find the Ph^1 chromosome in five cases of this leukæmia. Two of these had entered an acute leukæmia phase where diverse chromosome changes can be expected, whereas the other three cases had in common an unusually long history after diagnosis and followed a relatively benign course. Two of these latter cases had a previous history of radiotherapy for ankylosing spondylitis and there was a high probability that these leukæmias were radiation induced.

Two cases of leukæmia, which add to these findings, have been examined in this laboratory. The chromosome investigations were made on peripheral blood cells which had been cultured for two days by a modified form of the method of Moorhead *et al.*[4]. Case 1 is a 49-year-old woman who was recently diagnosed as chronic myeloid leukæmia, and was untreated at the time of the chromosome studies. The Ph^1 chromosome was found in 16 of the 27 cells which were examined (Table 1). This is a further example of the few cases which show that the presence of Ph^1 is not the result of any therapy measures causing chromosome breakage.

Table 1. CHROMOSOME COUNTS IN TWO CASES OF CHRONIC MYELOID LEUKÆMIA

Case no.	Chromosome counts 40 —	45	46	47	Total	Ph^1 present	Ph^1 absent	Ph^1 ?
1	1	1	24	1	27	16	10	1
2	–	–	53	2	55	0	49	6

Case 2 is a 49-year-old man whose white cell count was first found to be high in 1956, and fluctuated afterwards with an overall tendency to increase. In 1959, sternal bone marrow cells showed a marked granulocytic hyperplasia with a particular increase in myelocytes and metamyelocytes consistent with a diagnosis of asymptomatic chronic myeloid leukæmia. An increased white cell count and splenic enlargement were successfully treated with 'Myleran' in 1960. This patient has a long varied medical history, and since 1944 has received a minimum of 33, and probably more diagnostic irradiations from which it has been estimated he has received a total skin dose of at least 180 r. Although the dose is small compared with those given in radiotherapy, the possibility that this leukæmia was radiation-induced cannot be dismissed. The Ph^1 chromosome was not found in any of the 55 cells, in which the small acrocentric chromosomes were studied (Table 1). This case appears to be of the same nature as the three cases described by Tough *et al.*[3], and supports their view of the existence of a distinct sub-group of chronic myeloid leukæmia characterized by unusually slow progression and absence of the Ph^1 chromosome.

The existence of such a group raises a problem as to the relationship of the Ph^1 chromosome to chronic myeloid leukæmia. If this leukæmia can occur without the Ph^1 abnormality, the latter can then be only one of its causes and, indeed, a different, more fundamental cause common to all cases of chronic myeloid leukæmia might be suggested. Alternatively, the malignant nature of the clinically benign cases without the chromosome abnormality may be doubted; the blood abnormality in these may have the nature of a long-term leukæmoid reaction, or it may be a pre-malignant stage, malignancy being consequent on the occurrence of the Ph^1 chromosome abnormality. The greatest interest of this group of cases lies in the possibility that they represent an elementary stage in the ætiology of the disease and that progression from their present malignant, but benign, course awaits the development of the Ph^1 chromosome abnormality. The Ph^1 chromosome is not therefore a primary event causing the leukæmia, but is a secondary effect of the neoplastic condition which has some other cause. Secondary chromosome stem-lines, which are important in the progression of tumours, usually result from chromosome breakage and reunion, which occur in an essentially random manner, and consequently tumour stem-lines show marked individuality and are rarely if ever repeated. The Ph^1 chromosome is the only chromosome abnormality which has been found consistently in neoplastic tissue, and as such, it differs from known secondary chromosome changes. If it is a secondary effect, and the result of random chromosome breakage, its presence in all cases of chronic myeloid leukæmia would require a rigorous selection for this particular chromosome abnormality.

The specificity of the Ph^1 chromosome to a particular form of leukæmia is striking, whether it is primary and causal or a secondary development.

I thank Dr. J. B. Howie for hæmatological data and for the estimate of the number of diagnostic irradiations received by case 2, and Mr. H. D. Jamieson for the estimate of the total skin dose received.

Biogenesis of Glucobrassicin, the *in vitro* Precursor of Ascorbigen

RECENT work by Gmelin and Virtanen[1], concerning the isolation and elucidation of the structure of glucobrassicin, and its reaction with ascorbic acid in the presence of myrosinase to give rise to ascorbigen, prompted us to investigate some biochemical interrelations of indole derivatives in *Brassica oleracea* L. by means of labelled (radioactive) compounds. The main question in this connexion was why, in our previous communication[2], we were not able to prove the presence of glucobrassicin in our material. According to Gmelin[3], our method of working up the plant material was not suitable for demonstrating the presence of glucobrassicin in it. The reaction of glucobrassicin with ascorbic acid in the presence of

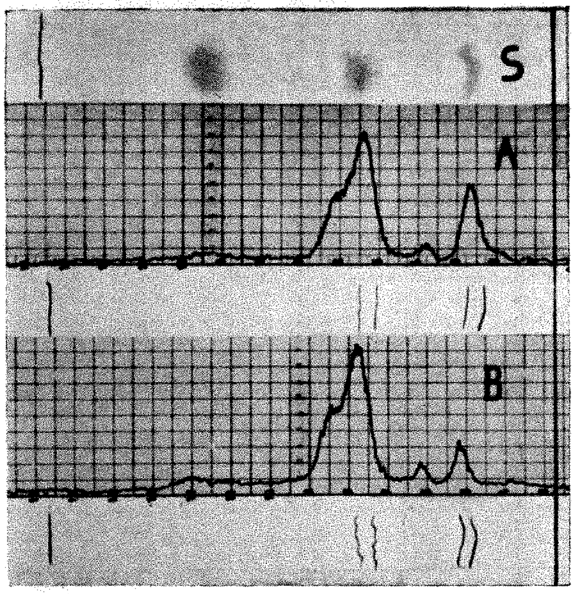

Fig. 1. Distribution of the radioactivity in chromatograms of the methanolic extracts of cabbage leaves given D,L-tryptophan-3-^{14}C. *S*, Chromatogram of standards: ascorbigen, tryptophan, glucobrassicin (in decreasing order of R_F values); *A*, radioactivity on a chromatogram (below) of the extract of leaves held in light; *B*, radioactivity on a chromatogram (below) of the extract of leaves held in darkness. Solvent system: *n*-butanol/acetic acid/water (4 : 1 : 3)

enzymes (myrosinase) set free in the damaged plant tissue is so rapid as to make impossible the proof of the presence of glucobrassicin in the fresh juice.

We have, therefore, tried another method of working up the plant material, suggested by Gmelin[3], namely, we first inactivated the myrosinase by heat, by placing the fresh, intact leaves in boiling methanol for 2 min. The methanol extract contained an appreciable amount of glucobrassicin; but we were not able to demonstrate either ascorbigen or 3-indolylacetonitrile.

When radioactive D,L-tryptophan-3-^{14}C (5·7 mgm. of specific activity 16·9 μc./mgm.) was administered to the plant[2] (50 gm. of fresh cabbage leaves) and the plant treated after 48 hr. with hot methanol, appreciable radioactivity was found in glucobrassicin (Fig. 1). In an experiment in which the plants were kept in the light, the synthesis of glucobrassicin from tryptophan proceeded more actively than in the plants held in darkness. This is in agreement with our earlier experiments[2,4], where more ascorbigen was formed from tryptophan in light than in the darkness. From these experiments at least two conclusions may be drawn: (1) ascorbigen is not present in the intact, living plant, but is an artefact formed in damaged or in stored, ageing tissue; (2) tryptophan is incorporated into glucobrassicin, which in certain circumstances[1] gives rise to a series of indole degradation products, notably ascorbigen, and relatively small amounts of indolyl-3-acetonitrile.

In order to prove whether the transformation of glucobrassicin to ascorbigen and 3-indolylacetonitrile is a purely *in vitro* degradation, or whether these reactions are involved in the metabolism of glucobrassicin, we have tried to ascertain experimentally whether the transformations referred to are reversible *in vivo*. Radioactive ascorbigen-^{14}C (ref. 5) (16·5 mgm. of specific activity 9·1 μc./mgm. per 85 mgm. of fresh Savoy cabbage leaves) and indolyl-3-acetonitrile-1-^{14}C (7·15 mgm. of specific activity 21·8 μc./mgm. per 20 gm. of fresh brussels sprouts leaves) were therefore administered to the plants. Radioactivity of ascorbigen was in the methylene bridge, connecting the indole nucleus with ascorbic acid. In neither case was glucobrassicin found radioactive after 48 hr. of incubation. In view of the physiological inertness of ascorbigen[6,7] and of its absence in the living and undamaged plant, we can conclude that it is physiologically unimportant. Many of our results, for example, those concerning the occurrence of ascorbigen in plants[8–11], the changes of its level during the vegetation period[12], its level in various parts of the plant[8,9,12,13], the influence of various external factors on its level in plants[4,13], must be understood as relating, in fact, to glucobrassicin. The question of the physiological activity of indolyl-3-acetonitrile seems more difficult to answer. We only can state that the reaction glucobrassicin→indolyl-3-acetonitrile is not reversible *in vivo*.

BIOLOGY

Storage of Fœtal Sheep Skin and its Growth as an Autograft on the Lamb

SKIN has been removed from sheep fœtuses, stored until after the birth of the donor and then replaced as an autograft to a position where its subsequent development could be closely watched. The object of this was to by-pass any systemic factors peculiar to the latter half of gestation which might influence the development of the skin. Also, by having the developing skin on the surface of the post-natal animal, there are many opportunities for experimental work such as altering the rate of expansion and imposing various other conditions.

To remove pieces of skin from the developing fœtus general anæsthesia of pregnant ewes was induced with sodium pentothal and maintained with *cyclo*propane. Through a 6-in. para-median incision of the abdominal wall the uterus was exteriorized and the fœtus held against an avascular portion of the greater curvature of the uterus. A 2-cm. incision was made through the horn of the uterus and the fœtal membranes over an area of the fœtus judged by palpation to be the mid-side. From this region a small piece of fœtal skin, 1–2 cm.^{2} in area, was excised. In most cases the skin wound in the fœtus was left open and a length of braided nylon was inserted at the wound edge to assist in the identification of the operation site in the post-natal animal. Loss of amniotic fluid was negligible. The incision in the amnion was closed by picking up the edges with small artery forceps and then carefully rotating them so as to form a pedicle of the membrane. This pedicle was then ligated with linen thread and the uterine horn repaired with a continuous Lembert suture using No. 0 'Chromic' catgut.

Of seven 2-year old Romney ewes, subjected to surgery between 75 and 90 days gestation time, only two produced living lambs. One ewe died two days after the operation. Three aborted, the first 15 days, the second 28 days and the third 54 days after surgery. The second abortion consisted of twins, the fœtus untouched at surgery apparently living until the time of abortion, while the fœtus, from which the skin had been removed, was distinctly smaller and probably had been dead for some brief but indeterminate time before abortion. The third abortion was a mummified fœtus which had died at or shortly after surgery. The remaining ewe apparently resorbed her fœtus.

Compared with the high proportion of survivors in Schinckel and Ferguson's[1] experiment, the greater loss of fœtuses in our work may be associated with the method of exteriorizing the uterus and the holding of the fœtus against the uterine wall. The breed of sheep might also have some influence.

The piece of skin from each fœtus was divided into three: a small portion for histological examination and two larger pieces, some 50 mm.^{2} in area, for storage. These were frozen according to the technique of Billingham and Medawar[2], being soaked for 1–1½ hr. in a 15 per cent glycerol/Ringer solution before being slowly frozen to – 79° C. in quartz tubes within stoppered 'Pyrex' tubes. One piece was stored continuously at this temperature in solid carbon dioxide, while after 3 days the other piece was transferred to a liquid nitrogen store and kept continuously at – 195° C.

The first lamb was born normally at 148 days and received the fœtal skin grafts 26 days after birth, the skin having been stored for 87 days. The second lamb was produced by Cæsarian operation, the ewe's gestation time apparently being 154 days, 5 more than the normal mean. It may possibly have been born naturally if events had been allowed to follow their normal course. This lamb did not thrive well at first, and transplantation of the fœtal skin was delayed until the lamb was 98 days old and the skin had been stored for 165 days. In both animals the two pieces of skin stored at the different temperatures were grafted to opposite sides of the lamb on to areas prepared by the removal under local anæsthetic of areas of skin about 5 cm. in diameter. The grafts were placed in the centre of these areas and were covered with polythene sheet. Pressure was then applied with a wad of cotton wool under an elastic bandage.

All four grafts survived and expanded rapidly, being kept moist with isotonic saline so long as they were still of a pre-natal age. Wool fibres penetrated the skin and became clearly visible to the naked eye at times equivalent to fœtal ages of 106 and 108 days in the first and second lambs respectively. There was no marked difference between grafts stored at the different temperatures and between grafts stored for the different times. It is very doubtful if the extra work involved in maintaining a liquid nitrogen store can be justified.

These techniques should be of great value in the study of factors controlling the development of fœtal tissues. The results of Schinckel and Ferguson[1] and of Barnard[3] suggest that the main disadvantage encountered, that is, the poor survival of fœtuses, can be overcome.

Experimental Evidence for Regeneration following Spinal Section in the Minnow (*Phoxinus phoxinus* L.)

Little is known of regenerative processes in the central nervous system of lower vertebrates. In fishes a few experiments have been made on the spinal cord. Koppányi and Weiss[1], Pearcy and Koppányi[2] and Hooker[3] cut the cord of *Carassius carassius* and *C. auratus* and reported the reappearance of locomotory movements after 8–10 weeks and cases of morphological regeneration. Hooker[4] transected the cord in young specimens of *Lebistes reticulatus* and claimed full co-ordination of movement in little over 4 days after the operation. Kirsche[5] carried out spinal section in adult *L. reticulatus* and reported both physiological and morphological regeneration of the cord 15 days after the operation. Like previous investigators he assessed physiological regeneration by observing the locomotory movements. He also reported a posterior twitch following electrical stimulation of the cord anterior to the section.

Two objections may be raised regarding experiments involving electrical stimulation and those involving estimation of co-ordinated motor activity. First, it is difficult to be certain that there is no spread of current when stimulating the spinal cords of such small animals. Secondly, it is difficult and sometimes impossible to be sure by direct observation that sinuous rhythmical movements throughout the length of the body of a fish are truly co-ordinated and not largely passive. In order to avoid these difficulties experiments were made which involved colour changes and the effects of a second spinal cut.

In the minnow the fibres controlling active aggregation of the melanophores pass from the medulla along the spinal cord, leaving the latter at about the level of the 15th vertebra to enter the sympathetic chain. From the chain they, or their post-ganglionic associates, reach the melanophores by way of the spinal nerves and the trigeminal nerve[6]. The existence of nerve fibres controlling active dispersion of the melanophores has not been satisfactorily demonstrated. If there are such fibres in the minnow, the evidence indicates that they follow a similar path to the aggregating fibres[7]. A minnow which is fully adapted to an illuminated black or white background and then subjected to background reversal changes colour very rapidly for the first 5–6 min. Thereafter it changes more and more slowly. After 15 min. the colour change is very advanced, but a total time of about 2 hr. is required for the complete change[8]. In these changes both nervous and hormonal mechanisms are concerned. The former may be eliminated by transecting the spinal cord anterior to the level at which the chromatic fibres leave it. If the operation is not carried out farther forward than about vertebra 8 the fish can generally still maintain an upright posture and so receive normal light stimuli on its retinæ. After the operation such chromatically spinal fish become dark, regardless of the background tint. However, an ability to change colour gradually returns and after about 10 days they are able to change slowly over a somewhat smaller range than before. These slow colour changes require about 3 days for their completion[8] and appear to be entirely under hormonal control[7].

In November 1959 thirty-two chromatically spinal fish were placed in illuminated black-and-white tanks and regular observations were made of their ability to change colour on background reversal. Colour changes were estimated by comparing the fish with slightly yellow-tinted black–grey–white cards based on the Ostwald series. The temperature of the water in the tanks varied from 10° to 18° C. in the course of a year.

For the first 4 months after the operation the fish showed a typical hormonal colour change, but in the fifth and sixth months the majority suddenly showed a rapid partial change and by the seventh month several had a rate and degree of colour change characteristic of the normal minnow with intact nervous system. A few, however, continued to change colour at the hormonal rate. The twenty-four surviving fish were kept until May 1961, that is, 18 months after the operation, to see whether those which had not developed a rapid rate of colour change in the first 7 months would do so after a longer time. However, it appeared that 7 months was the approximate limit and that there was no improvement after this time.

The spinal cord of each minnow was then transected a second time at a level about 2–3 vertebræ anterior to the original cut. Fish with rapid colour change darkened and after some days once more showed a slow colour change, typically hormonally controlled. It thus appears that in those fish which regained an ability to change colour rapidly after the first spinal section there had been some degree of re-establishment of nervous continuity in the cord. This was disrupted by the second cut.

So far as postural and locomotory reactions are concerned, changes following the original spinal section were not nearly so easy to judge in terms of nervous regeneration. Immediately after the operation the region posterior to the cut was usually immobilized and the animal was only able to progress along the bottom by means of a series of wags to the right and left of the anterior region combined with variably co-ordinated movements of the pectoral fins. These anterior wags were passively communicated to some extent to the posterior region. After some weeks the movements of the pectoral fins became better co-ordinated until many fish could use them very efficiently for progression through the water. The initial immobilization of the posterior region gradually gave place to activity. This typically first appeared as rhythmical to-and-fro movements of the tail fin and, later, of the entire tail. In time these became stronger and could, in many cases, raise the animal off the bottom and drive it through the water. Such movements have already been described[9]. Propulsive power came either from the region anterior to the spinal section or from the region posterior to it or from both regions at once, but the movement was obviously not co-ordinated throughout the animal. However, after some months it became, in many cases, increasingly difficult to be certain whether or not there was co-ordination. Finally, several fish swam so well that neither I nor impartial observers could detect any difference between them and normal minnows. It was easy to recognize the recovery of rapid colour change, but difficult to estimate the time necessary for this recovery of good swimming. However, the time appeared to be roughly the same in both cases and there was no very obvious improvement in locomotion after the first 6–8 months. Fish which could not swim well then never did so in the remaining 10–12 months of observation.

When the second section was made in the cord, co-ordination between the anterior and posterior regions was immediately lost. Here it is necessary to distinguish between the development of separate well co-ordinated movements in the anterior and posterior regions and a total co-ordination throughout the entire fish. It was this total co-ordination which was lost when the cord was cut for the second time. The separate well co-ordinated movements of the anterior and posterior regions appeared to be unaffected (Dijkgraaf[9] has reported a somewhat similar state of affairs), and several fish, immediately after recovery from the anæsthetic, were able to carry out locomotor movements which drove them efficiently through the water.

The second cut was made a little anterior to the first in order to allow a histological examination. This has no importance so far as the evidence from colour changes is concerned, but from the point of view of neuromuscular control it may well be significant. The observations on posture and locomotion following the second cut can therefore only be regarded as not contradicting the evidence obtained from colour changes. Definite evidence regarding the re-establishment of physiological continuity of fibres controlling posture and locomotion can only be given by a preparation in which the second cut is in the same position as the first. Series of fish are being prepared for this and other experiments and a full report will be published elsewhere.

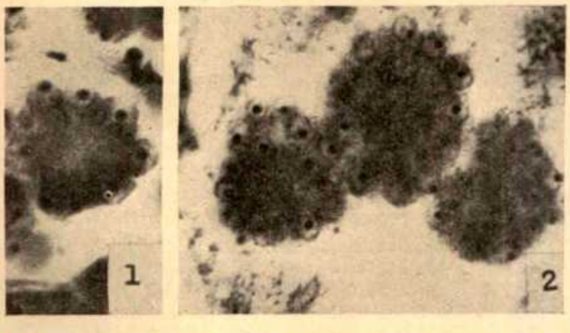
Spermatogenesis of a Cestode

THE interpretation of the structure of the spermatozoa of cestodes and of the process of spermatogenesis is subject to wide divergence of opinion. In 1935 Young[1] directed attention to the lack of knowledge regarding cestode structure and development, and among the main problems awaiting solution discussed the method of cell division and the structure of the sperm. Regarding the latter he wrote that "we have even less information than we have about most cestode tissues and until the spermatogenesis is known this ignorance will continue". His observations[2,3] and those of Child[4] "suggest a very simplified structure correlated with rapidity of development and the production of enormous numbers of spermatozoa"[1]. Watson[5] believed that the spermatozoon of *Gyrocotyle* is provided with a head. He did not, however, make a detailed study of spermatogenesis and described the sperm as "a slender thread tapering at the posterior end, with a well marked head, several times the diameter of the body". In a description of a figure of two spermatozoa he mentioned head, tail and acrosome. Presumably the acrosome is a short thread-like structure figured at the anterior end of the head. Since the publication of Young's paper[1] no further information on the spermatogenesis of cestodes has become available.

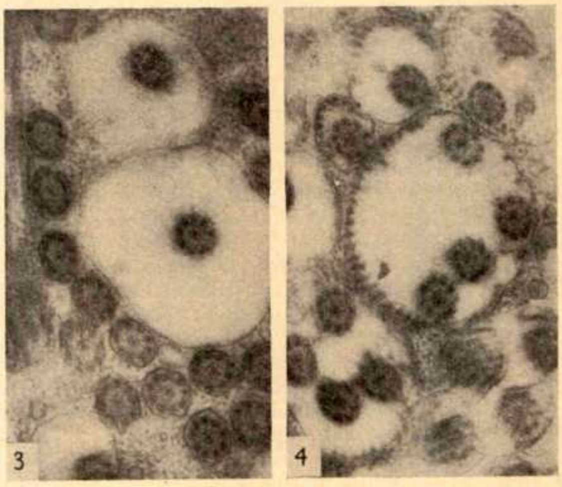
According to Young[2,3], the sperms of three species of cestodes "taper to a point at either end without any visible differentiation". On the other hand, Child[4] considered that the spermatozoa of *Moniezia expansa* and of *M. planissima* possess a head, derived from two granules in the nucleus. Child discussed earlier work, and pointed out that Sommer and Landois[6], for *Bothriocephalus latus*, and Leuckert[7] for *Taenia saginata*, stated that a small sperm-head is present. Other species were examined by Salensky[8], Sommer[9] and Moniez[10], who concluded that the spermatozoon does not possess a nucleus. Later, Roboz[11] described a minute structure which may represent the sperm-head of *Solenophorus megalocephalus*.

My examination of sections of the testes of *Proteocephalus pollanicola* Gresson[12] shows that in general spermatogenesis resembles that of trematodes[13-15] and indicates that 'the developmental processes' of cestodes are not, as Young suggested[1], markedly different from those of other animals. The primary spermatocytes occur in groups of eight cells whose nuclei contain Feulgen-positive material. These cells undergo the first meiotic division to form sixteen secondary spermatocytes (Fig. 1) that in turn divide to form a group of spermatids (Fig. 2). During spermateleosis the single large nucleolus (Feulgen-negative) disappears and the nucleus becomes spindle-shaped. At this stage Feulgen-positive granules are a prominent feature of the nucleus. The ripe spermatozoon is thread-like, possessing a Feulgen-positive nucleus and a long flagellum.



Figs. 1 and 2. 1, Section through a group of secondary spermatocytes (× 1,400). 2, Three groups of spermatids. At this stage the nuclei lie at the periphery of a mass of residual cytoplasm and the nucleolus is deeply stained (hæmatoxylin, × 1,000)

Electron micrographs of sections of the testes of *P. pollanicola* reveal the presence of electron-dense material in the nuclei of the spermatozoa and of a flagellum possessing an axial filament consisting of two central fibrils surrounded by nine double peripheral fibrils (Fig. 3). The two central fibrils lie in an area of moderate density limited by a thin membrane-like structure of higher density. Arms, similar to those first described by Afzelius[16], extend from the membrane to one of the members of each pair of peripheral fibrils. Each arm seems to be associated with the corresponding member of each pair of peripheral fibrils.



Figs. 3 and 4. Electron micrographs of tails of spermatids (× c. 32,500). 3, The axial filament is shown in the broad and terminal regions of flagella. 4, Sections of flagella to show the coiled or twisted condition of the axial filament

In micrographs of late spermatids the flagellum is often seen in transverse section as a relatively broad structure while in other cases it is narrow. Frequently micrographs of the broad flagella show two, three or four sections of the axial filament (Fig. 4). As the tails of ripe spermatozoa possess a single axial filament it is concluded that at a certain stage of spermateleosis the axial filament becomes coiled or twisted within the external sheath of the tail. In many cases fibril-like structures, frequently eleven or more in number, are spread out in contact with the inside of the external sheath (Fig. 4). Sometimes one or more of the peripheral fibrils of an axial filament, cut rather obliquely, appear to be continuous with a fibril or fibrils in contact with the sheath. Appearances suggest that not only is the axial filament coiled as a whole, but also that the individual fibrils are coiled independently of one another. Later, the axial filament uncoils and the sheath now closely surrounds the former throughout the whole or greater part of the length of the flagellum (Fig. 3). The above interpretation of the unusual appearance of the axial filament is put forward tentatively.

I wish to thank Associated Electrical Industries, Ltd., Barton Dock Road, Urmston, Manchester, for cutting ultra-thin sections, and taking the electron micrographs shown in Figs. 3 and 4.

Post-harvest Ripening of Avocados

It is a common observation that fruits of many species ripen quickly if they are harvested but more slowly or not at all if left on the tree. An extreme case of this behaviour is that of the Fuerte avocado (grown in southern California) which will not soften while attached to the tree by a healthy stem[1]. Similarly, Florida avocados (var. Choquette and others) are stimulated to ripen when they are detached, but they differ from the California fruit in that most varieties eventually will successfully ripen on the tree. Recently, several objections[1] to the theory that ethylene plays an important part in fruit ripening have been eliminated, and it has been established that an active concentration of the ripening hormone accumulates within cantaloupes[2], bananas, mangoes and probably many other fruits[3] before or coincident with the climacteric rise. From the work of Biale[4] it is known that Fuerte avocados are stimulated to ripen by as little as 0·1 p.p.m. ethylene, and this same minimum concentration of gas is effective with most other fruits and plant tissues which have been investigated[5]. Therefore, a very small change in ethylene content induced after separation of the fruit from the tree could lead to an acceleration in ripening, and this possibility is investigated in the present communication.

Late-season Choquette avocados were picked in a local orchard and the internal gas was immediately sampled (within 10 sec. of harvesting) by immersing the fruit in water and withdrawing a few ml. of air from beneath the skin with a hypodermic syringe. The fruit was kept at 24° C. and additional samples were taken at frequent intervals during a 5-day period. Carbon dioxide content was determined by gas chromatography using a silica-gel column and a high-sensitivity katharometer, and ethylene was assayed with a flame ionization instrument following chromatography on an aluminium oxide column. These methods have been discussed elsewhere[3,6]; but it is important here to note that the smallest amount of ethylene which could be measured was approximately 0·01 p.p.m. in a 2·5-ml. sample of air. The production of carbon dioxide by the fruits was determined at frequent intervals with an infra-red gas analyser.

Results are shown in Figs. 1 and 2. Data for the changes in internal concentration of carbon dioxide have been omitted because in general the pattern only reflects the respiration-rate. However, the observation by Ben-Yehoshua *et al.*[7] that outward diffusion of carbon dioxide is restricted in post-climacteric avocados was corroborated by the fact that the ratio between the internal carbon dioxide content and the rate at which the gas was produced increased 2–4-fold during the 5-day period. The average internal concentration of ethylene at the time of harvest was approximately 0·04 p.p.m.; fruit number 4 had the highest value (0·064) and fruit number 3 the lowest (< 0·01). Directly after the avocados were picked there occurred a transient emanation of ethylene and a subsequent decline to a very low value within 4 hr. (Fig. 1). This was followed by a surge of ethylene production, clearly in advance of the pre-climacteric respiratory minimum. In Fig. 2 the time to reach 0·1 p.p.m. ethylene is indicated by an arrow, and this occurs within 9 hr. after harvest and at least 12–24 hr. before the onset of the climacteric rise. By that time the ethylene content exceeds 0·5–1 p.p.m., and it rapidly increases to a maximum value of 300–700 p.p.m. When the fruit is picked the barrier

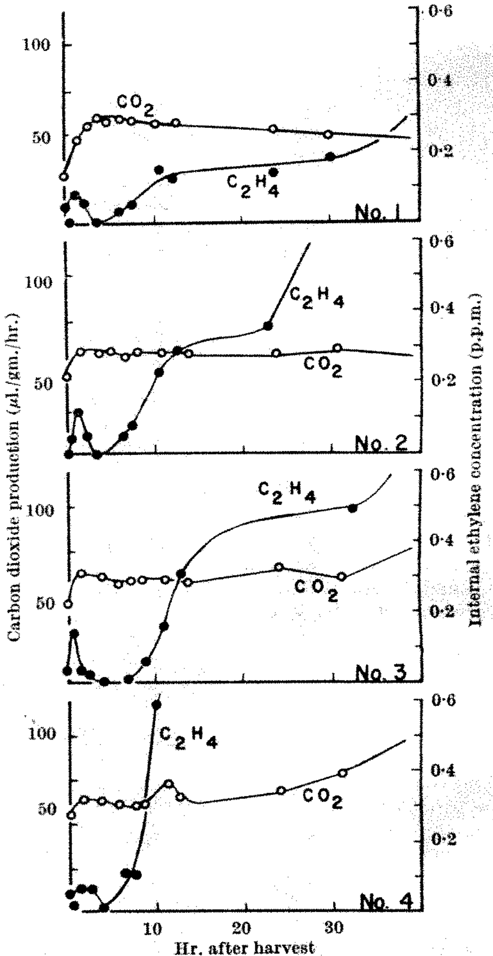

Fig. 1. Post-harvest changes in the respiration-rate and internal ethylene content of Choquette avocados at 24° C. The initial rate of respiration has been inferred from measurements of the internal carbon dioxide concentration taken during a 1-hr. period before the first infra-red gas analyser determination. It has been assumed that the barrier to outward diffusion of carbon dioxide remained constant throughout that interval

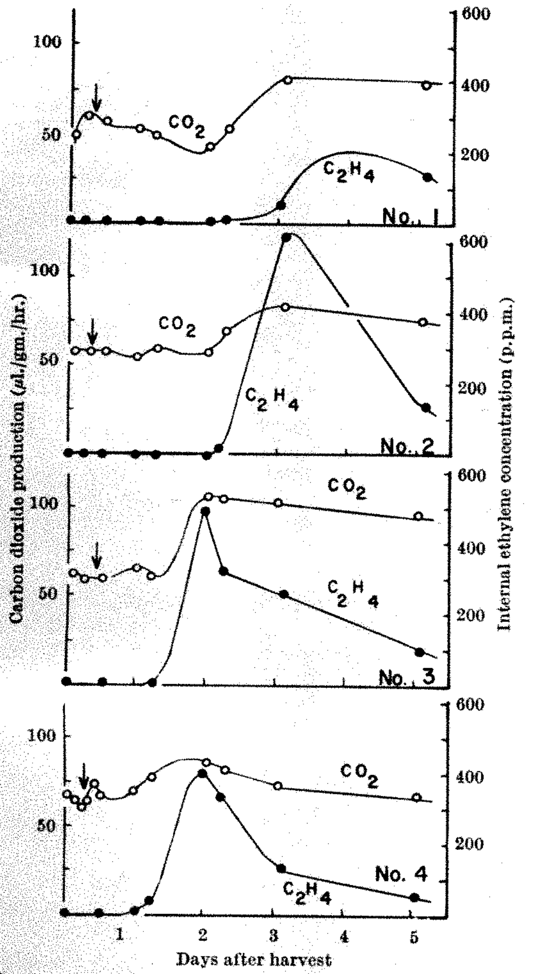

Fig. 2. Climacteric pattern of respiration and the associated changes in internal ethylene content of Choquette avocados at 24° C. The arrow indicates the time at which a 0·1-p.p.m. ethylene concentration has been reached (see Fig. 1)

to outward diffusion of ethylene is several fold lower than when it is ripe, but a rate of ethylene production of only 0·2 µl./kgm./hr. still suffices to create a physiologically active ethylene concentration (0·1 p.p.m.) and this clearly has been overlooked in previous work[1].

It is significant that ethylene could not be detected in early-season, full-sized Choquette avocados, and these fruits did not ripen properly unless they were gassed with ethylene. Since Biale has found that early-season avocados require higher concentrations of applied ethylene for a rapid climacteric rise than do late-season fruit[4], both the low production-rate and low susceptibility may work in unison to prevent fruit ripening on the tree at that time. That the production rate may be the critical factor is suggested by the experiments of Kidd and West[8] in which it was shown that a slight restriction in ventilation hastened the ripening of apples on the tree. Late-season avocados possess a quasi-stimulatory concentration of ethylene while attached to the tree, and tree-ripe fruit has a complete complement of the gas. Since the post-harvest acceleration in ripening is anticipated by a substantial increase in ethylene content, it follows that the Choquette avocado behaves at all times as if ethylene plays a vital hormonal part in its ripening processes.

Interference by Tungsten with Uptake of Molybdenum by Plants

ALTHOUGH tungsten competitively inhibits the functions of molybdenum in bacteria[1,2], fungi[3], and poultry[4], it has been reported as substituting for molybdenum in legumes[5]. Several workers have reported stimulatory effects on plant growth by low concentrations of tungsten[6–8]; but the element is toxic above 5 p.p.m.[6]. We have investigated the effect of growing tomato plants in sand culture using a wide range of molybdenum/tungsten ratios, supplied as molybdate and tungstate: other elements were supplied from Hewitt's nutrient solution[9].

Chemical nutrients were purified by scavenging with copper sulphide[9], and the sand used was washed successively with nitric acid, ammonia and demineralized rain water. Despite these precautions, molybdenum deficiency symptoms were not observed in plants grown without added molybdenum (treatment 6). Negligible amounts of molybdenum and tungsten were introduced with the seeds, from which plants were grown for 200 days, after which the leaf tissue and seeds were dried, ground in a 'Perspex' mill and analysed for molybdenum and tungsten by neutron activation analysis[10,11]. After activation for 24 hr. the samples were wet ashed with perchloric and nitric acids in the presence of known amounts of molybdenum and tungsten carriers. The tungstic acid precipitate was purified and counted as described previously[11], and the molybdenum was separated from the supernatant liquid by a chemical procedure including two sulphide precipitations, extraction into diethyl ether from 6 *N* hydrochloric acid, scavenging with tungstic acid, ferric hydroxide and magnesium ammonium phosphate, and finally precipitation with α-benzoin oxime.

The p.p.m. of molybdenum and tungsten in the nutrient solutions, dry plant tops and seeds are given in Table 1: all figures are means of three replicate analyses. There was no obvious difference in growth, fruit production, deficiency or toxicity symptoms between the treatments.

Table 1. P.P.M MOLYBDENUM AND TUNGSTEN IN NUTRIENT SOLUTIONS, TOMATO PLANTS AND SEEDS

Treatment	Mo Solution	W Solution	Mo Plant	W Plant	Mo Seed	W Seed
1	0·19	< 0·001	37·8	0·10	17·3	0·011
2	0·19	0·0019	47·2	0·31	17·1	0·038
3	0·19	0·019	43·4	1·38	17·5	0·121
4	0·19	0·19	44·2	19·8	16·7	1·64
5	0·019	0·19	11·2	15·5	6·28	1·46
6	< 0·001	0·19	0·60	15·1	0·42	1·59

The mole fractions of molybdenum (molybdenum/molybdenum + tungsten) in the solutions, plants and seeds are given in Table 2.

Table 2. Mole Fractions of Molybdenum in Nutrient Solution, Tomato Plants and Seeds

Treatment	Solution	Plant	Seed
1	> 0·997	0·998	> 0·999
2	0·995	0·996	0·999
3	0·952	0·985	0·996
4	0·667	0·810	0·951
5	0·167	0·582	0·892
6	< 0·010	0·068	0·336

Summarizing the results in Table 2 we can say that the tomato plant, and especially the seed, discriminates against tungsten at every level tested. This discrimination is especially marked when tungsten exceeds molybdenum in the nutrient solution, in which case the combined uptake of the two elements is considerably depressed. These observations suggest that tungsten is not essential for the growth of the tomato plant, but that it may be able partly to replace molybdenum when the latter element is in short supply.

Accumulation of a Distinct Macromolecular Component in Rye Embryos as a Result of Vernalization

Many attempts have been made to relate the phenomena of vernalization to chemical entities, particularly macromolecular components, such as nucleic acids[1], proteins[2], and related substances[3]. The results so far obtained have been either negative or inconclusive. The present communication reports a successful demonstration of the accumulation of an electrophoretically homogeneous macromolecular component in the vernalized embryos (and seedlings) of Petkus winter rye (supplied by F. von Lochow, Petkus Co., Bergen, Germany). This component was greatly reduced by devernalization and was absent from non-vernalized embryos.

Grains of Petkus winter rye were germinated in the dark in Petri dishes receiving full moisture supply and subjected to different temperature régimes (Table 1). The parts of the embryo above the base of the first internode were excised. This tissue was ground in the cold in a mortar with one half its volume of 0·05 *M* borate buffer (*p*H 9·2). This was further homogenized by hand in a glass homogenizer. Further extraction and analysis procedures have previously been described[4]. The results are summarized in Fig. 1 and Table 1.

Table 1. Concentration of Component V in Embryos attaining Different Sizes, as affected by Various Temperatures

(Total yield was calculated from the area of the electropherograms. Arrows designate transfer from one temperature to another)

Temperature (° C.)	Duration of treatment (days)	Average embryo weight (mgm.)	Component V as percentage of total yield	Total yield (mgm. per gm. embryos)
Small embryos				
26	7	4·9	0·6	11·3
20	7	4·8	7·0	8·4
18	7	3·7	3·7	11·7
14	9	3·5	8·1	7·0
2	8	3·0	12·1	12·7
2	20	3·6	17·5	9·4
2	40	8·7	43·7	14·4
2° (+30° 7 hr. daily)	9	4·0	4·0	7·6
Medium embryos				
26	7	14·4	5·3	—
20	11	23·2	19·5	12·7
18	7	14·2	11·9	11·5
14	14	14·4	23·2	10·5
2	20	17·1	37·1	12·8
2	40	30·0	49·8	15·2
2°, 20 days → 33°,	5 days	8·5	6·4	9·1
26°, 7 days →	2°, 18 days	14·9	46·5	13·5
Large embryos				
20	11	58·0	6·4	10·5
26°, 10 days →	2°, 18 days	62·0	45·1	6·9

As can be seen from Fig. 1, germination at 2° C. brings about the accumulation of a slow-moving, homogeneous macromolecular component. This component, having approximate mobility of $-2{\cdot}7\mu$ (corresponds to 1·3 mm. migration in Fig. 1), will be referred to as component V. This component is practically absent in the embryos germinating at 26°

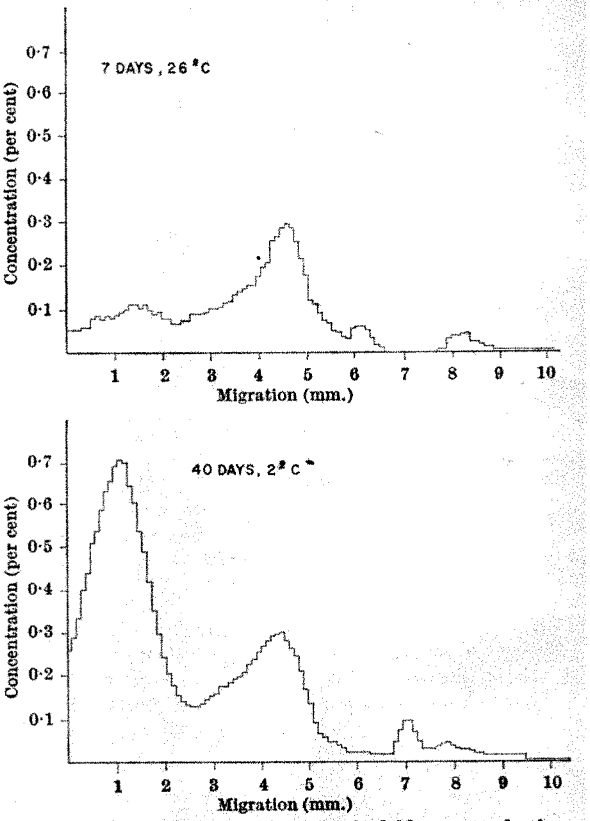

Fig. 1. Free-boundary electrophoresis of soluble macromolecular components from vernalized and unvernalized embryos of Petkus winter rye. Vernalized embryos (8·7 mgm.) were kept 40 days at 2° C. and unvernalized embryos (14·4 mgm.) 7 days at 26° C. Electrophoresis was carried out for 11 min. in 0·05 *M* borax *p*H 9·2 under 1·5 m.amp.

C. It is fairly evident from Table 1 that the accumulation of component V is closely associated with the phenomenon of vernalization. Since the rye embryos germinate and grow at different rates I was able to divide the seedlings, after 20 days at 2° C., into two groups; one with small seedlings having an average weight of 3·6 mgm., the other with larger seedlings having an average weight of 17·1 mgm. The concentration of component V was 3·5 times higher in the larger seedlings. An enhanced growth of the embryo is known to increase its response to vernalizing temperatures[5]. The gradual increase in component V at 2° C. from the 8th to the 40th day is in accordance with the kinetics of vernalization[6–8]. Similarly component V is greatly reduced under devernalizing conditions, that is, at 35° C. (ref. 9) and is absent from seedlings grown under non-vernalizing conditions—alternating high and low temperatures[10]. It is further evident from Table 1 that the accumulation of component V decreases with increasing temperatures and at 26° C. its accumulation is negligible. As the temperature is reduced from 26° to 14–20° C. component V increases. This reflects the increase observed in flowering response of *Hordeum bulbosum* as a function of decreasing growth-temperatures[11]. A re-investigation of the flowering response of Petkus winter rye in this range of temperatures seems warranted.

Parallel experiments under continuous light (100–200 foot-candles) in the low and higher temperatures were performed. Accumulation of component V was not affected significantly in any way by light.

Identical experiments with Petkus spring rye, obtained from the same source, showed that component V is also accumulated in this strain when exposed to low temperatures. It seems therefore reasonable that "the absence of flowering response (in spring varieties) when these are vernalized does not necessarily imply that the vernalization product is not formed in such varieties"[12].

ENTOMOLOGY

Heterologous Transplantation of Corpora Allata between Lepidoptera Diapausing in Egg and Pupal Stages

WHEN corpora allata from the same species of Lepidoptera are removed and implanted into naturally diapausing pupæ or pupæ diapausing as a result of extirpation of the brain ('Dauer pupæ'), the recipients develop into moths or pupal–adult mixtures (second pupæ)[1–4]. The results obtained when donor and host are not so closely related are also of interest. Therefore, heterologous grafts of corpora allata between insects usually diapausing in the pupal and egg period respectively have been made and the effect on metamorphosis compared to homologous transplants.

Species used were *Hyalophora cecropia*, *Samia cynthia*, *Antheraea polyphemus*, and *Bombyx mori*. Except for *Bombyx mori*, the insects were divided into two groups. Group *A* were the pupæ maintained at 5° C. for more than six months; Group *B* were pupæ maintained at 5° C. for less than one month. The F_1 hybrids between strains *J*. 122 and *C*. 115 of *Bombyx* were deprived of pupal brain immediately after pupation. These operations were facilitated by immobilization at 5° C., and the procedure in other species was carried out under narcosis with carbon dioxide. Post-operatively the wounds were sealed, and the operated animals were maintained at 25° C. Reciprocal experiments were performed. In the first, 'Dauer pupæ' of the *Bombyx* silkworm 55 days of age were the recipient of transplants from the three wild species; in the second, corpora allata from *Bombyx mori* were implanted into diapausing, chilled, brainless pupæ of the wild silkworms.

When corpora allata from wild silkworms were implanted into 'Dauer pupæ' of *Bombyx* silkworms, only 3 moths emerged within 30 days in a total of 25 implanted; and 4 additional eclosions occurred within 60 days with 18 of the 25 undeveloped at the end of 60 days. Therefore prompt emergence only occurred in 20 per cent of the group in which *cecropia A* and *B* and *cynthia B* were donors. Although the number was relatively small, at least one moth emerged in all groups of donor preparations.

In the second experiment, second pupæ appeared when corpora allata from *Bombyx* were implanted into brainless *cecropia*, but they did not appear in any other group. Five similar preparations of *polyphemus* resulted in the emergence of one moth and no second pupæ. The remainder of the preparations showed no imaginal differentiation within 100 days after implantation.

In contrast to these results of heterologous transplantation of corpora allata, previous experiments[4] demonstrated that 73 per cent of the 'Dauer pupæ' of *Bombyx* became imagines within 30 days at 25° C. following homologous implantation of corpora allata derived from 'Dauer pupæ'. Also, Kobayashi and Yamashita[3] found that 17 of 20 'Dauer pupæ' of *Bombyx mori* emerged when corpora allata from 0-hr. pupæ of the same species were implanted, and 45 per cent of 'Dauer pupæ' became moths and no pupal–adult mixtures occurred when the corpora allata were derived either from *Bombyx* pupæ 5 days old or from moths. Williams[2] noted the formation of second pupæ in work on heterologous implants of corpora allata into brainless pupæ of *cecropia*. When corpora allata from *Bombyx mori* moths were implanted by Ichikawa and Takahashi[5] into diapausing

Table 1. EFFECT OF HETEROLOGOUS IMPLANTATION OF CORPORA ALLATA ON THE INDUCTION OF IMAGINAL DIFFERENTIATION OF 'DAUER PUPÆ' OF *Bombyx mori*

Donor		Pairs of corpora allata implanted	No. of 'Dauer pupæ' recipients	No. of moths emerged		No. of undeveloped pupæ 60 days after operation
				1–30 days	31–60 days	
cecropia	(*A*)	3	5	1	2	2
	(*B*)	3	5	1	0	4
cynthia	(*A*)	3	5	0	1	4
	(*B*)	3	5	1	0	4
polyphemus	(*B*)	3	5	0	1	4
Control (mock implantation)		0	5	0	0	5

A, Pupæ maintained at 5° C. for more than 6 months; *B*, pupæ maintained at 5° C. for less than 1 month.

Table 2. Effect of Heterologous Implantation of Corpora Allata derived from *Bombyx* Silkworm into Brainless, Diapausing Pupæ of Other Lepidoptera

Host		Operation	No. of preparations	No. of second pupæ	No. of moths emerged	No. of undeveloped pupæ in 100 days after operation
cecropia	*A*	EB	5	0	0	5
		Control	4	0	4	0
		EB + CA *	2	2	0	0
cecropia	*B*	Control	5	0	3	2

* Corpora allata from moths originating from 'Dauer pupæ'.
† Corpora allata from 'Dauer pupæ'.
Control, mock operation.

pupæ of *Philosamia cynthia ricini*, 3 emerged as moths and the remaining 17 became pupal–adult mixtures.

The results tabulated in Tables 1 and 2 show less action of heterologous implants than homologous corpora allata implanted into 'Dauer pupæ' of *Bombyx mori* previously reported. However, these F_1 hybrids of *Bombyx* emerge more often than the wild species when the latter are implanted with corpora allata from *Bombyx*. In the recipient group of *cecropia*, there is suggestive evidence that response to heterologous transplants occurs more often when the chilling is longer (Table 2) and that corpora allata derived from pupæ chilled longer may induce differentiation more readily (Table 1). However, the corpora allata which were implanted into wild silkworms chilled longer than 6 months were from *Bombyx* moths, whereas transplants from pupæ were transferred into those chilled for less than one month in this experiment with *cecropia*.

Pupal–adult mixtures are induced by hormones from both the prothoracic gland and from the corpus allatum[2]. The two functions of brain hormone, tropic action on the prothoracic gland and synergistic induction of metamorphosis with ecdysone[6], involve it in the appearance of these mixtures as well. Pupæ of wild moths chilled for a long period may secrete more brain hormone than those chilled for a short time; and the host may become a moth, pupal–adult mixture, or undeveloped pupa depending on the amount of brain hormone secreted in combination with hormone secreted from prothoracic gland and also from the corpus allatum following its implantation.

How much of the differences in results observed are due to failure of the implanted corpora allata to function in a foreign environment, the physiological state of the gland when extirpated, the stage of metamorphosis and sensitivity of the recipient, and possible variations in the hormone secreted by different species cannot be distinguished by preliminary data. However, it is apparent that the action of corpora allata differs when they are functioning in natural and host environments and that the physiological state of the host and donor may affect the result of transplantation.

This work was aided by grants from the U.S. National Institutes of Health and the American Cancer Society.

Response of *Aedes aegypti* to Moist Convection Currents

The behaviour of *Aedes aegypti* in the vicinity of warm surfaces of various colours has been examined by mounting warmed copper bars (at 30°–45° C.) on the floor of a flight cage, covering them with cloth of different kinds and colours, and counting the number of alightments during a 5-min. interval. The insects were activated by human breath introduced through an opening midway between the test surfaces. The temperature was 20–25° C. and the relative humidity about 30 per cent.

It was found that cloth with high initial attractiveness to mosquitoes lost its attraction within 10–15 min. The attractiveness could be restored by washing the cloth or hanging it in the open air for a few days. The initial attractiveness depended in part on the colour—black was the most and white the least attractive—but even more on the material. Wool was nearly always very attractive initially, cotton moderately so, and synthetics like 'Terylene' almost unattractive. Bare copper was wholly unattractive.

The spectrum of the visible and ultra-violet light reflected from the surfaces was recorded with a Cary model 14 *M* spectrophotometer without revealing any differences sufficient to account for the difference between new and exposed cloth of the same kind, or between different cloths of the same colour.

In an attempt to examine the effect of surface texture, samples of cloth were ironed smooth. This reduced or wholly eliminated the attractiveness of all the samples, and suggested that guidance is brought about by warm, moist convection currents.

The experiments were repeated with samples of cloth which had been ironed, and then pre-dried in a desiccator or moistened in a humidity chamber. The results were striking. A pre-dried sample laid on a warm surface had little or no initial attraction. On the other hand, a humidified piece of black wool measuring 3 × 5 in. was very attractive initially, but after 15 min. it had lost both its attractiveness and about 0·25 gm. in weight. If a piece of wet filter paper was momentarily pressed on to its surface it immediately became attractive again, and if a piece of wet filter paper was placed between it and the warm under-surface it became very attractive indeed, and its attractiveness persisted for as long as the filter paper remained wet. Probably because of the larger specific surface, damp wool was more attractive than wool that was saturated and visibly wet.

A surface that was damp but not warm was as unattractive as one that was warm but not damp.

Water saturated with carbon dioxide but not warmed was also unattractive, but the presence of the carbon dioxide made other warm, wet surfaces in the chamber more attractive.

Thus it appears that *Aedes aegypti* are stimulated to fly in search of a warm-blooded host by an alteration in the ambient carbon dioxide level, and that they are guided to the appropriate surface partly by colour, but mainly by warm, moist convection currents rising from it.

This explains the decline in attractiveness of dark-coloured wool presented to the insects on a warm surface, and the poor initial attractiveness of a hydrophobic synthetic material like 'Terylene'. If the 'Terylene' was underlaid by wet filter paper it was as attractive as wool of the same colour presented in the same way.

There have been many attempts to isolate specific mosquito-attractive substances in blood or sweat or other biological fluids. The reported results have generally gone unconfirmed, and it seems possible that the difference in attractiveness of various solutions may have been related to the rate of evaporation of water from them. This rate of evaporation would be governed in part by the vapour pressure (a function of the concentration) but even more by the obstruction or otherwise of the surface by a surface film of some kind.

MICROBIOLOGY

Demonstration and Possible Significance of Uricase in Human Pathogenic Fungi

Uricase has been demonstrated in several moulds, bacteria, and yeasts[1-4] and in animal tissues[5,6]. The elimination of uric acid as the chief waste product of nitrogen metabolism from birds and the isolation of certain human pathogenic fungi from soils in poultry pens and yards[7-9] have suggested the possibility that these fungi may be able to utilize uric acid as a source of nitrogen for growth.

Uric acid (Merck) was washed three times with warm distilled water and used for preparing a semi-fluid medium containing 10 gm. glucose, 5 gm. sodium chloride, 0·5 gm. magnesium sulphate, 1·0 gm. uric acid, 25 mgm. calcium chloride, 10 mgm. ferric chloride, 50 μgm. biotin, and 1·0 gm. washed agar (Difco) in 1 litre of 0·03 *M* phosphate buffer. Stock culture and routine media were adjusted to *p*H 7·0. Sodium thioglycolate was made 0·001 *M* in media for *Histoplasma*. The media were dispensed in screw-capped tubes, autoclaved, cooled, and inoculated with 5- to 10-day yeast-phase cells. The inocula were prepared by collecting cells from a solid stock culture medium[10] or from infusion blood agar slants, washing them four times with sterile phosphate-buffered 0·85 per cent saline at *p*H 7·0, and finally suspending them in the above uric acid media. The reactions of the experimental media were varied from *p*H 6·5 to 9·0 by altering the proportions of the constituent phosphates in the buffer solution.

The organisms used were *Histoplasma capsulatum* (A.T.C.C., 11407) the natural occurrence of which has a recognized correlation with avian species and poultry yard soils, and *Blastomyces dermatitidis* (N.I.H., 6046) which until recently, although resembling *H. capsulatum* in many respects, has never been demonstrated in soils from any source. (The improved and successful methods used by Denton *et al.*[11] may explain why previous attempts to isolate the organisms from soils failed[7,8,12].)

Since uric acid was the sole source of nitrogen available for growth in the media, growth was used as the indicator of uricase activity in the fungi, and was determined by measuring the turbidity (per cent transmittance) of cultures at 600 mμ in a Coleman Junior spectrophotometer. Un-inoculated media were incubated and used as controls and blanks.

Uricase activity was not great in any series of cultures (Fig. 1). The rather heavy growth which occurred within 8–14 days in the 27° C. cultures is not represented to advantage in the spectrophotometer because the mycelial phase cells were difficult to suspend evenly throughout the medium. (Twelve-day cultures of *B. dermatitidis* at 27° C. could have been recorded as 4-plus; growth of *H. capsulatum* was slower and somewhat less extensive.)

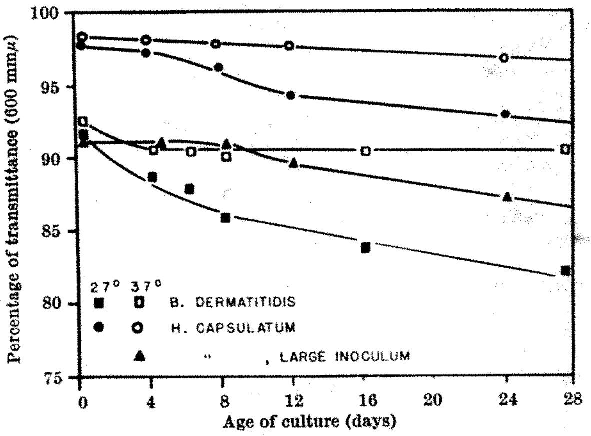

Fig. 1. Effects of incubation temperature on *B. dermatitidis* and *H. capsulatum* cultures in uric acid medium at *p*H 7·0

At 37° C., *B. dermatitidis* exhibited a slight initial decrease in per cent transmittance. This change does not seem significant when compared with the growth at 27° C. and with *H. capsulatum* cultures. If the change actually represents increase in cell numbers, then the increase probably occurred at the expense of traces of nitrogenous materials other than uric acid since such a change was not uniform among all cultures (Fig. 2).

Initially, growth of *H. capsulatum* was very slow at 37° C. (upper curve in Fig. 1). When the inoculum size was increased to that used in *B. dermatitidis* cultures, however, *H. capsulatum* grew out well following an 8-day lag period. This lag, similar to that which occurred initially in 27° C. cultures, is probably directly related to the oxidation-reduction potential of the medium and the thioglycolate added to it as a sulphydryl source. (Uricase activity is reported to be a strictly aerobic process.) Increasing the inoculum size has not as yet altered the slope of the curve representing 37° C. *B. dermatitidis* uric acid cultures.

Although the series of cultures indicated in Fig. 2 was not sufficiently varied to determine the precise

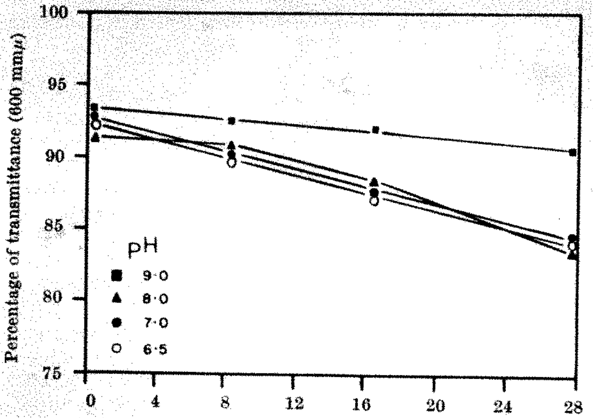

Fig. 2. Effects of *p*H on growth of *B. dermatitidis* in uric acid media at 27° C. (Similar results were obtained using *H. capsulatum*)

reaction for optimum uricase activity, it is apparent that growth was uniform and good from *p*H 6·5 to 8·0, but was strongly inhibited at *p*H 9·0. That the inhibition may have been the result of changes in the surface activity of the cell toward the uric acid molecule is indicated by: (1) the good growth of *B. dermatitidis* on routine laboratory media adjusted to *p*H 9·0; (2) the activity of extracted uricases at that reaction[5,6].

Since the reaction for optimum uricase activity could have differed from the mycelial to the yeast phase, thereby preventing growth in neutral media at 37° C. (a possibility which seemed remote), the reactions of 37° C. culture media were varied in an attempt to demonstrate growth. The results were negative (Fig. 3); no significant change occurred in any of the media.

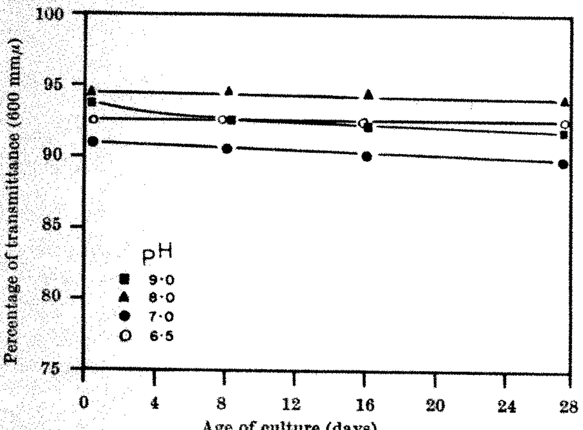

Fig. 3. Effects of *p*H on growth of *B. dermatitidis* in uric acid media at 37° C.

It appears that uricase may aid the survival of some human pathogenic fungi in soils containing uric acid from avian or other sources, and may be in part responsible for the unusual association of *H. capsulatum* with poultry. The fact that yeast-phase *B. dermatitidis* appears to be unable to utilize uric acid, although the mycelial phase utilizes it readily, stimulates some interesting conjectures on the necessity of yeast-phase cells shed from a host to undergo morphological variation in certain soil environments in order to survive. Additional investigations into the survival of pathogenic fungi in natural environments are at present in progress i this laboratory.

This is the first report, to my knowledge, of a apparent qualitative difference between the tw morphological phases of *B. dermatitidis* in activel growing cultures.

This work was supported in part by a grant (*E* 307 *C*1) from the National Institutes of Health, U.S Public Health Service.

Note added in proof. While this paper was in th press, I have demonstrated uricase activity in both culture phases of *Sporotrichum schenckii.*

An Immobilization Reaction against *Balantidium coli*

An immunological test, the immobilization reaction, has been found to be positive for a number of protozoa[1]. I have found it useful in differentiating various species of *Entamoeba* and strains of *E. histolytica*[2]. However, it is with *Tetrahymena*[3] and *Paramecium*[4] that the reaction has been studied in greatest detail. Against *Paramecium* it is a highly specific and sensitive test. In view of these positive results with various ciliates, it was thought of interest to determine whether a positive reaction could be obtained with *Balantidium coli.*

The strain of *B. coli* used was isolated from the cæcal contents of a pig slaughtered at the Singapore abattoir. The strain after some initial difficulty grew well in *hsm*+*S* (ref. 5) and Balamuth's medium[6], kept at 37° C.

A rabbit was immunized by subcutaneous injections of a washed suspension of *B. coli*. It received approximately 80,000 cells in eight divided doses given at 4-days interval each. The serum was obtained a week after the last injection.

When the washed organisms were mixed with the fresh immune serum they were rapidly immobilized and lysed in a dilution of 1 : 5 in normal saline. However, when the serum was inactivated lysis did not occur and the process of immobilization was observed clearly. The inactivated antiserum in dilutions up to 1 : 10 in normal saline produced immobilization almost immediately. Inactivated normal rabbit serum used in the same dilution had no effect on the activity of *Balantidium.*

The ciliates treated with antiserum remained immobilized for 6–7 hr., after which they gradually disintegrated. Although they remained stationary during the period of this reaction, local ciliary movement continued with gradually diminishing activity, until final disintegration.

It is suggested that the reaction may be of value in the differentiation of various species of *Balantidium* and possibly in the diagnosis of Balantidial infection in man.

Protective Action of Glycerol in the Freezing of *Shigella sonnei*

GLYCEROL has been used as a protective agent for frozen bacteria[1,2], *Leptospiræ*[3], trypanosomes[4], *Toxoplasma gondii*[5], *Entamoeba histolytica*[6], animal tissues[7], bull spermatozoa[4], and yeasts[8]. Although much work has been done on a variety of micro-organisms, little or no information is available regarding the protective action of glycerol on frozen *Shigella sonnei*. The purpose of the present investigation was to determine the effect of glycerol on frozen *S. sonnei* and also the effect of glycerol on cells frozen and thawed repeatedly. Four strains were studied: strain *CH*, obtained from Dr. Horace M. Gezon, University of Pittsburgh, Pittsburgh, Penna.; strains *B*–2501–3 and *B*–2506–3, obtained from the National Naval Medical Center, Bethesda, Md.; and strain 13–3, obtained from Dr. Arthur Abrams, Walter Reed Army Institute of Research, Washington, D.C.

Nutrient broth cultures of the four strains were grown for 48 hr. at 37° C. and mixed with sterile glycerol. The following glycerol concentrations were tested: 1, 2, 5, 10 and 20 per cent (final concentrations). The tubes containing the cells and glycerol were rotated in the palms of the hand to mix the contents thoroughly, then placed in the freezer (–20° C.), and allowed to freeze slowly. The frozen tubes were removed at weekly intervals for a period of 5 weeks; another series of tubes were frozen and thawed one, two, three, four, and five times and held frozen for a period of one week before the final thawing and plate counting. The bacterial populations were determined by removing 0·1 ml. of the cell suspensions, making an appropriate number of serial dilutions, and streaking 0·1 ml. of the final dilution over a nutrient agar plate and streaking with a bent glass-rod 'hockey stick'. These plates were inverted, incubated for 48 hr. at 37° C., and counted with the aid of a Quebec colony counter (Spencer).

All four strains of *S. sonnei* responded fairly uniformly to the freezing and thawing. A 10 per cent solution of glycerol produced maximum protection of the frozen cells. 5, 2 and 1 per cent glycerol afforded some protection, in terms of viability, but in an order of decreasing levels of protection. 20 per cent glycerol protected the cells at a level comparable with the 10 per cent level. Results of a typical experiment are given in Table 1. The bacterial population in the frozen preparations did not decrease significantly during the five-week storage period after attaining a stable population. This is in agreement with the observations of Clement[9]. Repeated freezing and thawing decreased the population of frozen cells substantially; the results are shown in Table 2.

Table 1. PROTECTIVE EFFECT OF GLYCEROL ON FROZEN *S. sonnei* CELLS*

Glycerol concentration (per cent)	Viable count (Initial population was $5 \cdot 9 \times 10^7$/ml.)	Fraction surviving (per cent)
0	$5 \cdot 8 \times 10^5$	0·98
1	$2 \cdot 2 \times 10^6$	3·7
2	$7 \cdot 7 \times 10^6$	13·0
5	$4 \cdot 8 \times 10^7$	81·3
10	$5 \cdot 4 \times 10^7$	91·4
20	$5 \cdot 0 \times 10^7$	84·8

* These data represent triplicate experiments.

Table 2. PROTECTIVE EFFECT OF GLYCEROL ON *S. sonnei* FROZEN REPEATEDLY*

No. of times frozen and thawed	Viable count (initial population was $5 \cdot 7 \times 10^7$/ml.)	
	Frozen in the absence of glycerol	Frozen in the presence of 10 per cent glycerol
1	$6 \cdot 0 \times 10^5$	$5 \cdot 5 \times 10^7$
2	$2 \cdot 1 \times 10^5$	$3 \cdot 5 \times 10^7$
3	$9 \cdot 5 \times 10^4$	$8 \cdot 9 \times 10^6$
4	$7 \cdot 7 \times 10^3$	$3 \cdot 3 \times 10^6$
5	$7 \cdot 7 \times 10^3$	$6 \cdot 6 \times 10^5$

* These data represent triplicate experiments.

Glycerol protected the cells against repeated freezing and thawing procedures; but the numbers did decrease slightly with each freezing. Additional work is being carried out to determine the effect of glycerol on the metabolic injury produced by freezing and thawing of *S. sonnei*. Metabolic injury has been reported by Straka and Stokes[10] in bacteria subjected to sub-zero temperatures. It would be interesting to follow up these investigations with the effects of freezing and thawing on the pathogenicity of *S. sonnei* in view of the findings of Szturm-Rubinsten *et al.*[11], who suspected a case of shigellosis transmitted by ice used in food which may have contained the *S. sonnei*.

This work was supported by a research grant (*E*–3734) from the National Institute of Allergy and Infectious Diseases, U.S. Public Health Service.

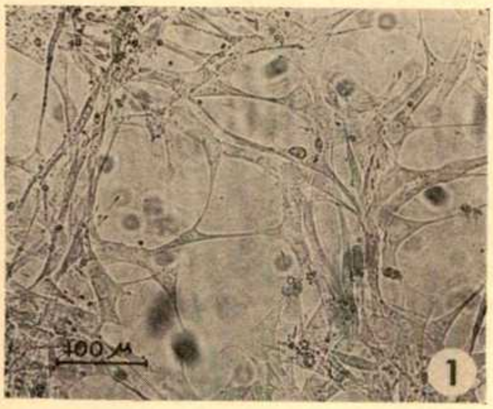
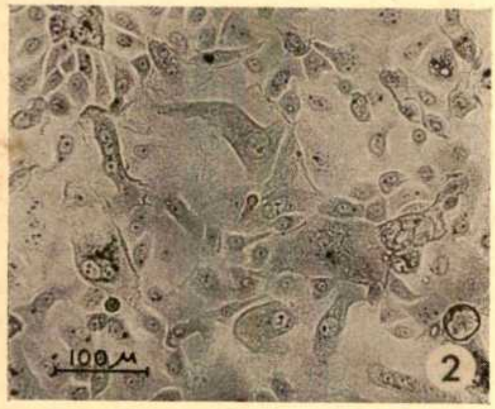
CYTOLOGY

Chromosomes in a Marsupial (*Potorous tridactylis*) Tissue Culture

The chromosome constitution of marsupial, *Potorous tridactylis*, was described by Sharman and Barber[1]. The males have five pairs of autosomes and three sex chromosomes. The low number of chromosomes plus the fact that the same investigators reported somatic pairing made this species desirable for genetic studies in tissue cultures.





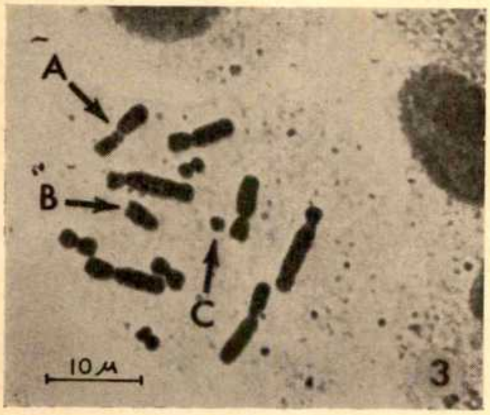


Fig. 1. Fibroblast-like testis cells of *Potorous tridactylis* in tissue culture

Fig. 2. Epithelial-like kidney cells of the same animal in tissue culture

Fig. 3. Somatic chromosome complement of a tissue culture cell of the male *Potorous tridactylis*. *A*, the *X*, *B*, the Y_1 and *C*, the Y_2 chromosomes

The animals were obtained through the courtesy of the Animals and Bird Protection Board. (We thank Dr. E. R. Guiler for help in obtaining these animals.) One male was killed and cultures were prepared from tissues of the brain, eye, lung, liver, kidney and testis with mammalian tissue culture methods[2]. Only the kidney and testis cells multiplied reasonably well; cultures of these have been actively growing through transfers for six months. The most satisfactory culture medium consisted of 90 per cent LEY (2 per cent lactalbumin enzymatic hydrolysate, 2 per cent yeast hydrolysate in Earle's salt solution) and 10 per cent fœtal calf serum. The cells adhered easily to the glass and eventually covered the surface of the culture bottle. Figs. 1 and 2 show the characteristic fibroblast-like testis cells and the epithelial-like kidney cells.

Chromosome examination of both types of cells was carried out on slides prepared in accordance with the technique reported by Ruddle *et al.*[3]. For the observation of somatic pairing pre-treatment with colchicine was not done.

In the kidney and the testis cultures both diploid and polyploid division figures were abundant. The chromosome complements were essentially similar to those reported by Sharman and Barber[1] for spermatogonial divisions. All five pairs of autosomes and the three sex chromosomes (X, Y_1, Y_2) were identifiable (Fig. 3). The X did not show the heteropycnosis described for spermatogonial divisions, but its characteristic centromeric structure was evident. Complete somatic pairing, as described for some spermatogonial metaphases, was quite rare in the tissue culture preparations; but some homologous chromosomes were frequently found close together at both prophase and metaphase. The low number of chromosomes as well as their clarity and individuality indicate that the *Potorous* material should prove suitable for cytogenetic studies with tissue cultures.

Repression of Growth of Mammalian Cells under Agar

When disaggregated mouse embryo cells are first cultivated *in vitro*, the cells grow into a confluent layer of fibroblasts on the bottom of the Petri dish, and then begin to grow additional layers on top of the first. If the cells are transferred, subsequent subcultures will show less tendency to form multiple layers. This effect is accompanied by a diminution in growth-rate of the cells and may be described as a progressive decrease in their growth potential. This behaviour is to be contrasted with that of *L* cells, an established cell line derived from mouse fibroblasts, which show no diminution in their growth potential upon transfer, and retain their ability to grow out of the monolayer.

In order to see how growth would be affected in these two types of cultures by the application of a force which would oppose growth out of the plane of the monolayer, the following experiment was performed. Casts containing 4 per cent of agar in addition to growth medium were prepared by pouring the melted mixture into Petri plates. When cooled, these casts, which are rather stiff, though only 1–2 mm. thick, were removed with a spatula and placed over primary or secondary mouse embryo cell cultures in Petri dishes of the same size, and additional liquid medium was added. At daily intervals, the agar was removed from a plate, the cells trypsinized and counted and the counts compared with those of parallel monolayers incubated in the absence of agar. The results of such an experiment are shown in Fig. 1. The rate of cell growth under the agar is reduced, over a 6-day period, so that the final number of cells is usually only about one-third that of the control. Parallel examination of the fresh or stained cultures shows that the difference in growth-rate is most appreciable after the cultures have approached confluence. Evidently the principal action of the agar is to retard the growth of cells out of the plane of the monolayer.

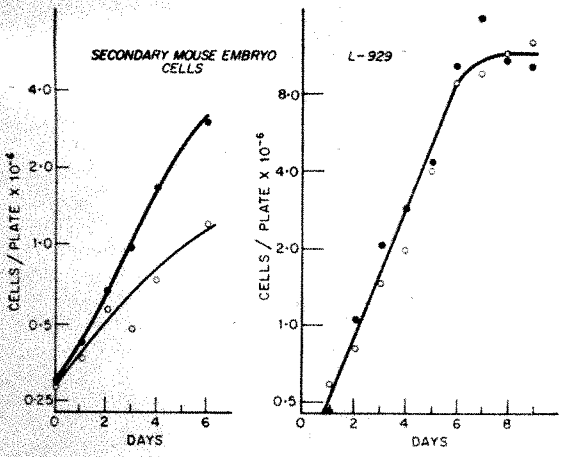

Fig. 1. Growth of secondary mouse embryo cells and *L*-929 under agar. Medium of Dulbecco and Vogt, containing 10 per cent calf serum. ●, Cells growing in absence of agar; ○, cells growing under agar layer

L cells do not show this effect. Fig. 1 demonstrates that the presence of a layer of agar does not appreciably inhibit the growth of *L* cells up to a density of 10^7 cells per plate (20 cm.^{2}). Microscopic examination shows that the cells form more than a single layer on the surface of the Petri dish as readily whether an agar layer is present or not.

Growth out of the plane of the monolayer can be prevented almost completely in the case of the *L* cells as well as the normal fibroblasts by increasing the pressure of the agar layer. Glass beads of a diameter of 0·2 mm. were found convenient for this purpose, as they are commercially available, easily washed and sterilized, and weighed aliquots in sterile tubes can be poured on to the agar layer and evenly distributed by gently tapping the Petri dish.

Growth of fibroblasts and of *L* cells under 5 or 10 gm. of glass occurs quite readily in the plane of the monolayer, but growth out of the plane of the monolayer is prevented. The cells appear somewhat flattened, small cell clumps are forced into a monolayer but few cells die, as judged cytologically. When 15 or 20 gm. of glass are placed over the agar, growth of *L* cells in the plane of the monolayer still occurs although there is more distortion of the shape of the cells than is the case under 5 or 10 gm. of glass. Normal fibroblasts, however, are not so resistant. A series of experiments was performed in which the growth of primary or secondary fibroblast cultures was followed by counting the number of fixed and stained cells on several Petri dishes just before agar and glass were applied, and three days later. In the case of the fibroblast cultures, growth was usually seriously affected under the higher quantities of glass, and 20 gm. was sometimes sufficient to prevent all growth. In some cases the number of cells actually declined, and many very distorted cell nuclei and degenerated cells could be seen. The growth-rate of *L* cells was not much affected by up to 20 gm. of glass in spite of distortion of cell shape.

It would seem most likely that the effects exerted by agar, or agar and glass, are due to the weight of these substances, though it is probably true that the agar slows the exchange of substances between the cells and the medium, especially of the larger molecules. This is also true of the glass, which immobilizes the water trapped between the beads.

The pressure exerted by the 4 per cent agar casts and the glass may be calculated from their density and that of the medium. The casts in medium weigh approximately 140 mgm. and the glass about 0·6 of its weight in air.

Under ordinary conditions of cell culture, there is no resistance to the growth of the cells, in at least one direction. This is rather different from the conditions in which animal cells grow *in vivo*. The present experiments suggest that cells in culture may differ from each other in behaviour when their growth is opposed by mechanical forces, very small forces readily inhibiting growth out of the plane of the monolayer in the case of normal fibroblasts. The inhibition of cell growth by such means may be related to the phenomenon of contact inhibition[1]. Experiments on other cell types will be necessary to determine if relative resistance to this inhibition is correlated with the 'established' or neoplastic condition.

Cell cultures have been maintained under agar and 5 gm. of glass for at least a month without transfer. Following the attainment of a confluent state, all growth was arrested, for the remainder of the period. A fairly high proportion of *L* cells maintained in the resting state in this way remained viable, judging from the growth of sub-cultures.

VIROLOGY

Antibodies of Low Molecular Weight in Normal Human Urine

THE presence of precipitating and viral neutralizing antibodies in normal human urine has been reported previously[1-3]. Some physicochemical properties of these antibodies are described in this communication.

Urine was collected from individuals with normal renal function who had been immunized with poliovirus vaccines or with tetanus toxoid. The urines were concentrated with 'Sephadex G-25' (ref. 4) or by lyophilization following dialysis. Proteins having electrophoretic mobilities and antigenic characteristics similar to but not identical with those of serum $7S$ γ-globulins were separated from the concentrated urines either on columns of diethylaminoethyl cellulose (DEAE), using phosphate buffer (0·0175 M, pH 6·3), or by starch-block electrophoresis in a borate buffer (μ0·064, pH 8·6).

Analysis of these γ-globulin fractions by sedimentation velocity in the ultracentrifuge revealed a major component with an average $S_{w,20}$ of 1·5 and a minor component with an average $S_{w,20}$ of 5·7 (Fig. 1A). The proportion of the latter as estimated from the area under the curve in the ultracentrifuge patterns, assuming the specific refractive index increment for the two components to be the same, was 0·5, 0·7, 2·0 and 10 per cent of the total γ-globulin in four samples. Separation of these two components was achieved by sedimentation in a sucrose gradient (1–20 per cent). The top and bottom fractions obtained from these separations were reacted in agar with a rabbit antiserum prepared against human $7S$ γ_2-globulins. The material obtained from the top fraction formed a precipitin line that showed a reaction of partial identity with serum $7S$ γ-globulins, whereas the material obtained from the bottom of the gradient gave a reaction of complete identity with serum $7S$ γ-globulins (Fig. 1B). Analysis of the top fraction in the ultra-centrifuge showed a single peak with an $S_{w,20}$ of 0·92.

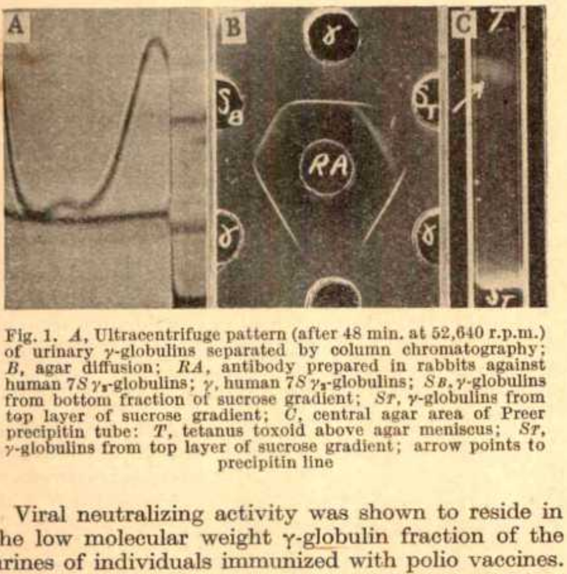

Fig. 1. A, Ultracentrifuge pattern (after 48 min. at 52,640 r.p.m.) of urinary γ-globulins separated by column chromatography; B, agar diffusion; RA, antibody prepared in rabbits against human $7S$ γ_2-globulins; γ, human $7S$ γ_2-globulins; S_B, γ-globulins from bottom fraction of sucrose gradient; S_T, γ-globulins from top layer of sucrose gradient; C, central agar area of Preer precipitin tube: T, tetanus toxoid above agar meniscus; S_T, γ-globulins from top layer of sucrose gradient; arrow points to precipitin line

Viral neutralizing activity was shown to reside in the low molecular weight γ-globulin fraction of the urines of individuals immunized with polio vaccines. The appearance or increase in antibodies to poliovirus types I and III in the serum following booster doses of vaccine was accompanied by the occurrence of measurable antibodies to the homologous viruses in the urine[3].

The presence of precipitating antibodies to tetanus toxoid was demonstrated in the low molecular weight γ-globulins separated from the urines of individuals who had been immunized with that antigen (Fig. 1C). The precipitin techniques used in these studies were those described by Preer[5] and Ouchterlony[6]. The precipitating activity of the serum of several individuals was compared with that of the corresponding low molecular weight γ-globulins prepared from their urine. Even though the amounts of γ-globulin in the serum and in the preparation of low molecular weight γ-globulins of urine appeared to be the same, 3–4 weeks were required for a visible precipitin line to appear when the urinary antibodies were used, in contrast to 4–9 days for serum antibodies, although the relative positions of the precipitin lines in the Preer tubes were the same for the antibodies derived from these two sources. The faster sedimenting component ($S_{w,20}$ 5·7) of the urinary γ-globulins did not precipitate with homologous antigen. This may have been due to the small amounts of this fraction in normal human urine.

Determination of the molecular weight of the precipitating urinary antibodies by Archibald's method[7] gave a value of 12,900. Thus, these γ-globulins have a molecular weight roughly one-third to one-fifth the molecular weight of the active fragments obtained by papain digestion of rabbit or human $7S$ γ_2-globulins[8,9], or one-thirteenth the molecular weight of human $7S$ γ_2-globulins. It is noteworthy that these naturally occurring low-molecular-weight antibodies, unlike the fragments obtained by papain digestion, have the ability to precipitate with antigen, suggesting that two antibody-combining sites are present on this relatively small unit.

Purification of Clover Yellow Mosaic Virus

A VIRUS occurring in a complex with white clover mosaic virus was isolated from white clover (*Trifolium repens* L.) plants growing in Montana[1]. Host-range and serological studies were made simultaneously at Vancouver[2] and Missoula[3] and the virus was named clover yellow mosaic virus. The Missoula authors at the same time made a study of the distribution of the virus in the United States. The present investigation was made using this virus maintained on clover plants.

Leaves from white clover plants infected for about 4 weeks were frozen in a deep freeze for 36 hr. Sap was extracted from this material by means of a meat

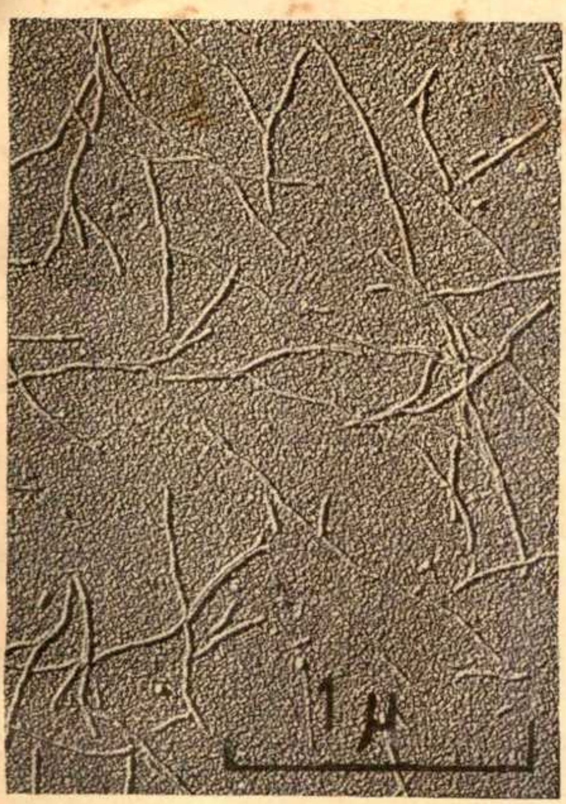

Fig. 1. Electron micrograph of purified clover yellow mosaic virus. (× 40,000)

grinder using 0·1 *M* disodium hydrogen phosphate (1 ml. to each gm. of leaf tissue). The extract was expressed through cheese-cloth and clarified by centrifuging for 60 min. at 2,500 r.p.m., after which the supernatant was again centrifuged for 30 min. at 10,000 r.p.m. in a No. 40 rotor of a Spinco model *L* ultracentrifuge. The pellet was discarded and the supernatant centrifuged for 60 min. at 40,000 r.p.m. Four such cycles of alternate low- and high-speed centrifugations were given, resuspending the pellet in 0·1 *M* phosphate buffer (*p*H 7·0) each time. This was then followed by centrifugation for 2 min. at 30,000 r.p.m. The resulting supernatant was given a final high-speed centrifugation, yielding a faintly pale yellow pellet. Further purification of this pellet was achieved utilizing cæsium chlorate according to the method described by Levintow and Darnell[4]. This gave a completely colourless virus preparation which on examination in the analytical ultracentrifuge showed a single distinct peak. Its purity was confirmed by electron microscope and ultra-violet absorption examination. No pellet was obtained with the healthy material processed in the same manner.

Electron microscope examination revealed flexuous rods (Fig. 1), measurements of which gave a peak around 525 mμ. Smaller and larger particles were also found, but these were regarded as fragments and aggregations of the regular virus particles. Pratt[5] reported an average length of about 530 mμ for his clover yellow mosaic virus.

We thank Dr. B. H. Hoyer of the National Institute of Allergy and Infectious Diseases, Rocky Mountain Laboratory, Montana, for his assistance with the analytical ultracentrifuge. This work was supported by the U.S. Public Health Service grant No. *E*–596 (*c*).

SOIL SCIENCE

Colloidal Silicic Acid in Terra Rossa

ACCORDING to Reifenberg[1] colloidal silicic acid has an important role in the development of terra rossa. In order to substantiate this theory the existence of water-soluble colloidal silicic acid should be proved. The present work is an attempt to estimate colloidal silicic acid in water extracts of Israel terra rossa.

The silicic acid was determined by colorimetric determination of the silicomolybdic acid[2]. Ionic silicic acid was considered to be that which enters into the silicomolybdic complex immediately, and colloidal that which enters only after treatment with sodium bicarbonate, which depolymerizes the colloid. A 0·1 per cent solution of sodium silicate was neutralized with hydrochloric acid and the presence of colloidal silicic acid proved by precipitation with gelatin[3]. From this dilutions 1 : 20–1 : 200 were prepared and the amount of ionic silicic acid was determined. On the day of preparation only about 10 per cent of the silicic acid was in ionic form. The amount of ionic acid increased steadily with the age of the solutions and after two weeks all the silicic acid was in the ionic state. It follows that in concentrations up to 500 p.p.m. colloidal silicic acid depolymerizes in neutral *p*H. In particular colloidal silicic acid may depolymerize during extraction with water. The theoretical aspects of this equilibrium have been discussed[4].

Next, the amounts of silicic acid in various natural waters in Israel were determined and found to be 10–50 p.p.m. All the silica was in ionic state.

The first problem in soil extracts is the ratio water : soil. In order to elucidate this the following experiment was carried out, summarized in the table : To 200 gm. water various amounts of Jerusalem terra rossa (column *a*) were added and allowed to equilibrate for a week. Then the amount of silica in the extract was determined (*b*) p.p.m. water and (*c*) p.p.m. soil:

(*a*)	(*b*)	(*c*)
10 gm.	5·6	112
40 gm.	9·2	46
100 gm.	13·0	26

All the silica was in ionic state and no colloidal silicic acid was detected. It appears that whereas more concentrated suspensions give more concentrated extracts, the amount of extractable silicic acid increases with the amount of water. This suggests that silicic acid is adsorbed on soil, which indeed was proved by the following experiment: To 40 gm. soil 200 c.c. of silicic acid solutions (55 and 106 p.p.m.) were added and allowed to equilibrate for a week, after which the solutions were analysed and found to contain 15 and 20 p.p.m. respectively. (All the silica was in ionic state.)

Finally the amount of soluble silicic acid in various top soils in Israel was determined by extracting 40 gm. soil with 200 c.c. water and was found to be 10–100 p.p.m., all in ionic state.

The present work can neither support Reifenberg's theory nor refute it. Though no colloidal silicic acid was found in the extracts, it may be argued that it was present in the soil samples and was depolymerized on extraction.

FOREST PRODUCTS

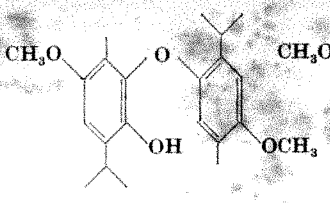
Chemistry of Decay of Heartwood on Ageing in Incense Cedar (*Librocedrus decurrens* Torrey)

IT is now generally recognized that the type of extractives present in certain woods accounts for practically all the decay resistance, and physical factors are of little significance. It has been repeatedly observed in tests of resistance to natural decay that the inner heartwood of many woods is less resistant to decay than the outer heartwood. This is particularly true in the lower trunk of larger and older trees. Moreover, it is a common observation that a hollow tree or log has sustained most loss of wood in the central portion of the trunk. The phenomenon of decreasing resistance to decay with ageing of the wood in the tree occurs in many species, so necessarily there will be a variety of chemical changes involved.

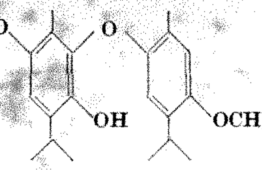
The fungitoxic properties of a number of compounds isolated from incense cedar heartwood were previously reported[1]. The observation was made that, while one of the extractive components, namely, *p*-methoxythymol, exhibited fungicidal properties against a number of wood-destroying fungi, its dimer, libocedrol (I), exhibited very little fungitoxic action.

It was suggested that this may be one type of chemical change that conceivably could account for the decrease in resistance to decay in heartwood on ageing.

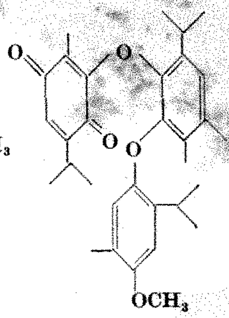
Recently, two new extractive components have been isolated from incense cedar heartwood—hyderiol (0·14 per cent dry wood basis) (II) and 3-libocedroxy-thymoquinone (0·02 per cent) (III)[2]. The former is a dimeric cryptophenol ether consisting of *p*-methoxythymol and *p*-methoxycarvacrol, while the latter is a trimeric ether consisting of two molecules of *p*-methoxythymol (libocedrol) and thymoquinone.



(I)



(II)



(III)

The decay-retarding characteristics of each of these compounds were determined, together with that of their monomeric counterparts, *p*-methoxythymol, *p*-methoxycarvacrol and thymoquinone. The method used, except for minor deviations, was the standard soil-block bioassay procedure ("Tentative Method of Testing Wood Preservatives by Laboratory Soil-Block Cultures", A.S.T.M. Designation *D* 1413-56 *T*, 1956). Test blocks of ponderosa pine sapwood were impregnated with each of the aforementioned compounds and subjected to decay by a pure culture of a wood-destroying fungus. Loss in block weight during the test constituted the measure of decay. The wood-destroying fungus used was *Lentinus lepideus* (Madison, 534). The results are summarized in Table 1.

Table 1. DECAY RETARDENT BIOASSAY USING *Lentinus lepideus**

Chemical	Weight-loss (per cent)
p-Methoxythymol	15
p-Methoxycarvacrol	16
Thymoquinone	26
Heyderiol	22
Libocedrol	27
3-Libocedroxythymoquinone	33
Control	32

* Test blocks containing 1·2 per cent, by weight of chemical. Test duration, six weeks.

It will be noted that heyderiol, while exhibiting faint fungitoxic properties, was not so potent as its monomeric counterparts. Libocedrol, as previously indicated, again showed, at best, weak fungicidal action. Similarly, but even more apparent, 3-libocedroxythymoquinone had virtually no decay-inhibiting capacity against *Lentinus lepideus*. It is even less fungitoxic than the dimers heyderiol and libocedrol and apparently retains little or none of the fungitoxic qualities inherent in the parent compounds.

The present finding of the denaturing of *p*-methoxythymol, *p*-methoxycarvacrol and thymoquinone via their several polymeric phenol ethers represents a type of chemical change that conceivably could account for relatively lower decay resistance, hence greater susceptibility to heart-rot, in the central lower trunk of mature incense cedar trees. As the tree or wood ages it may be reasonable to assume that, in the biogenesis of extractives, certain enzymatic systems and/or time convert certain phenols to polymeric phenol ethers which can reduce the resistance of heartwood to decay.

Further investigations are in progress.

UNIVERSITY OF LONDON (at the Institute of Education, Malet Street, London, W.C.1), at 5.30 p.m.—Prof. J. S. Bruner (Harvard): "Teaching and Learning".* (Further lectures on May 3 and 4).

BRITISH INSTITUTION OF RADIO ENGINEERS, ELECTRO-ACOUSTICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. M. Millett and Mr. Z. A. Kiss: "Loudspeaking Telephones".

INSTITUTION OF ELECTRICAL ENGINEERS, and ROYAL AERONAUTICAL SOCIETY, LONDON JOINT GROUP (at the Institution of Electrical Engineers, Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Aircraft Electrical Supply System Characteristics and their Effects on the Design of Electronic Equipment", opened by Mr. J. W. McPherson.

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Mr. R. Palmer: "The Texture of Polymers".

Wednesday, May 2—Thursday, May 3

IRON AND STEEL INSTITUTE (at the Royal Commonwealth Society, Northumberland Avenue, London, W.C.2; Church House, Great Smith Street, London, S.W.1; and at 4 Grosvenor Gardens, London, S.W.1)—Annual General Meeting.

Thursday, May 3

IRON AND STEEL INSTITUTE; and the SOCIETY OF CHEMICAL INDUSTRY, CORROSION GROUP (at Denison House, 296 Vauxhall Bridge Road, London, S.W.1), at 10 a.m.—Joint Conference on "New Horizons in Stainless Steel".

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Meeting for the election of Foreign Members, followed by Dr. F. P. Bowden, F.R.S., and Mr. L. T. Chadderton: "Fission Fragment Damage to Crystal Lattices: Dislocation Formation"; Mr. G. O. Harding and Mr. J. Wilks: "The Absorption of Sound in Dilute Solutions of ^{3}He in Liquid Helium II".

LINNEAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. Rudolf Florin (Stockholm): "The Distribution of Conifer and Taxad Genera".

UNIVERSITY OF LONDON (at the London School of Economics and Political Science, Houghton Street, Aldwych, London, W.C.2), at 5 p.m.—Prof. E. Jones: "The City in Geography" (Inaugural Lecture).*

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. H. G. Wittmann (Tubingen): "Genetic Code between Nucleic Acid and Protein".*

UNIVERSITY OF LONDON (at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2), at 5.30 p.m.—Dr. I. Friedmann: "Electron Microscopy in Otolaryngology".*

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting.

SOCIETY OF CHEMICAL INDUSTRY, CORROSION GROUP (at the Hoare Memorial Hall, Church House, Westminster, London, S.W.1), at 6.30 p.m.—Prof. A. B. Winterbottom: "Studying Surface Films on Metals Optically" (Spring Lecture).

Friday, May 4

INSTITUTION OF ELECTRICAL ENGINEERS, EDUCATION DISCUSSION CIRCLE (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Machines that Teach" opened by Mr. H. W. French.

Monday, May 7

UNIVERSITY OF LONDON (at St. Mary's Hospital Medical School, Wright–Fleming Institute of Microbiology, Paddington, London, W.2), at 5 p.m.—Prof. Frank Fenner: "Reactivation of Animal Viruses".* (First of four Almroth Wright Lectures.)

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. I. M. Glynn: "Sodium and Potassium Movements in Living Cells".* (Further lecture on May 14.)

UNIVERSITY OF LONDON (in the Physics Lecture Theatre, Queen Mary College, London, E.1), at 5.30 p.m.—Prof. R. Righini (Florence): "The Abundance of Isotopes in the Solar Atmosphere".*

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. A. Winegarten: "Agriculture". (First of three Cantor Lectures on "The Development of Natural Resources".)

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting. Prof. L. Jacqué (Paris): "The French Chemical Industry".

WOMEN'S ENGINEERING SOCIETY, LONDON BRANCH (at "Hope House", 45 Great Peter Street, Westminster, London, S.W.1), at 7 p.m.—Mr. P. F. Mariner: "Micro-miniaturisation".

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. John H. Hemming and Mr. Christopher S. Lambert: "The Iriri River Expedition".

Monday, May 7—Tuesday, May 8

POWDER METALLURGY JOINT GROUP of the IRON AND STEEL INSTITUTE and the INSTITUTE OF METALS (at Church House, Great Smith Street, London, S.W.1)—Spring Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT LECTURER IN STATISTICS—The Registrar, The University, Sheffield (May 5).

LECTURER IN THE DEPARTMENT OF MORAL PHILOSOPHY—The Secretary, The University, Edinburgh (May 7).

LECTURER (registered member of the veterinary profession) IN THE DEPARTMENT OF VETERINARY MEDICINE, Royal (Dick) School of Veterinary Studies—The Secretary, The University, Edinburgh (May 7).

LECTURER (graduate with medical qualifications) IN ANATOMY—The Registrar, King's College (University of London), Strand, London, W.C.2 (May 9).

LECTURER IN THE DEPARTMENT OF ZOOLOGY—The Secretary, The University, Edinburgh (May 12).

ERASMUS SMITH'S CHAIR OF MATHEMATICS in the University of Dublin—The Secretary, The University Council, Trinity College, Dublin 2, Republic of Ireland (May 14).

LECTURER IN THE DEPARTMENT OF MATHEMATICAL PHYSICS—The Secretary, The University, Edinburgh (May 14).

LECTURER or ASSISTANT LECTURER IN PHYSICAL OR INORGANIC CHEMISTRY—The Registrar, The University, Hull (May 14).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF ORGANIC CHEMISTRY—The Registrar, The University, Leeds 2 (May 14).

UNIVERSITY CHAIR OF NATURAL PHILOSOPHY in the University of Dublin—The Secretary, The University Council, Trinity College, Dublin 2, Republic of Ireland (May 14).

LECTURER (preferably with a special interest in rock structures and sedimentary processes) IN THE DEPARTMENT OF GEOLOGY—The Registrar, The University, Edgbaston, Birmingham 15 (May 15).

DEWAR RESEARCH FELLOW, to engage in research in radiation chemistry—The Secretary, The University, Edinburgh (May 18).

LECTURER IN PSYCHOLOGY at Newcastle University College, University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2, and The Appointments Section, University of New South Wales, Box 1, Post Office, Kensington, N.S.W., Australia (May 18).

LECTURER (with a special interest in the geochemistry of sedimentary rocks) IN THE DEPARTMENT OF GEOLOGY—The Secretary, The University, Edinburgh (May 19).

RESEARCH ASSISTANT IN THEORETICAL PHYSICS in St. Salvator's College—The Secretary, The University, College Gate, St. Andrews. (May 19).

LECTURER or ASSISTANT LECTURER IN PHYSICS at the University College of the West Indies—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 21).

LECTURER/SENIOR LECTURER IN MATHEMATICS at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 21).

LECTURERS and ASSISTANT LECTURERS IN MATHEMATICS—The Secretary, The Royal College of Science and Technology, Glasgow (May 21).

LECTURER or ASSISTANT LECTURER (with high qualifications in physics and some research experience, preferably (though not necessarily) in the field of biophysics) IN THE ASTBURY DEPARTMENT OF BIOPHYSICS—The Registrar, The University, Leeds 2 (May 21).

UNIVERSITY DEMONSTRATOR (with an appropriate honours degree) IN ANIMAL NUTRITION—The Secretary, School of Agriculture, The University, Cambridge (May 23).

ASSISTANT LECTURER or LECTURER (preferably with an interest in extraction metallurgy or refractories) IN THE DEPARTMENT OF METALLURGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 26).

LECTURER or ASSISTANT LECTURER IN BIOCHEMISTRY at the University of Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 31).

LECTURER (with a good honours degree in geology and preferably experience in teaching in a university department) IN GEOLOGY at the University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, May 31).

DIRECTOR OF THE NUFFIELD INSTITUTE OF COMPARATIVE MEDICINE which is to be built in the Zoological Society's grounds at Regent's Park—The Secretary, The Zoological Society of London, Regent's Park, London, N.W.1 (June 1).

LECTURER (with an honours degree in psychology, and preferably an interest in experimental psychology) IN PSYCHOLOGY at the University of Canterbury, Christchurch, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, June 15).

ASSISTANCE TO AGRICULTURE OVERSEAS

On May 17, 1961, Dr. P. V. Sukhatme, of the Food and Agriculture Organization, presented to the Royal Statistical Society a quantitative assessment of hunger in the world and of future needs for food supplies. The paper has since been published in the Society's *Journal* (124, 463): it should be obligatory reading not only for those professionally concerned with these problems but also for all interested in their political and humane implications. After giving an account of the scope, limitations and sources of error in the available data, Dr. Sukhatme shows that 300–500 million people (10–15 per cent of the world population) are undernourished (that is, their calorie intake is insufficient for normal health and activity), particularly in the Far East, where the gap between the average levels of consumption *per caput* and the requirement is 11 per cent, and he examines the distribution within populations, in various regions of the world, of undernourishment. Malnutrition (qualitative inadequacy of diet, with particular reference to intake of protein) and undernourishment probably affect from one-third to one-half of the human species. Linear programming is then used to calculate the quantities of additional food required to meet the nutritional needs of the estimated populations at various dates up to the year A.D. 2000, taking cost into account. To achieve this objective by the year 2000, cereal supplies in the Far East must be more than doubled, and those of animal products multiplied six times. For the world as a whole, the United Nations medium population forecast requires that food supplies be more than doubled by 1980 and trebled by the year 2000 to achieve a moderate improvement in the level of nutrition of mankind. This would mean (as Mr. Colin Clark pointed out in the discussion) a continuing increase of 3 per cent per annum in agricultural production. While this was, in fact, achieved even in the Far East in the period 1948–58, it cannot be expected to continue without special efforts to increase the yields of agricultural produce per acre, and wherever possible, to extend the area of agricultural land.

In the United States (as in some other industrialized countries) agricultural technology is progressing so fast that agricultural surpluses and enforced restriction of production are the order of the day, and great areas of potentially useful land lie uncultivated. The air traveller to New York may see below him, as he flies down the eastern seaboard, evidence of the great contraction of agricultural acreage in the New England States during the past eighty years. In the under-developed countries, by contrast, production methods and yields are still in the medieval or early neolithic stages of development, particularly in the tropics. There is ample technical evidence, much of which is marshalled in the British Association's pamphlet, *Hunger: Can it be Averted?* (edited by Sir John Russell and Dr. Norman Wright, August 1961), and in the papers read at a recent meeting of the Nutrition Society (*Nature*, 192, 1028; 1961) that while there are innumerable problems still to be resolved, and many social and economic obstacles, the application of known technical means can lead to very considerable advances in the output of agriculture in these areas. The social and economic difficulties call for political, educational and administrative action by Governments, most of which are now independent, but there remains a large and growing need for technical aid in research, agricultural education and extension.

For eighteen years past the Rockefeller Foundation has been supplying this need most effectively, first in Mexico, later in Colombia and Chile, and in the past few years in other American countries and in India. The first annual report of these activities, which brought the story up to the year 1959–60, was reviewed in *Nature* last year (191, 539; 1961). The second report has now been published*.

The Program is based on operating programmes in various countries, together with a fellowship and scholarship programme and a grants programme. The territorial programmes are intended to develop indigenous organizations for agricultural progress. The Foundation enters into an agreement with the national Government to establish an appropriate organization, included in, and co-operating with, the existing official structure, and staffed so far as possible by local scientists and technicians. The Foundation provides such senior staff as are required, to direct or participate in the planning and execution of the work. It helps to develop local institutions for higher agricultural and scientific education, and awards fellowships and scholarships for advanced study and training (mostly, but by no means entirely, in the United States), so that a higher cadre is built up to replace Foundation staff as soon as possible. Research stations and institutes are planned and developed, and particular attention is given to extension services. In Mexico, the Office of Special Studies, established in 1943 within the Ministry of Agriculture, was fused in 1960 with the Institute of Agricultural Research to form a National Institute, with a professional staff of nearly 300, of whom 11 only are Rockefeller staff acting as advisers or heads of sections. Many of the 136 Mexicans who have obtained their higher training under Rockefeller auspices now carry senior responsibilities in the Institute. Steady progress in the same direction is reported from Colombia and Chile, where the Rockefeller staffs number 17 and 5, respectively.

---

* The Rockefeller Foundation, 1961. Program in the Agricultural Sciences. Annual Report 1960–1. Pp. ix+326+many plates and diagrams. (New York: Office of Publications, The Rockefeller Foundation, 1961.) n.p.

Work on maize, potatoes and wheat is extended co-operatively to other Latin American countries by the Inter-American Crop Improvement Program, which also co-ordinates more basic research activities on these crops throughout the Americas, from Canada to Chile and the Argentine. Much fundamental work of great importance is being done through this agency on maize and potatoes, the two main indigenous American food crops, and clearly the Rockefeller team is accumulating unparalleled experience of the methods of agricultural improvement on a hemisphere scale. The programme is also providing training, under an arrangement with the Food and Agriculture Organization, for visiting crop technologists from the Middle East who are concerned with wheat, and the maize work now includes studies of the varieties in use in Europe, India and South-East Asia. The potato programme is providing material, especially of the less-well-known species of *Solanum*, for basic research and crop improvement work all over the world.

The steady extension of the Foundation's interests on a world scale is shown by the Indian Program and the support given to the operation of the new International Rice Institute in the Philippines. In India, where the Foundation started work in 1956, co-operation has been established with 26 Federal and State experiment stations in work on maize, sorghum and millets. Four maize double-cross hybrids, partly derived from inbreds previously produced in India, and partly from U.S. and South American material, were put into production in 1960. More than 3,300 samples have been collected in a study of Indian sorghums and millets, and hybrid sorghum varieties are being developed. Special attention is being given to the development of seed production. In many ways the most striking advance is the development, with Rockefeller help, of the Postgraduate School of the Indian Agricultural Research Institute. In October 1960 the first degrees (4 Ph.D., 78 M.Sc.) were awarded, and the third graduate class was admitted; in April 1961 there were 182 M.Sc. and 169 Ph.D. students. The teaching staff numbers 129, of whom almost all are Indian nationals, while the total Rockefeller staff in India numbers 7.

Most of the cost of all this work is borne by the Governments concerned. The total cost to the Foundation of the Rockefeller Agricultural Program, including operations, scholarships, fellowships and grants, for twenty years 1941–60, is given as less than 43 million U.S. dollars, and the total staff of the Program (including headquarters staff) in 1960–1 was only 57. This work, which is accumulating respect and experience of the greatest importance for the advancement of world agriculture, appears to be conducted with economy both of men and of money.

During the same period the British contribution to the agricultural services of under-developed countries has declined in the process of general disengagement from colonial responsibilities. Independence usually produces conditions of instability, and by the time the emergent Government realizes that intolerance of foreign rule is not incompatible with the continued service of individual expatriate scientists, the technical services may have collapsed. Usually there has been no one to replace departing officers, and continual staff changes, career uncertainty, and the shortage of senior experienced workers, have combined to reduce the effectiveness of the services, often to vanishing point. The employment of non-British expatriates has not, on the whole, succeeded, while the new university faculties of agriculture and science are only just beginning to produce a trickle of indigenous technologists genuinely capable of assuming the burden. Yet in many countries, once the tensions of the actual attainment of independence have passed, a solid residue of goodwill and a common educational system and language have led to a renewed demand for British agricultural science and scientists.

The central problem before us is to develop an economical method of deploying the British potential in the service of overseas agriculture. The objectives, *inter alia*, would be to maintain technical liaison with overseas Governments and agricultural organizations, to organize the provision of advice and the recruitment of staff for them, while seeking means of retaining staff at present working overseas, to catalyse agricultural development, to advise the United Kingdom Government on overseas financial aid in the agricultural field, and to co-operate with the international agencies like the Food and Agriculture Organization and Unesco. These activities are at present dispersed into many channels, including the British Council, the Ministry of Agriculture, the Department of Technical Co-operation, technical officers attached to overseas diplomatic missions, the Inter-University Council for Higher Education Overseas, the Commonwealth Agricultural Bureaux, the tropical commodity research organizations, commercial firms and demi-official and private contacts. Means must be found of bringing these efforts together and of encouraging active and continuing interest in overseas agriculture. The Department of Technical Co-operation, which is clearly the central official body in the field, has established a commendably small and distinguished advisory committee for agriculture, animal health, forestry and fisheries, with a supporting panel of consultants. From this arrangement might well develop a broadly based joint council for overseas agriculture, with which all official and unofficial interests capable of contributing effectively (including those in the Commonwealth) could be encouraged to co-operate. Such a body would not itself direct research and development, though it might help to develop programmes and to find the men who could carry them out as servants or consultants of overseas Governments.

The mode of action of such a joint council might well resemble that of the Inter-University Council (which also is now part of the charge of the Department of Technical Co-operation), the quiet but extremely effective activities of which have done so much for overseas territories during the past sixteen years. Its physical organization would be modest: it would need no technical headquarters; and much of its work could be done by an executive (perhaps the existing Advisory Committee) and a small permanent secretariat. Where it needed scientific and technical staff of its own, they might well (following some existing precedents) be based on university departments and research stations rather than on a headquarters office. It would, however, require mobility, and should have a reasonable budget for travelling. The autonomy of its operations should be sufficient to minimize the imputation of 'neo-colonialism', and to allow flexibility and directness in the relations between home and overseas institutions and individuals.

A great deal of the work of such a body, like that of the Inter-University Council, would be concerned with personnel for longer or shorter term assignments. Most overseas appointments at present are for a limited number of years, and this is likely to continue. Though the agricultural science curricula of the universities need to be strengthened, particularly in respect of studies of comparative agriculture on a crop physiological and ecological basis, there is no doubt that a sufficient number of suitable young recruits could be found in both applied and pure science, ready to devote a number of their earlier years to overseas service. They must, however, be offered some assistance in continuing their careers when they return. The really serious shortage is of more senior personnel, particularly of men with appropriate experience of agricultural science and research in tropical or continental environments. No effective way of conserving staff of this sort has been found during the past fifteen years: in this time a valuable asset has been dispersed and in part lost. It is clearly very difficult for a relatively senior man, who usually has family responsibilities, to give up post and prospects in order to serve abroad for a limited term.

An effective solution must involve an element of continuing responsibility in Britain for such staff. Secondment offers one solution to these problems, as Prof. P. M. S. Blackett pointed out in his Irvine Memorial Lecture at St. Andrews (*Nature*, 193, 416; 1962). It has been used sporadically both for universities and research institutions during the past fifteen years. Direct secondment is usually inexpensive, since the overseas institution normally has funds, and for larger departments or institutes it offers no real difficulties. Where staffs are small, as in most university agricultural science departments, direct secondment is seldom possible, and the creation of supernumerary posts is unlikely to commend itself. In these circumstances some form of joint recruitment with a guaranteed return is necessary. The University of Reading has developed a general secondment scheme with the University of Khartoum, based on joint recruitment, which provides a guaranteed period on the staff at Reading after the overseas service ends†. The scheme is essentially simple and it could readily be adapted for the use of other institutions. The Ministry of Education has a somewhat similar scheme for school teachers. An important recent report‡ on the future of research services in East Africa, of which the Secretary of the Agricultural Research Council was a signatory, proposes an even more broadly conceived arrangement involving the co-operation of the appropriate Research Councils in Britain. The Department of Technical Co-operation has set up a Committee on University Secondment, which, working in co-operation with the British Council and the Inter-University Council, may be expected to contribute effectively to thought and action in this general field.

In the years ahead, leadership and knowledge in agricultural science must come to be regarded as among our most important exports, so that periods of service abroad are normal in the careers of many, even most, British agricultural scientists. The benefits will not by any means be one-sided. A continuing interest, through a succession of visits and secondments, in tropical problems cannot but enrich a university department or research institute and raise the stature and professional value of its staff. Such a policy will meet many administrative obstacles; but this is the common hazard of all forward-looking policies, and it is the task of official and academic administrators to deal with them. Given policy and leadership, Britain can deliver the goods in this increasingly competitive field.

---

‡ Report of the Commission on the most suitable structure for the management, direction and financing of research on an East African basis. Under the chairmanship of Prof A. C. Frazer. Pp. (12+) 76. (Nairobi, East Africa High Commission, 1961) 5s.

THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

The Department of Scientific and Industrial Research
By Sir Harry Melville. (The New Whitehall Series, No. 9.) Pp. 200. (London: George Allen and Unwin, Ltd.; New York: Oxford University Press, Inc., 1962.) 25*s*. net.

THIS latest addition to the Whitehall series gives a comprehensive picture of the activities of the Department of Scientific and Industrial Research obtainable from no other work that has hitherto described the activities or functions of the Department. Its appearance is the more welcome at a time when the scope of the Department and its place in the organization of civil research generally is again the subject of some discussion. To that discussion it would be unreasonable to expect any direct contribution, and the only respect in which the book disappoints is in failing to lift appreciably the veil which the Department's own reports keep drawn over the activities of the Information Division.

On this function Sir Harry Melville touches in two chapters dealing with the dissemination and use of the results of research and with international relations, chapters which well display the Department's potentialities in this field both in Britain and abroad. Clearly, it would have been difficult for Sir Harry to have written more without disturbing the balance of the book or entering on questions of policy, but a simple comparison of this volume or of an annual report from the Department with an annual report of the U.S. National Science Foundation demonstrates what is lacking and the root of the trouble lies outside the Department and at a higher level.

For the rest the book, lucid and authoritative, is admirably conceived. After setting forth first the constitution and functions of the Department as re-stated in the Act of 1956 and outlining the extent and magnitude of its existing activities, Sir Harry gives an excellent summary of the origin and development of the Department from 1915 to the present time. This account, which pays deserved tribute to those who played so large a part in getting the Department started and steering it safely through the early years, is supplemented in the appendix by lists of successive Lord Presidents of the Council, Chairman of the Advisory Council and Secretaries of the Department. A brief chapter on the organization and control of the Department follows, and there is one describing the Department's system of grants for postgraduate training and research.

In this chapter, as in that on the co-operative research associations, Sir Harry attempts to assess impartially the benefits to Britain which have flowed from these activities, and at the same time to indicate some of the implications and questions of policy which arise. Four chapters on the Department's own research establishment, apart from a brief concluding survey, complete the volume and these chapters cover the stations which have now been closed, or for which the responsibility has been transferred to other Departments or Research Councils. In his impressive picture of the benefits which the Nation draws from the activities of all these research establishments, it is curious, however, that Sir Harry makes no reference to work done, notably at the Road Research Station and the Building Research Station, on behalf of overseas territories. Some work for overseas is also done by the Pest Infestation Laboratory, now the responsibility of the Agricultural Research Council, and by the Tropical Products Institute for which the Department became responsible in 1959, and in assessing the significance of the work of the Department as a whole it should be recognized that the overseas territories benefit as well as Britain herself.

R. BRIGHTMAN

TEXT-BOOK OF VIROLOGY

Wirusologia Ogolna

Edited by Dr. E. Mikulaszek and Dr. W. Dobrzanski. Pp. 580. (Warszawa: Panstwowe Wydawnictwo Naukowe, 1960.) Cena zl. 70.

IN the world literature there are relatively few text-books on general virology; this book is the first and only one on the subject written in Polish by Polish authors.

The editors are obviously in step with present-day trends in virology which, after a period of interest in practical application of the existing knowledge, is now entering a phase of very rapid theoretical advance due largely to general progress in all biological sciences and to the active interest in virology of scientists specializing in other biological disciplines.

A young and vigorously developing science like virology is often faced with divergences not only in observations but also in their interpretation; this makes adequate presentation in a text-book no easy matter. Fortunately, this problem seems to have been overcome in this book.

It is never easy to arrange for uniform presentation in a book written by numerous authors. In this instance it is clear from the references that not all the chapters were written at the same time; some are two or three years older than others, and this has made the problem even more difficult. Some chapters are rather reminiscent of monographs, while others—elaborated in masterly fashion—uphold the tradition of the high quality university text-books.

The book is evidently intended for science students and graduates who wish to become acquainted with virology or to broaden their knowledge of the subject. It attains its object on the whole, but suffers from the fact that much of it is based on the literature up to 1956 or 1957—only in some chapters are references from 1959 quoted—and that some important publications from the period summarized are not referred to.

These criticisms, however, do not alter the fact that the book is of great value in that it attempts to give a general conspectus of virology, and to integrate all our knowledge of viruses into one biological discipline. There is a chapter on "Viruses in Biocenotic Complexes" which 'enlivens' the whole subject, and also a chapter on "Plant Viruses" skilfully written in an introductory form; similar chapters on animal and bacterial viruses would have been very valuable.

The chapters are well planned, the illustrations are good and the discussion is lucid; there are numerous tables. The indexes are good. What is needed, besides what we have already noted, is further integration of the contents, uniformity of presentation and avoidance of repetition; a chapter outlining technical methods would be desirable. A new edition revised on these lines would be well worth while, and it would be such a good book that a translation into English would be of the greatest value.

J. W. CZEKALOWSKI

VIBRATIONS AND WAVES

An Introduction to the Physics of Vibrations and Waves

By Prof. Norman Feather. (Science and Mathematics Texts, No. 4.) Pp. viii + 330. (Edinburgh: At the University Press, 1961. Distributed by Thomas Nelson and Sons, Ltd.) 30*s.* net.

WITH *Mass, Length, and Time*, Prof. Feather gave us a book which went quite deeply into the foundations of physics, and traced the historical emergence of the concepts; this was for the "beginning specialist" in physics, and the mathematical treatment was elementary. The present volume, based on lectures for second-year honours students who had worked through the previous course, deals with strings and rods and pipes, the propagation of plane waves in an infinite medium, water waves, interference and diffraction, and the wave-particle duality. The mathematics is appropriate to this more advanced level.

The author speaks in the preface of his "unorthodox" approach. This really means that he proceeds by a careful analysis of a number of particular cases, and has selected a limited field for detailed study. Thus, in Chapter 3 on coupled vibrations, he discusses the loaded string, Barton's pendulums, and two interesting experiments by Searle and Wilberforce, and goes very fully into the incidence of damping in a system of limited energy content. Earlier, in considering the dissipation of energy from a vibrating string, he arrives at the logarithmic decrement without benefit of a differential equation. This may be unorthodox, and a fluent mathematician might find it slow; but the average student would, one feels, really understand that he is dealing with a physical process rather than a mathematical solution.

The difficulty of explaining one-way propagation by Huygens's construction is faced but not completely resolved; there is a reference forward from this section to Fresnel's treatment of diffraction, and it is there implied that this is the justification for accepting Huygens's construction. But can one do much more at this stage ?

Inevitably, the book swings over to physical optics in the treatment of interference and diffraction, rather from the point of view of the major historical experiments: and the chapter on wave-particle duality is little more than an outline sketch of the origins of modern ideas. I learned a great deal from the earlier chapters, and found the whole enjoyable to read. Its great merit is that it introduces students to wave-motion slowly and deliberately, and prepares them for the forthcoming dive into deep waters; for it is re-assuringly fathomable and clear.

G. R. NOAKES

ANALYSIS, CLASSICAL AND FUNCTIONAL

Riesz Frigyes :

Ósszegyűjtött Munkái. A Magyar Tudományos Akadémia Megbizásából sajtó alá rendezte Császár Akos. (Friedrich Riesz: Gesammelte Arbeiten.) Elso Kötet: Pp. 1–760. Második Kotet: Pp. 761–1601. (Budapest: Akadémiai Kiado, Publishing House of the Hungarian Academy of Sciences, 1960.) I, II kötet ára: 400,-Ft.

THE publication of the collected works of F. Riesz in two large volumes is due to the Hungarian Academy of Sciences. He wrote in Hungarian, French, German, English and Italian. Of the papers which appeared only in Hungarian, a translation into French is supplied. The tract (1913) "Les systèmes d'équations linéaires à une infinité d'inconnues" is reproduced in Volume 2. (The much longer Riesz–Nagy, "Leçons d'analyse fonctionnelle" (1952) is naturally not reprinted here.)

Riesz was born in 1880 and studied at Zürich, Budapest and Göttingen. Most of his life was spent at Szeged (1920–46) and Budapest (1946–56). Together with Haar he made Szeged a centre of mathematical activity and founded the flourishing journal *Acta Scientiarum Mathematicarum*.

Riesz's papers are classified in this collection under nine headings: topology, real functions, function spaces, analytic functions, harmonic and subharmonic functions, functional analysis, ergodic theory, geometry, miscellaneous. To the first seven of these subjects his contributions were of fundamental significance. He was one of the chief architects of function spaces and functional analysis and he created the theory of subharmonic functions.

Riesz's influence on mathematical analysis is illustrated by his early papers. The Riesz Fischer theorem (*C*2 in the collection) appeared in 1907. The expression of a linear functional operation by a Stieltjes integral $\int f(x)d\alpha(x)$ followed in 1909 (*C*7). We see here classical analysis broadening into functional analysis. Concurrently, Riesz was working at general topology and he formulated in 1908 a set of axioms for a general topological space (*A*8). In 1910 followed the long paper on the class of functions L^p with the notions of strong and weak convergence (*C*10). This fertilization of analysis by topology was due to F. Riesz more than to any one else.

Among the many later papers of major importance which are characteristic of Riesz may be mentioned those on the boundary values of analytic functions (*D*7), the Young–Hausdorff theorems (*C*13) and linear operations (*F*16).

Riesz's papers are models of elegance and deceptive simplicity. The clarity of his vision enabled him on one hand to see existing theorems in different and more general settings and, on the other, to present radically simplified versions of complicated arguments. The reader will find instances in the exposition of the integral (*B*15), proofs of the differentiability of monotonic functions (*B*12, 13) and of some inequalities of Hardy and Littlewood (*B*8, 9), and the work on ergodic theorems (*G*1–4).

The books are a fitting memorial to a great mathematician.

J. C. BURKILL

CHROMATOGRAPHY OF STEROIDS

The Chromatography of Steroids

By Prof. I. E. Bush. (International Series of Monographs on Pure and Applied Biology. Division: Biochemistry, Vol. 2.) Pp. xxi + 437. (London and New York: Pergamon Press, 1961.) 80*s*. net.

THE author set out to link the general theory and background of partition chromatography with the practical aspects of steroid chromatography. He has succeeded. In the first chapter he describes with masterly clarity the basic theory of chromatography, the derivation of R_F and R_M values, the interactions between solvent, and solvent structure, and solute; the effect of chemical structure of simple compounds on their chromatographic behaviour is dealt with fully and numerous examples from the non-steroid field are included. In Chapter 2 a general survey of adsorption and partition chromatography as applied to steroids is given. The extent of the field is indicated by a table that quotes published examples of partition chromatography of steroids. This table extends to 15 pages. In Section 2 of this chapter, the quantitative treatment, based on R_M values, of steroid behaviour on chromatograms is exhaustively developed. The next chapter describes techniques and equipment. No effort is spared to give details that are essential for successful chromatography. A useful and authoritative contribution is a description of the preparation of extracts suitable for chromatography. Chapter 4 is devoted to quantitative chromatography, including colorimetric and radioisotopic techniques. The technique of direct scanning of stained chromatograms occupies, deservedly, 24 pages in which modifications are fully described and possible sources of errors indicated. In Chapter 5, the identification of steroids by chromatography and the procedure for structural analysis is described with commendable clarity. The generalizations in this chapter appear to be well founded and are based on the extensive experience of the author. The final chapter deals with some specific problems, such as chromatography of cortisol in blood, œstrogens and aldosterone in urine, the procedures dealing with conjugates of urinary steroids and fractionation of mixtures of steroids. Since, as the author says, "there is more than one way to skin a cat", the techniques are critically evaluated and guidance given as to the best procedure to be adopted. A useful contribution is in the appendixes that contain technical information necessary for the chromatographist.

Prof. Bush is to be congratulated on having written this massive book that will not only be an important source of information to the expert but also a guide to newcomers in this complex field of biochemistry. The lively style makes easy reading; the print, tables, illustrations and indexes are impeccable.

E. Kodicek

KERATIN

Keratin and Keratinization

An Essay in Molecular Biology. By Dr. E. H. Mercer. (International Series of Monographs on Pure and Applied Biology. Division: Modern Trends in Physiological Sciences, Vol. 12.) Pp. xiv+316+24 plates. (London and New York: Pergamon Press, 1961.) 70*s.* net.

The year 1961 saw the untimely death of Prof. W. T. Astbury, to whose inspiration the development of molecular biology and in particular the study of keratin structure owes so much, and it is fitting that the year should also see the publication of a book on this subject dedicated to his memory. The main ideas of the molecular structure were outlined by Astbury and his co-workers thirty years ago as a result of X-ray analysis and investigation of the mechanical properties of hard keratins, and the extension of the work to the soft keratins so confirmed the similarities at this level that these ideas still form the framework of our theories. The older study of the cytology and histology was well advanced at this time, but the biological and the physical lines of attack were separated by a size-factor of 100–1,000, and it remained for electron microscopy to provide a link between them. During the past 15 years the author has taken a considerable part in forging this link and is well qualified to 'look both ways' into this subject.

In the early chapters he deals with the two lines of attack, partially outlining the physical methods, as well as their results, for the benefit of the biologist and explaining the relevant biological findings for the benefit of the physicist. Unfortunately, this process has produced a lot of forward cross-references which are commendable but irritating. The later chapters are devoted to recent developments, culminating in a discussion of keratinization, and here the author has had a difficult task because of the rapidity of these developments. As a result the treatment is uneven, for example, as between electron microscopy, where much recent work is reported, and the mechanical properties of wool fibres where the work of the Australian school has been neglected almost completely. It seems also that the presentation has suffered because of the necessary haste of writing, and it is perhaps symptomatic of the present state of this subject that the book should end in mid-page, and mid-air, with a sentence in parentheses. However, while this work is scarcely an 'essay' with a steady progression from introduction through development to conclusion, it is to be recommended as a comprehensive review, filling, as its bibliography shows, an important gap in the formal literature.

The reproduction of electron micrographs is adequate, although the descriptive keys for these and the many sketches are not always comprehensive, but the X-ray photographs are marred by poor printing —indeed, they are better printed on the dust jacket, although here mis-orientation gives then a slightly inebriated air.

N. Peacock

THE FATHER OF BRITISH DENTISTRY

Sir John Tomes

A Pioneer of British Dentistry. By Sir Zachary Cope. Pp. ix+108+11 plates. (London: Dawsons of Pall Mall, 1961.) 25*s.* net.

When John Tomes was born in 1815 dentistry was no more a profession than it had been when an ancestral John Tomes of Longmarston, near Stratford, gave a night's shelter to the fugitive Charles Stuart after the battle of Worcester.

The young Tomes, born three months before the Battle of Waterloo, went to the grammar school at Stratford on Avon, and at the age of sixteen became apprenticed to an apothecary of Evesham. At the end of his apprenticeship he came to London to walk the hospitals with the intention of taking a medical diploma. Very soon he became interested in the structure of the teeth and of bone, an interest that led him to the practice of dentistry as a career, and ultimately to his high place in the hall of dental fame as the 'father of British dentistry'.

Though there are many records of Tomes's public life and actions, very little evidence has remained to tell us much of the man himself. Nevertheless, the author, with his great skill and experience as a medical historian, succeeds admirably in this necessarily short account in conveying the essence of Tomes's character. Tomes's inventive and scientific genius led to many contributions to dentistry, including his classical description of the dentinal fibrils, which is reproduced in the book in full and which, as the author says, deserves the designation "classic" more than many writings to which that term has been applied. However, Tomes's greatest achievements lay in the key part he played in the raising of dentistry from the level of a trade plied by any who wished, without restriction or supervision, to the status of an honourable profession.

The record of the struggle for recognition by dentistry, with Tomes always at the forefront, with the 'memorials' to the Royal College of Surgeons, the formation of the abortive College of Dentists, the eventual institution of the Licentiate in Dental Surgery and the passing of the Dental Act establishing the registration of dentists, makes fascinating reading for the dentist or doctor. The book is also sufficiently concise and so well written as to constitute a well-worth-while excursion for the more general reader into, perhaps, an unfamiliar field.

R. B. Lucas

Notes on Operations Research

Assembled by the Operations Research Center, Massachusetts Institute of Technology. Pp. viii+256. (London: Crosby Lockwood and Son, Ltd., 1959.) 30*s*.

THIS book consists of eleven chapters by various authors, and covers the programme of lectures on operations research, given in August 1959 at Brussels, for members of European NATO countries. It starts with a chapter on probability, then one on search, and one on Markov processes. The latter is by Prof. Morse. There are chapters on queueing, control processes, organization, sequential decisions, reliability, information theory, production scheduling and simulation. Several of the chapters are followed by a list of exercises, and there is an adequate bibliography.

This work, modest in price and good from the expository point of view, will make an excellent text-book for courses on operations research. It represents the sort of publication which we should see more of—books which can be used as solid texts for the training of future personnel for operation research, rather than books which merely review or comment on the content of the subject.

L. S. GODDARD

Experiments for Young Scientists

By Don Herbert. Pp. 160. (London: G. Bell and Sons, Ltd.) 15*s*. net.

EACH of the thirteen chapters of this book contains one or two experiments referring to a particular branch of science, together with some brief comments on the work of a scientist in that field—astronomy, physical chemistry, meteorology, zoology, etc. Some good modern photographs are included.

The directions, accompanied by clear diagrams, are easy to follow, but a few of the experiments demand a fair degree of skill for their successful completion; the construction of a barometer using a 'plumber's friend' a rubber plunger, and the illustration of a Gaussian distribution with marbles running to rest down a bagatelle-type board, are two cases in point. The making of a microscope using a bead of water as a lens could be less elaborate, but the details given would appeal to the mechanically minded boy. Some of the other experiments are very simple, and the general level of the book is for the young person coming into first real contact with scientific matters. The style of the American author is pleasantly informal, and the elements of scientific method are unobtrusively emphasized throughout.

The book should find its best use in awakening interest and providing a useful starting point from which an absorbing hobby or professional interest could develop.

D. C. PRICE

The Nerve of Some Animals

By Robert Froman. Pp. 250. (London: Victor Gollancz, Ltd., 1961.) 21*s*. net.

THIS book is a collection of true incidents about certain animals that can be found in the American Continent—namely, the wolf, mustang, mountain lion, buffalo, coyote, beaver, llama, bear, jaguar, rat and dolphin.

It is the belief of the author that in all species there are far greater variances between individuals than is usually realized. Therefore, many of the animals mentioned do not conform to generally accepted ideas and theories on pattern behaviour, and are not necessarily typical of their species. All show relentless spirit and unfailing nerve in dealing with particular problems. For example, there is the wolf that defies all attempts at capture; the mustang that resists every would-be rider; the friendly dolphins that adapt themselves to befriending man.

The book will appeal to a wide range of people. Each chapter reads as an interesting story, or group of stories. At the same time, much information is gained on the history, habitat and environment of the animals. There are many surprises and contrasts, made all the more fascinating by dealing with the exception rather than the rule.

B. J. G. MAITLAND

Government and Science

Their Dynamic Relation in American Democracy. By Don K. Price. (Galaxy Book, No. 72.) Pp. ix+203. (London and New York: Oxford University Press, 1962.) 10*s*. 6*d*. net.; 1.65 dollars.

MR. PRICE'S penetrating study of Government and science deserved a reprint, but it is a pity that after eight years it should have been reprinted unchanged and without addition of either index or bibliography to repair the two conspicuous defects of the first edition. In the interval the relations between Government and science in the United States have somewhat altered and a bibliography would have helped to keep the book up to date without significant revision of its two most valuable chapters on the machinery of advice and the structure of policy. A bibliography, moreover, could have extended its appeal and relevance to the British reader.

R. BRIGHTMAN

The Moon

A Complete Description of the Surface of the Moon, containing the 300-inch Wilkins Lunar Map. By Dr. H. Percy Wilkins and Patrick Moore. Pp. 388+15 plates. (London: Faber and Faber, Ltd., 1961.) 63*s*. net.

SINCE its publication nearly seven years ago *The Moon* has remained one of the greatest accomplishments of modern amateur astronomy. Containing a reduced form of Wilkins's lunar map and comprehensive descriptions of all named lunar formations this book far surpasses the previous similar works by Elger and Goodacre in describing the intricacies of the lunar surface.

In the new edition Moore has aimed at bringing *The Moon* more into line with contemporary developments. The Soviet chart of the averted side of the moon has been included, together with short explanatory comments. Descriptions are provided of the few additional named formations the names of which had not been assigned at the time of the first edition.

The major part of the book, the description of lunar features, has not been significantly changed from the first edition. The only major alteration is in the description of the crater Alphonsus, which now contains a mention of Kozyrev's reported outbreak near the central mountain of this crater. It is a pity that the text could not have been more thoroughly overhauled as a very large amount of work has been carried out by amateurs all over the world since the original publication date. As it stands, the text is rather inhomogeneous; it often contains elaborate descriptions of insignificant pits and craterlets and omits detailed description of the more important topographical features.

BRIAN WARNER

THE CHANGING SCENE IN UNIVERSITY EDUCATION

By PROF. F. C. STEWARD, F.R.S.
Cornell University, Ithaca, New York

WITHIN the life-time of anyone now in his mid-fifties, universities have been subject to radical change. This is particularly true in science. The impact of two World Wars and the increasing dependence of modern society on technology have played their part. It is safe to say that the pressures in the future are to be even greater, if the universities of Britain and the United States are to meet the needs of their respective societies for educated and trained personnel. In both countries expansion is essential. In the United States the pressure is to meet the vociferous demands of an increasing population. The already high percentage of the population which either submits to, or profits from, higher education must continue to do so, or this percentage may even need to be increased. In Britain the pressure is to close the gap between the two countries and to pass a much larger percentage of the population through the universities than hitherto. In the United States existing university establishments will be and are being expanded and their resources strained; in Britain the slow trend to increase the number of universities by conferring university status on a number of pre-existing institutions will now be accelerated by creating a somewhat surprising number of new universities. All this presupposes that in the past only a few of those in the population who were fitted by genetics, by interest and by motivation to profit from a higher education were in fact able to receive it and to reach the highest levels of their capability. One suspects that these untapped scholastic reservoirs, which are obviously calculable, are not as great as are often supposed. In all this somewhat phrenetic activity to increase the quantity of university education the important question is: What is to happen to its quality ?

These observations come from one who has spent about half his career in the universities of Britain and the other half in the American universities, and who happens to believe that if each system can learn from the other the ideal might not be far to seek. Thus, as Britain expands its university system, it is well to be alert to some of the warnings, as well as to the stimulus, that may come from the United States.

One may ask first, what is the distinguishing characteristic of a true university ? Size alone does not suffice, and age and tradition may enrich or enfeeble a university community. There is perhaps no generally acceptable answer to this question; but the often very different character of universities in Britain and in the United States suggests that the answers, if formulated, would in the past at least have been very different. The university is clearly not and should not be merely an enlarged school, in the sense that school is the proper place where students acquire general, and often their terminal, education. Similarly, the university is not and should not be only a trade school to supply a flow of trained, but not necessarily creative, personnel to industry. Ideally, the university should still be the guardian of standards of scholarship in a world preoccupied with the superficial things; in this competition the university should provide the environment and the way of life in which the knowledge inherited from the past is not only disseminated but also, more important, is extended by scholarly research. Universities are first places where knowledge is sought; schools where it is taught. While in a measure these ideas would be approved in most universities, it is the degree of emphasis given to them which has imparted to universities in Britain and in the United States much of their respective characteristics.

In the United States, and in the past, the general education achieved in the schools fell short—often far short—even of those which were generally deemed necessary for a terminal education. Therefore, in that country the average university undergraduate curriculum has had much more of the character of a school than its British counterpart. Conversely, because in the past the British school was, rightly or wrongly, believed to furnish a sufficient general and basic education, except for fields of specialization, the British university became primarily a place for specialized study and training. (One went 'up' to the university from the school, whereas the American student continues to go to 'school' throughout his university life.) But the difference is deeper than this. A general education in a given area of subject-matter for large masses of the population can only be provided in a standardized way and cannot be given solely by those engaged in scholarly or creative work in these fields, for there simply are not enough of them to go round. Hence, in the United States more than in Britain, much undergraduate instruction has tended to become routine, and the prerogative of teachers who may not be productive scholars and for whom teaching is an end in itself. Thus, effective contact of the student with the more creative aspects of his subject, or subjects, is normally deferred until postgraduate work. (There are, of course, notable exceptions, especially in some of the smaller and private institutions where personal contact between a research-minded staff and their students is decidedly more intimate.) Thus, the undergraduate tuition in most of the large American universities has assumed more and more of the traditional role of the school, in that it imparts information over a broad front rather than fostering understanding and ideas in a limited area. In turn this has, inevitably, had an effect on the postgraduate schools which, by British standards, have become almost frighteningly large. One has had the experience of lecturing in the United States to much larger groups of graduate students studying for the Ph.D. than the number in a British university who might be reading even for the honours degrees. These are, therefore, two different ways of achieving what may be the same ultimate goals.

In Britain it was largely between the two World Wars that the Ph.D. became a natural sequel to the bachelor's degree. In practice, however, the relatively few who embarked on this very specialized road were believed to be already equipped by knowledge and training from their bachelor's degrees with honours to do original research for the doctor's degree. In the United States, however, the shortcomings of the great variety of bachelor's degrees, which qualified so many candidates for entry into the graduate school, needed to be met by courses which, even at the graduate-level, again communicated information. Thus, even the Ph.D. became at least in part a degree for which a student was 'taught' rather than being trained through the medium of original inquiry. Therefore, what happens to the school curriculum inevitably changes the face of the undergraduate university, and what happens to the undergraduate determines what sort of higher postgraduate education he may receive, the kind of work he may do and the degree of maturity he may reach. Thus, as new universities spring into being, care should be taken to preserve those values that have contributed to the essential quality of the distinctively British higher education.

Among these values the integrity of the honours schools in the universities should rank high, and this should be preserved against all the pressures for more general training for more people. Unless the system of selecting able students has in the past been completely inefficient, it is inevitable that as more students enter the university there may not be a proportional increase in those able to reach the highest standards; and, at a distance, one wonders whether the standards of the honours degrees have not, in consequence, already suffered. It is sad, but true, that whenever the appeal is to process numbers the standards go down, and when this insidious decline begins at one level in the school, the undergraduate curriculum, or the postgraduate school, it has repercussions throughout the rest of the system.

There is obviously a very subtle balance between having quality on one hand and size and quantity on the other: it is very difficult to have both. The great advantage of the smaller universities is that, for them, undiluted quality is more attainable.

In the United States, with its different standards of democracy, there has always been, and no doubt will continue to be, a greater respect for numbers; the United Kingdom, at least in the past, has laid the emphasis on quality. As the winds of change blow through the British universities, their obvious problem is to retain their quality while they produce more in quantity; the problem in the United States is more often to regain quality and standards without indefinitely prolonging the education of the able few into ever-lengthening Ph.D. courses and post-doctoral training. The latter is now almost as common as the ubiquitous Ph.D. When standards are lost at the lower levels, courses of university postgraduate instruction may be diluted and prescribed study is unwholesomely prolonged. Indeed, the most creative years of many a student in the United States may, even now, be spent in learning his subject from others instead of becoming a practising scientist or a scholar. This takes so long that the zest for discovery may be quenched, and often all that is left is to teach someone else how to learn to do the same in even longer time.

If even a fraction of the present annual crop of Ph.D.s in the United States (10,500 in 1960–61, of whom at least 45 per cent were in the physical and biological sciences) retained any real contact with creative work, it would seem that even this addition to the already large body of trained research personnel (*American Men of Science* in the tenth edition will list about 100,000 names in the physical and biological sciences and 24,000 in the social and behavioural sciences) should equip the United States to solve almost any scientific problem. But these are measures of quantity: they have little bearing on quality. When outstanding abilities are needed, an infinite number of the merely competent will not suffice. As universities are being 'tooled-up' to more quantity production of graduates, they should, above all, preserve the milieu in which outstanding ability may flourish and be recognized.

It is true that the British graduate, and even the British Ph.D.s, were often not as mature as the system supposed. Thus, both postgraduate courses of study and even post-doctoral training can be usefully, if judiciously, interpolated into the existing system. But the dangers of doing this at the cost of the essentially research and original character of the work for advanced degrees should be guarded against; higher degrees earned very largely by undergraduate techniques of study, as may too often occur in the United States, should certainly not be encouraged. In fact, one of the outstanding problems in the ever-increasing American graduate schools is to bring the students to an adequate state of preparation for research in their field without making them into perennial undergraduates. The formal graduate courses that need to be taught to achieve this should be quite different from courses in the undergraduate school; the first should not merely be an extension or enlargement of the latter, as they too often are. Instruction as it is, or used to be, offered in a British honours school may be a better model here.

As new universities come into being, they may well be, at first, ill-equipped with research resources and productive research scholars on their staffs, for the supply can scarcely be equal to the increased demand. The obvious temptation will be to stress teaching through courses and not through creative work; but if this practice were to be widely adopted in a seeming imitation of a pattern often found in the United States, it could easily undermine the chief strength of the British system. Obviously, what is needed to-day are larger numbers educated to a higher general level, and particularly more of the skilled technicians that industry and a technological society needs. If, to meet these needs, all this extra traffic is passed through the university, this may threaten its chief strength, for creativity, scholarship and research may be submerged beneath the need to impart information and to teach skills. Special steps should be taken to guard against this outcome.

But perhaps another consequence of size and numbers is not always appreciated in Britain. While a minimum size is necessary to give a university the balance and diversity it needs, excessive size often leads to a separation of instruction by teaching and through scholarly research. As the communication of information becomes an end for larger and larger numbers, teachers and research scholars become separately identified; they are more rarely found in the same person. Moreover, as departments become larger, staffs more specialized, rarely are scholarship and knowledge so comprehensive as they used to be. Since numbers of students sway administrative policies, it is a short step to the predominance and ascendancy of a teaching cult rather than of a creative, essentially scholarly outlook in the policy-making of the universities. Anti-intellectualism is not unknown even in the university itself, and there is no surer way of engendering this than the fostering of a teaching staff which is divorced from creative scholarship and research; and this happens all too easily under the pressure of numbers and large classes. With the increasing support for research and the need for larger and more specialized research teams, it is often the case that teaching and research lose their essentially complementary nature and even university faculties become divided on their relative importance. (One may note that it is wise to locate, wherever possible, such essential research functions as those which are supported by the Agricultural or Medical Research Councils or the Department of Scientific and Industrial Research in selected units which are placed alongside and affiliated with the universities. These arrangements undoubtedly enrich the universities by contact with a highly specialized research staff, but they also help the research worker. This happens by keeping the research investigator in some contact with the teaching profession and with students, and even by providing him with an otherwise much-needed opportunity to expound his speciality in the class-room with consequential benefits to the quality and range of the research done.)

There are, however, two important safeguards in the British system which should be jealously guarded; one is academic, the other is administrative. First, the external examiner system (virtually unknown in the United States) should prevent any university, school or department from too blatantly 'branding its own herrings'. The second is inherent in the very different concepts of university administration in Britain and in the United States.

The average American university runs like a corporation; and the trustees, like a board of directors, either collectively or in executive committee, make over-all policy. The president of the university, like the board chairman of a corporation, 'runs the show'; and often the chief finance officer, by exercising the power of the purse, exercises influence even over academic policy. A whole 'chain of command' also, often of erstwhile academicians, become professional and career administrators, carry the administrative policy down to the lower levels via vice-presidents, deans, assistant deans, directors of this and that, and often heads of departments, the last-named often being selected more for their performance of routine administrative chores than for their mastery, or direction, of an area of academic subject-matter. By contrast, the senate of the average British university, stuffy or conservative though it may sometimes seem to be, at least places the destinies of the university in the hands of those who, if any, are dedicated to the preservation of its academic and scholarly values, and who do not, or should not, mistake or glorify the organization at the expense of its objectives. In Britain, fortunately, there has been much less vested interest in university administration than in the United States.

As universities expand in Britain, both in number and size, there may well be a trend to create more and more organization, with the inevitable dichotomy between administrative and academic functions; it is this dichotomy which often creates problems in the average American university and results from the way it is administered and the way it has grown in size and in complexity. It is often difficult for those in American universities to realize that one rarely used to hear in Britain about difficulties between the 'faculty' and the 'administration', for in very large part the senior faculty of a British university really administers the university. The corporation, on which the American university is so closely modelled, may be judged by a balance sheet, and similarly the American university by its buildings, its endowments, its numbers of student body, of graduates, etc. But these are all criteria of quantity, not quality. Though necessary enough in a modern society, they need to be tempered by some criteria that measure whether the university of to-morrow will continue to create the milieu in which discoverers are nurtured and discoveries are made; discoveries like those of chromatography or the advances in the ultra-structure of large molecules like hæmoglobin and deoxyribonucleic acid (to mention but two distinctively British advances). Where shall these ends be met if not in the university or its immediate environs ?

Moreover, in times of crisis, numbers alone rarely suffice. A relatively few aircraft and pilots of superior quality saved the country in the Battle of Britain; probably an equally good case can be made for the relatively few highly able scholars and scientists, who in radar, anti-submarine activities and numerous other ways also played a decisive part. The one remaining natural resource is the British reservoir of brains; this should be jealously guarded. If it is an avowed objective to increase the quantity of scientifically trained personnel, the university system should not be geared to this end alone in ways that retard, or reduce the role of, those few with the outstanding qualities on which progress really depends. It should be remembered also that the American system has, at least in the past, been able to recruit heavily from the countries of Europe and thus acquire, ready trained, people with unique knowledge or attributes; Britain presumably must grow her own, even enough to compensate for the inevitable losses to the United States. The American university, especially the larger State ones, often tends to work on a pattern that reflects the American concept of democracy, and it therefore tends to treat all alike, at least in theory. There are many reasons, however, for the belief that to attain its highest standards and developments, a university cannot conform to this idea of democracy, for it must be an autocracy, or oligarchy, of scholarship. Otherwise, the larger the percentage of the population that passes through the university, the more it will come to represent an average intellectual sample of the whole. Obviously, however, the real strength of the university is not with the average, but with those who are far from the mean at the extreme of the distribution curve of ability.

Perhaps some of the new universities of Britain should take on something of the role of the junior colleges of some American States, and the older and more expensively equipped centres provide more for advanced studies and scholarly research and discovery ? But can any new university continue to assume indefinitely what will seem to be a secondary role ? Will not its staff begin to feel that they are academically second-class citizens ? Moreover, with more centres of advanced education and more departments of this and that, the total resources available for the support of scholarly work, without which these new universities cannot fulfil their true function, will prove increasingly inadequate. In fact, one may ask whether all universities really need to offer all courses of study, for there might well be a measure of specialization with resultant efficiency. (If all the new universities are to have, for example, a department of botany, they can at least develop different aspects in agreement and at the advanced level make their specialists available to each other. Otherwise there will simply not be enough qualified people to go round, at least for some time to come.) It seems inevitable, however, that the existing governmental sources to support research and advanced study in science will need to be vastly enlarged to nourish, on something approaching the American scale, the greatly increased numbers of academic personnel who will be engaged in university work—otherwise most of these will be condemned to the uncreative imparting of information which is the proper function of the school, or the trade school, and is not the role of a true university. Some may wonder whether the governmental largess to support research in the United States, at least in science, is always as wise as it is lavish. However, the fact remains that single American investigators may now receive funds that in the recent past would have had to suffice in Britain for a whole department or a major school of research. Admittedly, money cannot, and does not, purchase creativity; but the ideal must surely be somewhere between the two systems.

On the American scene, it is an ideal combination when the unrivalled resources of the United States for research and the advancement of knowledge can be used in the truly creative fashion which is more often fostered by the training in the universities in Europe. On the British scene, the goal should be that resources more nearly on the American scale should be made more generally available to those university scholars with proved ability to utilize them effectively. Thus, without vastly increased funds for the support of research, an increase in the number of universities and in the volume of students may not result in a proportionate increase in the fully qualified personnel that the university should produce nor in the rate of that advancement of knowledge on which industry and technology will ultimately depend.

Another topic is also relevant; this is the proper place of the 'applied' rather than the 'basic' studies in the modern university—new or old. Such essentially applied disciplines as medicine or engineering and many aspects of technology find a proper place in the instruction offered by the universities of to-day; but there is a real question, which the newer universities of Britain will need to face, to determine how far they need to, or should, go in the direction of technological instruction. The more subtle point is, however, to determine what part of the applied discipline is a proper subject for a university education or a degree.

This is a sensitive subject, especially in the United States, where the professional and technical schools are so strong and where there has been a tendency to proliferate university education into all manner of applied areas. Obviously, however, the university should not do what the industry can do better, or the profession by 'on the job' training. It is a needless dissipation of the resources of the universities and an unwise use of their limited effect on youth in the formative period to allow departments or colleges to become so pre-occupied with the problems peculiar to a trade or profession that they cease to make scholarly contact with other branches of learning. Thus, the role of the university should be to bring to all technological disciplines within its shelter the resources of academic personnel who will, within its area of subject-matter, make scholarly contributions to knowledge which can be recognized as such by those in other branches of learning. As soon as the work of the applied department becomes so obsessed with developments from existing knowledge, with screening tests or with other aspects of commercial operation (as may so easily happen in response to the pressure of industry), then the question should be asked whether this type of activity is not more proper for industry or the technological research institute.

In other words, it is only in as much as the applied disciplines add to basic knowledge, which may be recognized as such by those outside the particular technology, that they are suitable areas of university study or of work for advanced degrees. But when this is not so and when they become pre-occupied with the affairs of the industry they represent and become, in effect, 'trade schools', their continued presence in the university system ceases to be a source of strength and may even become debilitating.

One may note here that it is generally unwise to place basic areas of subject-matter under the control of an applied discipline to which they relate. Mathematics obviously should not be controlled by engineering, biology by medicine or agriculture, chemistry by chemical engineering, etc. When this happens, the basic subject assumes a service role to the technological department. This is bad for both, for development tends to loom larger than basic research. The newer universities in Britain, as they spring up to meet the needs of an increasingly industrial and technological society, will need to be protected from these hazards.

Obviously, neither system—British or American—has a monopoly of wisdom. In fact, individual variations in each country make it perhaps unwise to speak of characteristics which define either system. It is, however, interesting to note how in our time the two countries adopted from the German universities the idea of the Ph.D. degree and of more general postgraduate education than either had previously practised. From the same roots very different structures have grown. One could feel sure, however, of the future of Western scientific education if there were more signs that some of the best features of both systems—British and American—could now be blended. On balance, however, the Ph.D. degree seems to have fared better academically in Britain than in the United States, where it has become the essential status symbol for entry into a profession, or as a qualification for a post, merely because the bachelor's degree has lost its significance in this regard. In the United States, however, even the Ph.D. ceases to suffice, and postdoctoral training is now the vogue. One may wonder how many of the annual, and increasing, crop of Ph.D.s, produced in the modern quantity really do become the 'practitioners of the love of learning' which the symbols of their degree imply. Or are the Ph.D. degrees like the 1962 mass-produced cars: temporarily useful, but with their own brand of inevitable 'build-in obsolescence' like the rest of the products of mass production ? Especially at the levels of the graduate school, the supply of scholars cannot be turned on and off at will, and numbers here are no substitute for quality of training. Unless the university student is brought to a sense of the historical development of his subject, he cannot really understand its present; unless from this he gains a sense of philosophy, he cannot hope to anticipate its future. If to achieve mere quantity of trained personnel, technically equipped to meet the needs of the moment, these essential values are lost, the price to be paid is too high. The hope is, however, that the university training, like other products that bear the symbol 'Made in Great Britain', shall continue to stand first for quality, however much pressure there may be to yield, in competition with the United States and the U.S.S.R., to the need for quantity production of university graduates.

This article is obviously and admittedly written mainly from the point of view of science. Few men of science are to-day unaware of the need to foster the humanities, especially as so much greater support now comes to the aid of science. The more alarming trend, however, is not toward an imbalance between the humanities and the sciences but rather between the basic, fundamental or creative studies on one hand and the applied or technological subjects on the other. Contributions which are made through the application of knowledge, that is by development without necessarily making any ultimate additions to knowledge, can readily be dramatized. For this reason these functions can be, and should be, left largely to the industries that will profit from them or to their technological research institutes. The limited resources of the universities should, however, be fully geared to the work for which they alone provide the proper milieu which fosters the creativity on which the flow of new knowledge depends. It will be interesting to see how successfully the universities in Britain can be preserved for this function, while they respond to the inevitable pressure to produce greater numbers of graduates as in the United States.

OUTER VAN ALLEN BELTS AND NEUTRAL POINTS ON INTERFACE BETWEEN SOLAR WIND AND GEOMAGNETIC FIELD

By Prof. C. C. CHANG
Aerospace Corporation, El Segundo, California

ALTHOUGH many contributions[1-3] have been made to the nature and origin of Van Allen belts, the mechanism of trapping high-energy particles from solar wind in the outer belts is still not understood. This article suggests a physical model of such a trapping mechanism.

Beard[4] obtained analytically the interface between the steady solar wind and geomagnetic field (essentially being a vacuum, the region is called hollow), with some approximate boundary conditions. The general features of the interface, although approximate, are consistent with the exact two-dimensional theory[5-7]. Beard's theory was recently generalized to some other geomagnetic orientations by Spreiter and Briggs[8]. One interesting result of their calculations yields a pair of neutral points (called N-1 hereafter), on the interface or discontinuous surface between the plasma of solar wind entirely on one side and the geomagnetic field entirely on the other, as shown in Fig. 1*a*. They are located opposite to the geomagnetic poles, each leaning about 19° with vertical polar axis toward the upstream of the horizontal solar wind. This type of singularity on a discontinuous surface is new in mathematical physics. Its instability and physical significance have not yet been recognized. Some features will be discussed here qualitatively. On the other hand, Aström[9], Dungey[10,11], Chapman and Akasofu[12,13], and Grad and Norton[14] studied the particle trajectories and plasma instability near another type of neutral point (called N-2 hereafter), which lies entirely in a continuous magnetic field. The N-2 point is a mathematical saddle point. There is some similarity between the two types of singularities, as shown in Fig. 1*b*. Their treatments can be interpreted to shed some light on the nature of the new type of singularity.

Trapping Mechanisms of Charged Particles

With the Chapman–Ferraro model of particle specular reflexion of solar wind on the interface, it has been shown[8,15,16] that across the interface, magnetic pressure $\frac{H^2}{8\pi}$ or the equivalent effect of surface current sheath J balances to approximately one-half Newtonian dynamic pressure $mnv^2\cos^2\psi$ as follows:

$$\frac{H^2}{8\pi} = 2\pi J^2 \approx mnv^2 \cos^2\psi$$

Here m is assumed essentially the mass of one proton, and n is the number of electrons or protons in the

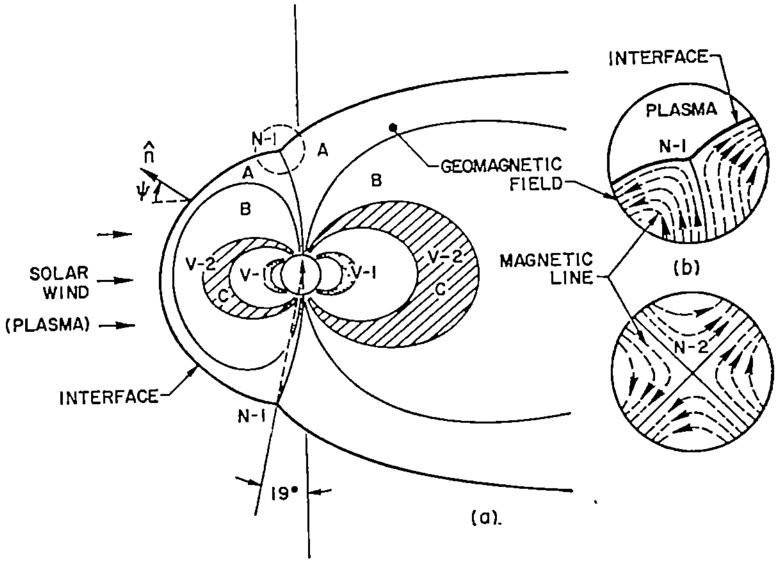

Fig. 1. *a*, Two neutral points (N-1) on the interface between solar wind plasma and geomagnetic field. Orbit zones A, B, and C in the hollow and Van Allen belts are also roughly indicated. *b*, Comparison of types of neutral points, N-1 and N-2

neutral plasma stream, which possesses a horizontal constant velocity v at an angle ψ with the normal n to the interface surface, as indicated. The magnetic field H can be shown to be parallel locally to the interface. At N-1 points, $\psi = \pm \frac{\pi}{2}$. Consequently, both $\frac{H^2}{8\pi}$ and J have to be zero. Near each N-1 point, the magnetic field has to be very weak and non-homogeneous (Fig. 1*b*) and energetic protons and electrons of the solar wind can penetrate much deeper into the hollow. Furthermore, the trajectories of these particles are non-adiabatic[14] and somewhat irregular because of drifting through field gradient and curvature. Thus, they become trapped instead of reflecting back to the solar wind, as conceived before[4,13,15]. In other words, the interface has two local weak spots of the geomagnetic field near the N-1 points, through which charged particles can seep into the hollow instead of undergoing total reflexion.

As the charged particles are trapped inside the geomagnetic field, three possible trajectory zones, A, B and C, in the hollow can be classified according to their locations, which are related to the N-1 points and the adiabaticity of particle magnetic moments. In zone A, the particle trajectories are at some instants very near to the N-1 points, unstable, and highly non-adiabatic[14]. As soon as many charged particles leak continuously into this zone, their accumulations and orbital motions demagnetize and weaken the field further. Three consequences arise: (1) The leading regions near the N-1 points are enlarged and more plasma from solar wind can be trapped in zone A. (2) Some of the particles diffuse into neighbouring zone B, according to Fick's law of diffusion on particle concentration gradient[17]. (3) The mirror reflexion points of each orbiting particle along a magnetic line move closer to geomagnetic poles. Some of the particles may possess sufficiently high velocity components along the magnetic lines to penetrate deeply into the atmosphere and become lost through colliding with low-energy hydrogen atoms and other species. The resulting ionization phenomena will first be observed as auroræ in polar regions[12]. In zone B, the particle trajectories are slightly non-adiabatic and the magnetic moment can change[14] to the order of 20 per cent or less during one round trip reflecting between the two mirror end-points of the geomagnetic poles. If too many charged particles crowd in zone B, some may similarly diffuse into zone C. In zone C, the particle trajectory is practically adiabatically invariant, and the particles are trapped for a long period between mirror reflexion points, until charged particles are accumulated excessively. This accumulation weakens the magnetic field further and some particles are finally also lost with the auroral display. In the case of exceptionally strong solar wind (10^3–10^4 particles/cm.^{3}), they can diffuse even beyond zone C, as identified from some aurora seen in Mexico[12]. In short, with the mechanism described here, the solar wind particles can leak into the hollow of the geomagnetic field passing through a cascade of feeding processes into the above different zones. It is estimated that zone C is the region of the second Van Allen belt (V-2). Zones A and B may be the region of the third Van Allen belt[3,12].

Mechanism of Boosting Particle Energy

Now we can investigate the possible mechanism of boosting up the energy-levels of the trapped particles in the outer belts. According to Teller's principle[18,19] of interchange (flute) instability in plasma physics, it is briefly stated: the plasma region is stable against disturbance, if the curvature of the boundary or interface next to the magnetic field is concave, and unstable if convex. In the present case, stream plasma interface is concave everywhere, except convex in the vicinity of the N-1 points. Therefore, the N-1 points and surrounding areas of interface are unstable, while the main portion of the interface is stable. The interface, being parallel to the magnetic field, possesses surface tension. The combination of the interface and two N-1 points act mechanically as a springy elastic membrane with two holes leaking plasma. The membrane-like interface is supported by plasma dynamic pressure outside and geomagnetic pressure inside. In case of a pressure disturbance, there is always an interplay among the two pressures and surface tension in the interface. The N-1 points, and neighbouring unstable areas of interface, start to move out of place, but the remaining stable interface resists moving along with them. The spring action in the interface and the pressure disturbance cause the local oscillations to travel continuously up and down with the N-1 points (Fig. 2).

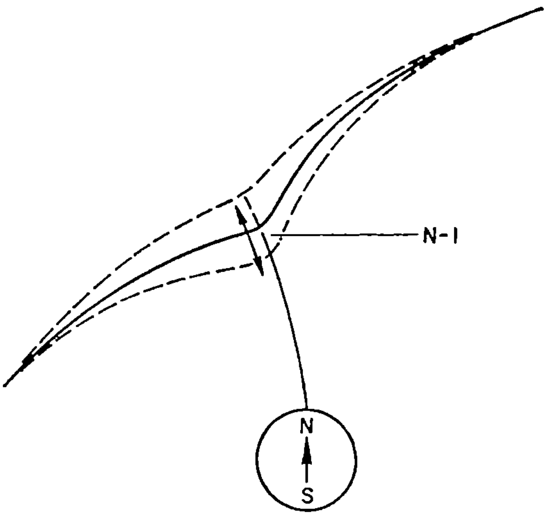

Fig. 2. Probable interface oscillation region near neutral point N-1 due to instability (exaggerated scale)

The two N-1 points, although unstable and oscillatory, always appear on the interface, so long as solar wind is present. This is quite different from the instability of N-2 points. The N-2 points move farther away with time from initial position and may finally collapse[10,12]. The fields in the two geomagnetic polar regions act as oscillatory magnetic mirrors or pistons to accelerate the charge particles. The locally oscillating interface will alternately compress and relax the geomagnetic field and thus induce magnetohydrodynamic waves in the hollow. The period of the magnetic fluctuation is much smaller than the period of the particle trajectory between the two polar regions. Therefore, the longitudinal invariant of particle trajectory is no longer valid as pointed out by Northrop and Teller[20]. This scheme of generating magnetohydrodynamic waves may be related to the so-called Fermi mechanism accelerating electrons in the outer Van Allen belt as discussed in Parker's theory[21]. As the interface oscillates, the plasma particles in the solar wind also reflect an uneven rate, thereby inducing plasma oscillation in the solar wind.

These oscillatory mirror fields can step by step transform the low-energy particles (proton energy ≈ 20 keV., electron energy ≈ 2 eV.) (ref. 12) into higher energy-levels, passing succeedingly through zones A, B and C of the outer Van Allen belts. The energy-levels in the second Van Allen belt is not known exactly. Some recent measurements gave the estimated values of proton energy ≈ 1 MeV. and electron energy ≈ 40 keV. This process of stepping up particle energy-levels is consistent with the observations reported by Jastrow[22]. In other words, a part of the kinetic energy of the solar wind feeds to the interface: (1) to maintain the oscillations of the N-1 points and local interface; (2) to create the magnetohydrodynamic waves, which boost the energy-levels of the trapped particles higher and higher in succeeding zones; (3) to induce plasma waves in solar wind.

The existence of solar winds and the interface seems to be confirmed by recent measurements of the United States Satellite *Explorer XII*; but the local oscillations of the interface and existence of magnetohydrodynamic waves have not been verified. It will be of scientific interest to have satellite measurements checking the above postulations.

Helium ions, being abundant on the Sun, are also likely to be trapped in the solar flare and wind. They can leak into the hollow through vicinities of N-1 points by a similar process. This may be the main source of atomic helium zone recently found between zones of atomic oxygen and atomic hydrogen of the magnetosphere[22], although the amount of helium released from decaying radioactive materials in the earth should also be considered.

Conclusions

In conclusion, the two N-1 points are believed to be the key mechanisms of trapping high-energy particles in the outer Van Allen belts. Their neighbourhoods allow the solar wind plasma to seep into the geomagnetic field without reflexion. Their instability causes the connected interface to oscillate locally, inducing magnetohydrodynamic waves, which increases the energy of the trapped particles in succeeding steps to much higher levels. Even when the solar wind is not steady, the above conclusions are expected to be valid, except the interface may change its position. Furthermore, those mechanisms of trapped particles and boosting energy become more effective.

As a result of Prof. S. Chapman's lectures, I was inspired to further study of this problem. I thank Drs. L. Davis, R. Jastrow, S. F. Singer and E. Smith for private discussions. I also thank Drs. C. F. Curtiss, R. Huddlestone, L. Johnston, V. Josephson, R. Meyer, F. S. Mozer, G. A. Paulikas and A. R. Sims for criticisms and valuable discussions. This work was performed under the auspices of the U.S. Air Force through Deputy Commander, Aerospace Systems Air Force Systems Command.

STIMULATED EMISSION OF RADIATION AND ITS PRACTICAL APPLICATION TO MASERS AND LASERS*

By PROF. R. A. SMITH, C.B.E.

THE realization that light is a form of electromagnetic radiation must be regarded as one of the most outstanding consequences of Maxwell's theory of the electromagnetic field. On many previous occasions it had been postulated that light is a form of wave-motion, but no one had dared to suggest what was the quantity that varied in the motion. The experimental verification by Hertz of the existence of electromagnetic waves in what is now known as the short-wave region of the radio spectrum was indeed a triumph since this was a phenomenon which had not previously been observed. Light was, however, familiar to all, and an explanation of its properties in terms of electromagnetic waves gave a 'new look' to a familiar phenomenon. It was mainly measurements in the infra-red, for example by H. Rubens *et al.*, which showed that the theory could account quantitatively for a number of observations such as the reflectivity of metals.

The initial success of the electromagnetic theory of light was, however, short-lived, and it was not long before it was in very serious difficulty. The new century had scarcely begun when the first major trouble arose in connexion with the spectral distribution of the light from a glowing black-body. The spectral intensity has a marked peak at a wave-length which depends on the temperature, whereas an application of statistical consideration to the wave theory shows that the intensity should increase indefinitely towards the short-wave end of the spectrum. This would lead to what was known as the

---

'violet catastrophe'—radiation would tend to have shorter and shorter wave-lengths. This difficulty was overcome by Planck by introducing the assumption that radiation can exchange energy with atoms only in discrete amounts or quanta. The quantum of energy exchanged at frequency ν has a value $h\nu$, and was, as a result of the work of Bohr, shown to be equal to the energy difference between two allowed atomic levels of energy E_1 and E_2, so that if $E_2 > E_1$:

$$h\nu = E_2 - E_1$$

This quantum hypothesis led also to the explanation of many other phenomena, such as the photoelectric effect, in which the energy given to an electron depends on the frequency of the incident light and not on its intensity—an observation which is very difficult to explain in terms of a wave theory of light. A tendency grew up to regard light quanta as like billiard balls flying through space, but one was never quite able to forget the wave nature of light as evidenced by the beautiful interference phenomena which it exhibits. It was not until the arrival of the new quantum mechanics and the Uncertainty Principle that the duality of light in having both the properties of waves and of particles was appreciated. Prof. R. E. Peierls has described not only the similarity of light quanta and electrons but also their essential difference, in this connexion.

There are a number of phenomena in which both the wave nature and particle nature of the light must be appreciated. If we regard a light beam as a stream of 'classical' particles each carrying energy $h\nu$ so that the mean number passing a point in the beam in unit time is n we may calculate the fluctuation $\overline{\Delta n^2}$ in this number. It is given by $\overline{\Delta n^2} = n$. The fluctuation $\overline{\Delta W^2}$ in the light power W is thus given by $\overline{\Delta W^2} = h^2\nu^2 \, \overline{\Delta n^2} = h\nu \, \overline{W}$ where W is the mean power. If, however, we regard the beam as made up of a number of modes of wave motion and calculate the power, assuming each mode has energy given by the classical equipartition law, namely kT, then it may be shown that the fluctuation $\overline{\Delta W^2}$ is given by $\overline{\Delta W^2} = kT\overline{W}$, where T is the absolute temperature. A correct quantum mechanical calculation, on the other hand, gives:

$$\overline{\Delta W^2} = h\nu \, \overline{W}\left[1 + \frac{1}{e^{h\nu/kT} - 1}\right]$$

The first term corresponds to the fluctuation given by the particle picture and is the dominant term when $h\nu \gg kT$; the second term is dominant when $h\nu \ll kT$ and then reduces to $kT \, \overline{W}$. It therefore corresponds to the fluctuation given by the wave picture. An interesting alternative interpretation of the fluctuation can be given in terms of the bunching of quanta into groups of two, three, etc.

There are a number of other phenomena which are subtly linked with the dual property of light, for example, the correlation between photo-electrons produced by different parts of a coherent beam of light as shown in the experiment of Hanbury Brown and Twiss.

Here, we shall be concerned with the processes involved in the exchange of energy between radiation and matter. As we have already seen, radiation is absorbed in quanta, the absorption process consisting of the raising of an atom from a state (1) to a state (2), with the disappearance of a quantum. (The term 'atom' is used here to denote any atomic system such as a molecule or paramagnetic ion). In the reverse process, in which radiation is emitted by an atom, it drops from an upper energy-level (2) to a lower level (1) with emission of a quantum of radiation, the frequency being given also by Planck's law. This process is frequently regarded as a random process, the time in which the atom remains in an excited state being determined only by statistical considerations, assuming that it is not disturbed by collisions with other atomic systems. This process indeed is one which occurs in the emission of light. The excitation of atoms to higher states may be accomplished by thermal vibrations, as in a hot metal, or by electron impact, as in a low-pressure gas discharge. That there is a second process of emission was shown by Einstein early in the century. This is the process of stimulated emission in which an atom is induced to fall down from a state (2) to state (1) by the presence of radiation of frequency ν also given by $h\nu = E_1 - E_2$.

The probability of this process occurring is, under normal conditions of light excitation, small compared with the probability of spontaneous emission and is frequently overlooked except when some of the subtler properties of radiation, such as those discussed earlier, are under discussion. In the microwave region of the spectrum, however, it turns out that stimulated emission may be much more probable than spontaneous emission, especially at low temperatures. It was shown by Einstein that, for a given intensity of radiation of appropriate frequency, the probability of stimulating an atom already in an upper state (2) to fall to a lower energy state (1) with emission of a quantum is exactly equal to the probability of exciting such an atom in the lower state into the upper with absorption of a quantum. Stimulated emission can therefore be regarded as the converse of absorption.

It may be shown that in conditions of thermal equilibrium the ratio of the probabilities of spontaneous emission to stimulated emission is equal to $[\exp(h\nu/kT) - 1]$. For red light $h\nu \simeq 1\cdot5$ eV. and for $T = 300°$ K., kT is about 1/40 eV., so the ratio is very large.

When $h\nu \ll kT$, however, the ratio is approximately equal to $h\nu/kT$. For the microwave radiation of wave-length 10 cm. $h\nu$ is approximately equal to 10^{-5} eV., so that the ratio is 4×10^{-4}. In this case stimulated emission clearly predominates.

On the classical wave theory of the interaction of radiation with matter, absorption and both processes of emission occur naturally. Spontaneous emission corresponds to radiation damping of the atomic system regarded as a harmonic oscillator. Absorption and stimulated emission correspond to forced oscillations induced by the incident waves. Whether one obtains emission or absorption depends on the state of oscillation of the system when the wave is incident on it. It is in the quantitative description of the energy exchange that the wave-theory fails.

Let us now consider the absorption of a beam of microwave radiation by material in which we have N atomic systems in state (1) and N_2 in state (2). We shall consider only these two states for simplicity, taking their energies as E_1 and E_2 with $E_2 > E_1$. We shall also neglect spontaneous emission and consider the effect of absorption and stimulated emission. The number of quanta absorbed will clearly be proportional to N, and the number emitted which, as may be shown, must travel in the same direction as the beam, will be proportional to N_2, with the same constant of proportionality. The net absorption will therefore be proportional to $(N_1 - N_2)$, that is, to the differences in populations. The ratio N_2/N_1, in equilibrium, is given by Boltzmann's law, namely:

$$N_2/N_1 = e^{(E_1 - E_2)/kT} = e^{-h\nu/kT}$$

If $h\nu k \ll T$ we have approximately, if $N = N_1 + N_2$:

$$N_1 - N_2 = Nh\nu/2kT$$

In this case, the population difference is small and increases as the temperature is lowered. The net absorption is simply a balance between absorption and stimulated emission, and if N_2 is nearly equal to N_1 they very nearly cancel each other. This equivalence of the two processes leads to a far-reaching conclusion on the nature of stimulated emission. The absorption process is a coherent one; a beam retains its direction and coherence even when a considerable part of it is absorbed. We can therefore conclude that the same applies to stimulated emission, the incident beam grows in intensity and retains its coherence. The process can be regarded, therefore, as a true amplification of the beam. Spontaneous emission, on the other hand, is a random process, the emitted quanta travelling in all directions.

When microwave radiation is absorbed by a system of atoms as described above, the number N_2 in the upper level will begin to increase and the number N_1 in the lower level to decrease, since more make the upward transition than the downward one. If no other processes were occurring the numbers of atoms in the two states would tend to equality and the absorption would be reduced to zero. In fact, other processes do take place, for example, interactions with the lattice vibrations in a solid or collisions with other atoms or with the walls of the containing vessel in a gas, and these will tend to restore the equilibrium values N_{10} and N_{20} with a relaxation time τ. If τ is very short the departure from the equilibrium values will be small. In many instances sufficiently large values of τ are found so that N_1 can be made very nearly equal to N_2 with microwave signals of reasonable power. This phenomenon is known as 'saturation' of the two levels.

Since it is possible to tamper with the populations of atomic energy-levels in this way the question arises as to whether one can go further and make N_2 greater than N_1. If this could be done a very interesting situation would arise, since stimulated emission would exceed absorption and we should have a net amplification. It turns out that this also can be done. The possibility of the use of this process to obtain microwave amplification was realized about the same time by a number of people in different places, but was first successfully demonstrated by Prof. C. H. Townes and his colleagues at Columbia University in 1955. An amplifier based on the process is known as a 'maser' (*m*icrowave *a*mplification through *s*timulated *e*mission of *r*adiation).

Under normal conditions there will always be more atoms in the lower state than in the upper ($N_1 > N_2$), because of Boltzmann's Law. Suppose by some means we could distinguish between the two states and could filter out most of those in the lower state leaving only those in the upper state. The material would then be in what is known as an emissive condition, that is, it could be stimulated to produce coherent radiation. Let us imagine for example that we had an atomic (or molecular) beam consisting of an admixture of atoms (or molecules) in states (1) and (2) separated by a small energy difference corresponding to a microwave frequency. Now let us imagine that the beam passes a gate at which is seated a demon, such as envisaged by Maxwell, who recognizes the two states by means of a label which each atom carries. He rejects those labelled (1) and passes those labelled (2). The beam consisting only of atoms in state (2) then can be passed into a resonant cavity to interact with microwaves. This is exactly what Prof. Townes and his colleagues did. The beam consisted of ammonia molecules which have two states separated by a small energy corresponding to microwave radiation of wave-length about 3 cm. The label used for distinguishing the two states was the sign of the induced dipole moment in an electric field and the gate simply consisted of an inhomogeneous electric field which focused those in the upper state on a slit of a resonant cavity and dispersed those in the lower state. By this means both microwave amplification and oscillation were obtained. This experiment would have delighted the heart of Maxwell.

It is mainly as an oscillator that the ammonia maser has found a practical use. The frequency band-width over which amplification is obtainable is very narrow, and the amplifier is not tunable although there are a number of adjacent absorption lines which can be used. As an oscillator it produces a very stable frequency determined largely by the natural frequencies of the ammonia molecule. An even more sharply determined frequency can be obtained from a maser of this type using hydrogen as the active material. An oscillator of this type has been developed at Harvard University and may have important applications as an 'atomic clock'.

Various other tricks have been used to obtain 'inversion' of the population of two levels. For example, a single unpaired electron in a paramagnetic ion has two levels separated by an amount $2\ \mu H$ when placed in a magnetic field of strength H, μ being the magnetic moment of the electron. For values of H of the order of 10^4 œrsteds the energy separation of the levels is such as to give radiation of the order of 1 cm. in wave-length. In principle, two such levels could be 'inverted' simply by reversing the magnetic field. In practice, this takes too long a time so that the populations can relax back to their equilibrium values; but the same effect can be obtained by sweeping in frequency a strong microwave signal so that it passes through the resonant frequency. The frequency band-width of the microwave absorption lines in paramagnetic solids is considerably greater than for a gas and amplifiers of reasonable band-width can be made in this way. These would, however, be pulsed amplifiers, since the population inversion would relax soon after the inversion process and could have to be regenerated.

A method of obtaining continuous inversion of the population of two levels and of maintaining a crystal containing paramagnetic ions in an emissive condition was proposed by Prof. Bloembergen of Harvard and has been made the basis of practical microwave amplifiers. For this, three energy-levels are required so that paramagnetic ions with magnetic moment greater than that corresponding to a single unpaired electron are necessary. Cr^{3+} ions diluted in alumina are commonly used for this purpose in the form of a ruby crystal.

If we have three levels with energies E_1, E_2, E_3 ($E_1 < E_2 < E_3$) and their populations are N_{10}, N_{20}, N_{30} in equilibrium then by Boltzmann's Law, $N_{10} > N_{20} > N_{30}$. Now if we apply a strong microwave signal of frequency ν_p given by $h\nu_p = E_3 - E_1$ we can 'saturate' the levels (1) and (3), as explained earlier, and so make $N_1 \simeq N_3$. Now if level (2) and level (3) are closely coupled thermally, and no disturbing signal is applied, we must have $N_2 > N_3$. This implies that when the levels (1) and (3) are 'saturated' $N_2 > N_1$ and we have an emissive condition set up between levels (1) and (2). We can then obtain amplification at a frequency ν_s given by $h\nu_s = E_2 - E_1$. The frequency ν_p is generally called the pump frequency and ν_s the signal frequency. We note that $\nu_s < \nu_p$.

Two types of practical amplifier have been made using this principle. In the first the paramagnetic material is contained in a resonant cavity, which is generally cooled to liquid helium temperature, and is placed in a magnetic field. Both the incoming signal and pump-power are fed to the cavity and the amplified signal, 'reflected' from the cavity, is separated from the incoming signal by means of an arrangement of wave-guides called an 'isolator'. An amplifier of this kind is known as a cavity maser. An alternative, and in many ways preferable, arrangement is to have the paramagnetic crystal set along the length of a wave-guide. The signal is fed in at one end and taken out at the other end of the wave-guide, which also carries the pump power. The wave-guide is of rather special construction in order to slow up the signal wave so as to give it as long a time as possible to interact with the 'emissive' material. In this case no 'isolator' is required. This type is known as a travelling-wave maser. Its main advantages over the cavity types are greater band-width and greater stability in operation.

The chief advantage of maser amplifiers over conventional microwave amplifiers using crystal mixers or travelling-wave tubes is that they generate very much less electrical 'noise' and so can receive weaker signals without their loss in the noise background. There are two main reasons for this. First, in these amplifiers no streams of electrons are involved in the amplification process so that shot noise, due to the discrete nature of the charges making up a current of electrons, is avoided. Secondly, they are operated at very low temperatures so that thermal fluctuation noise (Johnson noise) is very small. It is of interest to note that the equivalent of this kind of noise in the maser amplifier comes from the random spontaneous emission of radiation.

In order to appreciate the marked improvement in signal-to-noise ratio which may be obtained with maser amplifiers we must say a word about the way in which amplifier performance is specified. Let us take for granted that adequate gain is available and attend only to the noise problem. The noise-level generated by an amplifier is generally described by means of a noise temperature T_n measured in degrees absolute. When we say that an amplifier has a noise temperature T_n we mean that it generates noise-power equivalent to the maximum noise-power available from a resistor at temperature T_n at its input. For example, a conventional microwave amplifier might have a noise temperature of 3,000° K.; this would mean that it generates about ten times as much noise-power as a matched resistive input load at room temperature. With maser amplifiers on the other hand, noise temperatures of the order of 3° K. may be obtained. Such an amplifier would really be wasted in working with an input which is effectively at room temperature.

When a nearly loss-free microwave aerial has its beam directed well above the horizon it behaves like a low-temperature load, receiving very little noise from outer space. When pointing nearly horizontally so as to receive an appreciable amount of noise from the ground (which is at a temperature of about 300° K.) such an aerial behaves like a resistive load having a temperature of the order of 300° K. Maser amplifiers are therefore mainly of use in receiving signals from elevated objects. They have been used successfully in radio astronomy and in reception of reflected signals from artificial satellites. For example, a maser receiver was used in conjunction with the recent experiment known as 'Project Echo' in which trans-continental communication was obtained by reflecting signals from a satellite in the form of a large spherical balloon. Figures given for the performance of this receiving system operated at the Bell Telephone Laboratories in the United States are quite remarkable.

The overall noise temperature of the receiving system was only 18·5° K. Of this the maser amplifier contributed 10·5° K. with a power gain of 3,000 at a wave-length of 5·3 cm. The aerial and feeder system contributed 5·5° K., the remaining 2·5° K. being attributed to noise coming in from the sky. This should be compared with the noise temperature obtainable with the best conventional microwave receivers for this wave-length, which is not much less than 1,000° K.

When we come to consider the use of stimulated emission to obtain coherent amplification of a light beam the situation looks far from promising, in view of the very small ratio of the probability of stimulated emission to that of spontaneous emission. In the usual light sources, either in the form of hot solids, fluorescent solids or gas discharges, by far the greatest number of light quanta are generated as a result of spontaneous emission, and the light has a rather similar nature to random noise. In spite of this, conditions have now been found in which stimulated emission of light may predominate, and the phenomenon has been used to produce narrow coherent beams of light which approximate more clearly to the plane wave trains envisaged by Maxwell than one would have ever imagined to be possible some years ago.

The method used to obtain such beams depends on the fact that stimulated emission is not a random process. If we have a large number N of atoms radiating with random phases they produce at any point an intensity NI where I is the intensity each would produce by itself. If on the other hand they radiate with phases such that, in a specified direction, their radiations are in phase, then they produce an intensity equal to N^2I. If N is a very large number, a very great intensity may be obtained in a closely specified direction. Some device must be used to ensure that the radiations from the individual atoms are in phase. The device normally used consists of two accurately parallel highly reflecting plates as in a Fabry–Perot interferometer. If the active material is placed between the plates only light waves travelling in a direction accurately at right-angles to the plates will be reflected many times through the active material and will be amplified by stimulated emission if the material is in an emissive condition. If such a condition could be achieved, and amplification sufficient to overcome the losses on reflexion could be obtained, an intense standing-wave light pattern would be set up between the plates and if one plate were slightly transparent an accurately parallel beam could be made to emerge. The main difficulty is to produce the emissive condition. This was first achieved by Maiman and soon after by a group at the Bell Telephone Laboratories, again using ruby as the active material. In the latter case the parallel plates were made by grinding optical flats on the ends of a ruby rod about 0·5 cm. in diameter and 4 cm. in length and then coating them with silver.

The emitted light was red and had wave-lengths corresponding to the red fluorescence of ruby. A very intense source of light of much shorter wave-length was used to depopulate the ground-state of the Cr^{3+} ions, so that originally only short pulses were used. Electrons then fell back into the metastable states (a doublet) from which the fluorescent radiation originates so that these acqured a population in excess of that of the ground state, so producing an emissive condition. A large part of the radiation absorbed as pump-power is re-emitted in all directions through spontaneous emission, only a small fraction going into the coherent radiation in the beam. Nevertheless very high intensities can be produced; for example, a light pulse lasting 0·5 m.sec. and having energy 0·2 joule has been achieved. The beam is only partly coherent due to defects in the ruby but it may be focused to a spot of about 0·1 mm. diameter. The mean output is thus 0·4 kW. and the power flux of the order of 4×10^6 W./cm.^{2}. This should be compared with a value of the order of 500 W./cm.^{2} obtainable by focusing the Sun with an *f*1 lens. A device of this kind is known as a 'laser' the *l* standing for light. Many possible uses have been proposed including signalling from the Moon. The most practical use made so far would appear to be in flash photomicrography. If continuous operation could be obtained, and we understand that this has now been achieved with a ruby laser although no details are available, the higher power flux could be used to melt refractory materials.

Lasers may also be made to operate in the near infra-red using U^{3+} ions in calcium fluoride. In this case the final state for the emission lies a little above the ground-state and can be effectively emptied by cooling the sample with liquid helium. Much less pump power is now required. Continuous operation of a laser has been obtained by Javan *et al.* using a mixture of hydrogen and helium as the active medium. The parallel plates in this case are placed in the gas, which is excited by a high-frequency discharge, exchange of excitation between the hydrogen and a metastable state of helium producing the emissive condition. The Fabry–Perot plates need to be flat to a very high degree of accuracy and have a multi-layer coating to give high reflectivity and low absorption. This is required because many passages through the gas are needed because of its low density compared with that of the ions in ruby. A much more accurately phase coherent beam is obtained, however, interferometric experiments showing coherence over the whole diameter of the beam, which was about 1·5 cm.

These devices are clearly in an early stage, and many new developments may be expected in the near future. Monochromatic sources in the infra-red will be of the greatest value and intense coherent sources of light open up many possibilities for optical experiments. Already lasers have been used for demonstrating beats between light waves and the generation of harmonies at optical frequencies.

An important new chapter has been started in the study and use of light and radio waves. It is curious how long it has taken in this case to find this new application of theory now more than half a century old.

There was, of course, also quite a gap between the first publication of Maxwell's theory of the electromagnetic field and its practical use in radio communication. These developments in the use of stimulated emission are also likely to lead to exciting new episodes in the story started by Maxwell in King's College, London, about a century ago.

OBITUARY

Prof. F. Richter

BEILSTEIN'S *Handbuch der Organischen Chemie* is now in its fourth edition and has been extended by two complete supplements so that with comparatively few exceptions all compounds prepared up to 1929 are included. A third supplement is now appearing. If those who use this great work had time to look back to 1881, when the first edition appeared, they would be conscious of a simpler and less-hurried existence. The devotees of chemical science were few, their laboratories by present-day standards were poorly equipped and the physical aids now so valuable had never been imagined. Nevertheless, thankfulness for the privilege of being a chemist or a student of chemistry and the slow, sometimes painful, but always exciting process of acquiring at the laboratory bench that invaluable 'feel' for organic compounds produced the results and laid the foundations on which the modern edifice of carbon chemistry has been constructed.

Four names have been specially associated with the development of the *Handbuch*: Konrad Friedrich Beilstein, Paul Jacobson, Bernhard Prager and Friedrich Richter. At the time of his death on November 22, 1961, at the age of sixty-five, Richter was director of the Beilstein Institut fur Literatur der Organischen Chemie in Frankfurt a/d Main. Since 1933 he had been responsible for the production of *Beilstein* during the most difficult period of its history and had seen eighty volumes through the press. On many occasions he recorded or lectured on the history of this great undertaking. It is remarkable that long-continued work on a production of this kind should, nevertheless, have given rise to so much loyalty and self-sacrifice, to so much real joy and justifiable pride in achievement and to such deep satisfaction in serving the needs of chemical science. Those who have read Richter's writings on *Beilstein*—the man and the work—realize that this description of his own outlook and that of his staff and predecessors is not exaggerated.

Friedrich Richter was born in Berlin on September 1, 1896, and educated at the humanistic Friedrichs-Gymnasium, where he was a remarkably outstanding pupil. At the University of Berlin he first studied classical and semitic philology, but soon decided that his interests lay in natural science. His command of languages dates from this time, however, and he read English, French, Italian, Spanish, modern Greek and

Russian with ease. His written and spoken English were of a high order. His teachers in Berlin were Emil Fischer, Leuchs, Traube and also Tiede, with whom he worked on the phosphorescence of magnesium sulphide. It is interesting that Richter, whose whole life was to be devoted to organic chemistry, should have carried out his first research on such a subject. It may be mentioned, however, that even Ramsay's early researches were concerned with the toluic acids and then with pyridine bases. Richter left Tiede in 1917 and worked for a year with Haber on methods for the analysis and counteraction of 'war gases'. He also began to abstract papers for the *Chemisches Central Blatt* and soon afterwards became associated with the production of the first volume of the fourth edition of *Beilstein* which was published in 1918; his name appears on page xxviii.

Shortly after the death of Paul Jacobson in 1923 the German Chemical Society asked him to undertake the preparation of the first and second *Ergänzungswerke* which, with the *Hauptwerk* of the fourth edition, would provide a survey of the literature up to 1929. Bernhard Prager, who had succeeded Jacobson, retired in 1933 and from that time Richter was responsible for the production of the whole work.

The years that followed were marked by ever-increasing difficulties. Many members of his staff were lost owing to the racial policy of the Government; during the Second World War the Hofmann Haus was destroyed and the editorial office transferred first to Silesia and then to Tharandt in Saxony. It was finally re-established as the Beilstein Institut in Frankfort a/d Main. The next fifteen years, though presenting many problems for Richter and his colleagues, were characterized by steady progress, confidence in the value of their work and by wide recognition of Richter's outstanding qualities not only as an organizer with a unique knowledge of chemical literature but also as a dedicated scholar and a cultivated man. The success with which he carried out an almost superhuman labour was largely due to what his brother, Dr. Hans Richter, has described as his economy of mental effort (*geistige Ökonomie*). Without this capacity the magnitude of his task, both in its broad conception and in detail, might have become overwhelming.

In 1956 the University of Frankfurt elected Richter to an honorary professorship, and there, and in the University of Mainz, he lectured on nomenclature and documentation. Heidelberg made him an honorary doctor and the Gesellschaft Deutscher Chemiker awarded him the Gmelin-Beilstein Medal. His lecture on this occasion has been published.

Between 1923 and 1931 Richter found time for research on aspects of terpene chemistry and related topics, in the laboratory of the Hofmann Haus. He studied first the bromination of thymol in glacial acetic acid and showed that one of the products, tribromomenthadienone, readily loses the isopropyl group when treated with sulphuric acid. In later papers he found that unexpected structural changes may occur during the hydrogenation of various unsaturated compounds of the terpene series. Thus β-pinene gave α-pinene and finally pinane in presence of palladium black. Sabinene under similar conditions suffered fission of the three-membered ring to give an unsaturated and then a saturated derivative of *cyclo*-pentane. Hydrogenation with platinum black, however, proceeded normally giving thujane. α- and γ-terpinene in a nitrogen atmosphere with palladium saturated with hydrogen reacted violently, giving cymene as well as menthene and menthane. This work on terpinene led him directly to a study of the physical properties of cymene and the reactions of ascaridole.

About 1930 Richter's laboratory was dismantled owing to the need of the Hofmann Haus for more library space. For a time he secured accommodation in the laboratory of Prof. Rosenheim, but after 1932 his publications were confined to articles dealing with stereochemistry, the life of von Baeyer and especially the life and work of Beilstein and the history of his *Handbuch*.

In 1952 Richter visited the Department of Organic Chemistry in the University of Leeds. A research student had just synthesized the solid isomer of thiophthen and felt greatly honoured that the first chemist from outside the Department to whom he showed his specimen was the head of the Beilstein organization.

Richter was no mean pianist and organist; he was an authority on the art of East Asia, especially on Chinese and Korean ceramics, and steadily refused to allow his heavy professional work to interfere with these interests. His appreciation of Japanese wood-carving led him to study the language, with the result that during the long evenings spent in Silesia he translated a collection of ghost stories from Japanese into both German and Russian. He also utilized his knowledge of Japanese in his professional work.

In spite of Richter's deep knowledge of his chosen science and his wide cultural interests, he was never pedantic or merely erudite. He was always ready to discuss, with a characteristic clarity, professional, literary or artistic matters and to answer questions. To have solved a problem, whether in discussion or in the laboratory was to him a source of deep satisfaction. Whenever he learned a new language Richter studied its literature. He loved books, and his library and art collections were a treasure house. Their destruction during the War was a grievous blow to him which he bore without complaint.

Richter's physique was not robust, but he inherited from his mother a great tenacity of spirit. Moreover, like St. Paul, whose epistles he and a student translated from the original text, he learned to come to terms with his physical limitations. He was never married but lived for many years with his brother in ideal understanding. Though always courteous, he was very diffident and reserved and at times may have appeared aloof. Not many people knew him well. This was not due to conceit or to any kind of arrogance on his part but rather to his very independent and restrained judgment of men and things.

On the other hand, he possessed great social gifts and when among congenial people he was a brilliant, polished and, at times, humorous conversationalist. with a light and gracious touch which gave great pleasure to those who understood him. Richter had a love for southern Europe and its people, to whom his agile and imaginative nature made him akin. Those for whom he lifted his curtain of reserve and gave of his friendship were permanently enriched by the experience.

I am grateful to Dr. Hans Richter and to Frau R. Knoll for sending me much valuable information about Richter's scientific work and cultural interests and a striking assessment of his character.

FREDERICK CHALLENGER

NEWS and VIEWS

First Anglo-American Satellite, *Ariel*

At 18.00 U.T. on April 26 an American *Thor–Delta* Rocket was launched from Cape Canaveral carrying the first Anglo-American Satellite, *Ariel* (*U.K.*1). This Satellite is the first of a series, which arose from an offer to the Committee on Space Research of the International Council of Scientific Unions in March 1959 by the National Aeronautics and Space Administration to launch satellites instrumented by other countries. *Ariel* has a higher orbit than intended; its height above the Earth varies between 242 and 754 miles, and its initial period was 100·86 min. The orbit is inclined to the equator at 53·87°. *Ariel* passes over Britain and is visible through binoculars at certain times. The Satellite, which weighs 132 lb., is a cylinder with rounded ends, being 23 in. in diameter and 21 in. long. Extending from this cylinder are sensors and paddles, giving an overall width of 10 ft. *Ariel* has been designated 1962 o 1, and its carrier rocket, which is in a similar orbit, has been designated 1962 o 2. The equipment aboard *Ariel* is intended to send back information for a year, though the Satellite itself is expected to remain in orbit for 20–30 years. The main purpose of the experiments is to investigate the properties of the ionosphere. Instruments provided by University College, London, are intended to measure the electron temperature and density, the ion mass spectrum and the intensity of solar radiation. Equipment designed by the Imperial College of Science and Technology is to measure cosmic rays, while that provided by the University of Birmingham is to measure electron density.

Royal Naval Scientific Service :

Dr. H. F. Willis, C.B.

Dr. H. F. Willis, who has been Chief of the Royal Naval Scientific Service since 1954, has joined the Ministry of Defence as a scientific adviser. Dr. Willis, who is fifty-three, is a graduate of University College, Cardiff, where he obtained first-class honours in mathematics in 1930 and physics in 1931. In the following year he gained the M.Sc. degree for research on relativity, and became a Fellow of the University of Wales in 1933. He spent the next two years at Trinity College, Cambridge, engaged on experimental research into the optical properties of molecules, and for this work was awarded the Ph.D. degree. In 1935 he joined the British Cotton Industry Research Association and carried out fundamental research on the diffusion of dye-stuffs into cellulose fibres. These early researches were described in papers published in the *Philosophical Magazine* and in the *Proceedings of the Royal Society* and of the *Faraday Society*. Dr. Willis entered Admiralty service in 1938, and until 1945 was engaged on underwater acoustics research in the anti-submarine experimental group, where he served with notable success. He was then transferred to the Admiralty Research Laboratory, and until 1953 was leader of the group concerned with problems in electromagnetics and underwater ballistics. He was promoted to the rank of deputy chief scientific officer in January 1950, and became superintendent of the Admiralty Research Laboratory in 1953.

Dr. R. H. Purcell, C.B.

Dr. R. H. Purcell, chief scientific adviser to the Home Office, has been appointed to succeed Dr. H. F. Willis as Chief of the Royal Naval Scientific Service. Dr. Purcell, born on July 14, 1904, graduated at the Royal College of Science, South Kensington, with first-class honours in chemistry in 1924. He then worked under Prof. H. B. Baker and gained the Ph.D. degree in 1927 for a thesis on the influence of intensive drying on the velocity of heterogeneous reactions. Obtaining first a University of London Travelling Fellowship and then a Ramsay Memorial Fellowship, he spent some time working under Prof. A. Smits in Amsterdam on physico-chemical topics. He was appointed lecturer in physical chemistry at the Royal College of Science in 1929 and later assumed charge of the teaching laboratories in that subject. From 1939 onwards he was, for an increasingly high proportion of his time, engaged on defence research. He acted as scientific adviser to the then Department of Miscellaneous Weapons and Devices, Admiralty, and his services to the Admiralty became full-time from 1944 onwards. After the War, when the Royal Naval Scientific Service was formed, he was appointed to the Department of Aeronautical and Engineering Research, and was responsible for the organization of materials research and development work. Periods of attachment to the Admiralty Materials Laboratory and then to the Admiralty Research Laboratory followed. His work was characterized by the great range of his scientific interests and this was reflected in his appointment in 1951 as deputy director of the Department of Physical Research, Admiralty. He left in March 1954 in order to become chief scientific adviser to the Home Office, and his appointment as chief of the Royal Naval Scientific Service is a return to a field of research and development of which he possesses wide experience and where he has already achieved conspicuous success.

Soil Survey of England and Wales :

Dr. D. A. Osmond

Dr. Donald Arthur Osmond, formerly deputy director of the Soil Survey of England and Wales, has been appointed director, in succession to Dr. A. Muir, who died on February 1 (*Nature*, 194, 135; 1962). Dr. Osmond, who has been with the Soil Survey since it was constituted under the late Prof. G. W. Robinson in 1939, had previously been engaged on soil survey while on the staff of the Long Ashton Research Station, Bristol, and made notable contributions to the study of the soils of the Vale of Evesham, Shropshire and Somersetshire, where he investigated the 'teart' condition of cattle, caused by excess of molybdenum in the herbage. During the War, when work on soil surveying was suspended, he was engaged on advisory work, and later took a major part in land-classification projects in the West Midlands, Gloucestershire, Somersetshire and Wiltshire. He has been largely responsible for the introduction of micro-morphological methods into English soil surveying. He is the British member of the Food and Agriculture Organization team which is preparing a soil map of Europe. For some years he was assistant editor of the *Journal of Soil Science*.

New U.S. Division of Research Facilities and Resources at the National Institutes of Health

A NEW Division of Research Facilities and Resources at the National Institutes of Health, Bethesda, is to be established, taking effect from July 15. Dr. F. L. Stone, at present acting chief of the Division of General Medical Sciences, will be in charge of the new Division, and Dr. C. C. Powell, assistant director of the National Institute of Allergy and Infectious Diseases, will become chief of the Division of General Medical Sciences. The new Division will centralize the administration of some of the major activities and programmes of the National Institutes of Health which provide broad support to biomedical research institutions in the United States. The responsibilities of the new Division will include the following programmes and activities: the Health Research Facilities Construction Programme; the Programme of Support for Primate Centers; the General Clinical Research Centers Programme; the Special Resource Centers Programme; and the General Research Support Grant Programme. Dr. Powell will take charge of the programmes for the support of fundamental research and research training. The Center for Aging Research and the Center for Research in Child Health will come within the Division of General Medical Sciences.

Dr. F. L. Stone

BORN in Biloxi, Mississippi, in 1915, Dr. Stone received a Ph.D. degree at the University of Rochester in 1948. He was commissioned in the U.S. Public Health Service at that time and served at the National Institutes of Health until 1954. He was chief of the Research Fellowships Branch in the Division of Research Grants until 1951 and chief of the Extramural Programs in the National Institute of Neurological Diseases and Blindness from 1951 until 1954. During 1954–55, Dr. Stone was assistant vice-chancellor for professional services in the Schools of the Health Professions at the University of Pittsburgh, and during 1955–56 was director, Medical and Scientific Department, National Multiple Sclerosis Society, New York City. Dr. Stone returned to the National Institutes of Health in 1956, becoming assistant to the Associate Director in 1956, assistant chief, Division of Research Grants, in 1957, and assistant chief, Division of General Medical Sciences, and chief of its Research Training Branch in 1958.

Dr. C. C. Powell

DR. POWELL's work in the Public Health Service has been in the areas of general programme development and grants management—both in the Division of Research Grants and in the National Institute of Allergy and Infectious Diseases. From 1958 until 1960, he was in the Division of Research Grants, National Institutes of Health, first as an executive secretary and later as assistant chief of the Research Grants Review Branch, and as deputy chief of the Division. He has been assistant director of the National Institute of Allergy and Infectious Diseases. Dr. Powell was born in Hartford, Connecticut, in 1918, and received a B.S. degree from the Massachusetts Institute of Technology in 1940, and an M.D. degree from Boston University in 1944. He was commissioned in the U.S. Public Health Service in 1946, and from 1951 was a resident in radiology at the U.S. Public Health Service Hospital, Baltimore. During 1952–54 he was a fellow in radiology at the University of Pennsylvania Hospital, but returned to the National Institutes of Health in 1954. In 1955 he served in the National Cancer Institute's Research Grants and Fellowship Branch, and from 1956 until 1958 Dr. Powell was chief of the Radiological Health Medical Program in the Division of Special Health Services.

Expansion Trends in British Universities

ON April 10, Sir Edward Boyle said that in the academic years 1959–60, 1960–61 and 1961–62, university entrants as a percentage of the relevant age groups were 4·5, 4·8 and 4·6, respectively. For the years 1962–63, 1963–64, 1964–65 and 1965–66 the corresponding percentages were estimated at 4·6, 4·6, 5·3 and 4·6, respectively. The figures excluded British students going to universities overseas, including Ireland. In reply to a question in the House of Commons on April 12, the Chief Secretary to the Treasury, Mr. H. Brooke, said that allocations from public funds to the universities had been doubled in the past five years and would increase by 50 per cent in the next five. Excluding expenditure by research councils towards university research and postgraduate awards, public expenditure, including recurrent and non-recurrent Exchequer grants, public expenditure on student awards, endowment income and fees, had risen from £56·3 million in the financial year 1957–58, or 0·29 per cent of the gross National Product, to £67·3 million, or 0·33 per cent in 1958–59; £76·7 million, or 0·36 per cent in 1959–60; £85·8 million, or 0·4 per cent in 1960–61; and £109·7 million, or 0·46 per cent in 1961–62. It was expected to reach about £150 million by 1965–66.

1961 Conference of the Universities of the United Kingdom

THE 1961 report of proceedings of the Conference of the Universities of the United Kingdom, held in London during December 15–16, provides the usual concise record of the main speeches and discussions at the Conference (Pp. 82. The Association of the Universities of the British Commonwealth, 1962. 5*s*.). The Conference was concerned with the structure and organization of the university teaching profession and with problems of the maturity of students, particularly their welfare and discipline. The speeches of Dr. C. E. F. Chilver and Prof. R. L. Brett opening the former discussion are given in full, as are those of the Rev. J. C. Blackie and Dr. N. Mallison, who opened the second discussion.

Manpower of the British Scientific Civil Service

IN answer to a question in the House of Commons on April 3, Sir Edward Boyle said that in 1960, 3,235 members of the scientific officer class of the Scientific Civil Service were mainly concerned with research and its direction in England and Wales, compared with 2,903 in 1955 and 3,303 in 1950; for Scotland, the comparable figures were 172, 145 and 109. On the same day, the Secretary for Technical Co-operation, Mr. D. Vosper, said that the results of the campaign launched in November for filling key teaching posts abroad were disappointing. Britain was willing to subsidize up to 400 such posts, but so far only 147 out of more than 200 applications dealt with had been approved, and 19 out of another 70 which were still being examined.

The Institution of Professional Civil Servants

The annual report for 1961 of the Institution of Professional Civil Servants, published in *State Service* for April 1962, records a membership at December 31, 1961, of 56,927, compared with 53,923 the previous year, but uneasiness about future methods of settling pay in the Civil Service. Government policy over the 'pay pause' is regarded as jeopardizing the work of the Pay Research Unit, but a fresh campaign is to be planned for the recognition of temporary service in full for pension purposes. The recommendations of the Zuckerman Report are still being examined by the Institution, but while any effort to implement the recommendation regarding the transfer of scientists to administrative posts would be welcomed, some of the recommendations are regarded as inconsistent with the concept of a stable career in the Civil Service. Satisfaction is expressed that most of the features in the plans for the new National Reference Library for Science and Invention to which the Institution had objected have now been removed.

The Manchester Museum

The most important event of the year 1960–61 at the Manchester Museum was the opening of the gallery containing the extensive and important R. W. Lloyd Japanese collection. The lovely ivories, lacquers, examples of sword furniture, etc., have been displayed and lighted so that the incredibly detailed workmanship can be seen to the best advantage. The most interesting temporary exhibition was entitled "Pioneer Research around Manchester", in which an endeavour was made to show, by means of actual apparatus, the experiments and advances made in science and engineering in and near Manchester during the past 200 years. Apparatus of Dalton the chemist, Joule the physicist, Osborne-Reynolds the engineer was placed with the "Logical Machine" of Jevons the economist. The small chamber in which Rutherford first 'split the atom' was displayed, together with Whitworths' gauges and Royce's first automobile engine.

Colloque Ampère and the *Archives des Sciences*

The *Colloque Ampère* issue, which in former years has been a special supplement of the *Archives des Sciences*, is this year to become a separate publication and will no longer be incorporated in the *Archives*. The subscription price for the *Archives* has been reduced accordingly to 50 Swiss francs per annum, starting with Volume 15, 1962. Subscription forms for the *Colloque Ampère* issue can be obtained from Prof. G. Béné, Institut de Physique de l'Université, Boulevard d'Yvoy, Geneva, and for the *Archives* from the Muséum d'Histoire naturelle, Geneva.

The British Society for Parasitology

At its annual general meeting during April 3–4, the Parasitology Group (Institute of Biology) was dissolved and the British Society for Parasitology was formed. Membership is open to anyone actively interested in parasitology, and a scheme for founder membership is in operation whereby persons can apply for membership before July 31, 1962, without having to obtain the signatures of a proposer and seconder. The annual subscription is £1. Anyone interested in applying for founder membership should write to the honorary general secretary, Dr. J. R. Baker, Department of Parasitology, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1.

The Granada Lectures 1961

The annual lectures organized by the British Association for the Advancement of Science and sponsored by Granada Television network are given in Guildhall, London, before an invited audience. A shortened version of each lecture is transmitted on television. During October 1961 the three lectures were given by Sir James Gray on "The Language of Animals", Prof. H. Bondi on "Why Scientists Talk", and Sir John Wolfenden on "The Gap and the Bridge". The lectures have now been published in booklet form (University of London Press. 4*s*. 6*d*.).

Society of Chemical Industry : Food Group

The following have been elected officers for the Food Group of the Society of Chemical Industry: *Chairman*, Dr. J. G. Davis; *Vice-Chairman*, Mr. T. McLachlan; *Honorary Treasurer*, Mr. R. De Giacomi; *Joint Honorary Secretaries*, Mr. G. Clewlow and Dr. B. R. J. Thomas; *Honorary Recorder*, Mr. L. C. Dutton. The following were elected members of the Committee: Mr. W. Price Davis, Dr. H. G. Smith, Mr. H. W. Symons and Mr. G. R. A. Short.

Television Society Premiums

The Television Society has awarded the following premiums, for outstanding papers read before the Society in 1960–61: the *Electronic Engineering Premium*, to Mr. I. J. P. James (Research Laboratories, E.M.I., Ltd.) for his paper on "Colour Television Camera Problems"; the *E.M.I. Premium*, to Dr. W. E. Glenn (General Electric Research Laboratory, Schenectady, New York) for his paper on "Thermoplastic Recording"; the *Mervyn Premium*, to Dr. D. E. N. King (the Hirst Research Centre, G.E.C.) for his paper on "Transparent Phosphor Screens"; the *Mullard Premium*, to Mr. D. C. Brothers (B.B.C.) for his paper on "Contrast Law Correction in Television Picture Generators"; the *Pye Premium*, to Messrs. E. R. Rout and R. F. Vigurs (B.B.C.) for their paper on "A Wide Range Standards Converter"; the *T.T.C. Premium*, to Dr. H. Barnes (the Marine Station, Millport) for his paper on "Underwater Television in Marine Biology"; the *Wireless World Premium*, to Mr. J. Roizen (Ampex International, Switzerland) for his paper on "The Use of Video Tape for Colour Television Recording".

Gordon Research Conferences, 1962

The Gordon Research Conferences, which are aimed at fostering the exchange of ideas and information between research scientists from industrial, Government and academic laboratories, are to be held this year in four residential schools in New Hampshire during the period June 11–August 31. Forty-two informal conferences, each lasting a week, will be held, their subjects covering a wide range of topics in the physical and biological sciences. Residence and registration charges for a week amount to 100 dollars. Applications should be addressed to, and further information can be obtained from, Dr. W. George Parks, University of Rhode Island, Kingston, Rhode Island.

International Visiting Professorships in Oceanography and Fisheries

The Institute of Marine Science, University of Miami, has established a programme of visiting professorships in all branches of oceanography. Each visitor will offer special lectures and provide instruction and advice to graduate students, for periods ranging from six months to a year. Visiting professors will not be limited to United States citizens, but will include scientists from overseas. The programme is partially supported by the National Science Foundation. Advance notice will be provided, giving information as to the names of visiting professors and the special fields of study in which they will lecture. Students from other institutes and universities will be invited to engage in the research and to study under the supervision of the visiting professors. Further information can be obtained from Dr. C. Richard Robins, Institute of Marine Science, University of Miami, 1 Rickenbacker Causeway, Miami, 49.

Course on High Polymer Chemistry

A postgraduate course on "High Polymer Chemistry" has been arranged by the Bradford Institute of Technology. The course, which will last for one academic year, is primarily designed for graduates entering, or already engaged in, research or production in those industries connected with plastics, synthetic fibres, surface coating and rubber. The course will include detailed treatment of the principles of high polymer chemistry together with aspects of polymer physics and a survey of polymer technology, laboratory work introducing research techniques, research projects and colloquia, and general and economic studies. Further information can be obtained from the Registrar, Bradford Institute of Technology, Bradford 7.

University News : East Anglia

Prof. T. A. Bennet-Clark, professor of botany in King's College, University of London, has been appointed professor of botany and dean of the School of Biological Studies.

London

The title of professor of oral pathology has been conferred on Mr. I. H. R. Kramer, in respect of his post at the Institute of Dental Surgery, and that of professor of industrial relations on Mr. B. C. Roberts, in respect of his post at the London School of Economics and Political Science. Dr. J. N. Hunt, reader in physiology at Guy's Hospital Medical School, has been appointed to the chair of physiology tenable at that School, and Mr. J. L. Stafford, senior lecturer in hæmatology at St. George's Hospital Medical School, has been appointed to the readership in hæmatology tenable at that School.

Yale

The following have been appointed to the Department of Botany: Theodore Delevoryas, formerly of the University of Illinois, as associate professor (palæobotany); Bruce C. Carlton, formerly of Stanford University, as assistant professor (biochemical genetics); James Cronshaw, formerly of the C.S.I.R.O., Australia, as assistant professor (electron microscopy); G. Benjamin Bouck, formerly of Harvard University, as instructor (electron microscopy); Beatrice M. Sweeney, formerly of Scripps Institute, La Jolla, California, as lecturer (algal physiology).

Announcements

Under the terms of the scheme to commemorate the late Lord Rutherford of Nelson, Sir Nevill Mott, Master of Gonville and Caius College and Cavendish professor of experimental physics in the University of Cambridge, has been appointed Rutherford Memorial Lecturer for 1962, to lecture during October–November in Uganda (Makerere University College), Kenya (Royal College, Nairobi), Southern Rhodesia (University College of Rhodesia and Nyasaland, Salisbury), Nigeria (University College, Ibadan, and Zaria) and Ghana (Accra and Kumasi).

Dr. G. E. R. Deacon, director of the National Institute of Oceanography, has been awarded the Agassiz Medal by the U.S. National Academy of Sciences for his contribution to the development of oceanography in the exploration and interpretation of the hydrography of the Southern Ocean.

Dr. P. Gross, principal scientist of the Fulmer Research Institute, has been appointed to the Board of Directors of the Institute. Mr. E. A. G. Liddiard, director of research, remains as senior executive director with responsibility for administration.

Prof. J. B. Speakman, head of the Department of Textile Industries in the University of Leeds, has been elected president of the Textile Institute.

A *Neurospora Newsletter* has been initiated to facilitate communication among research workers interested in this organism. The *Newsletter*, the first of which appeared on May 1, will be sent, free of charge, to all investigators requesting it from the editor, B. J. Bachmann, Department of Microbiology, Yale University, New Haven 11, Connecticut.

A field meeting on the theme "Soil Organic Matter", the last in the present session of the Welsh Soils Discussion Group, will be held at Aber, near Bangor, on May 9. Further information can be obtained from Mr. James A. Taylor, Department of Geography, University College of Wales, Alexandra Road, Aberystwyth.

A special short course on "Technology of the Newer Plastics and Polymers" will be held in the Bradford Institute of Technology during June 22–23. Subjects under discussion will include: newer plastics and polymers; polyvinyl chloride; polypropylene; acetal resins; polyurethanes. Further information can be obtained from the Registrar, Bradford Institute of Technology, Bradford 7.

The second congress of the International Federation of Societies of Cosmetic Chemists, organized by the Society of Cosmetic Chemists of Great Britain, will be held in the School of Pharmacy, University of London, during July 2–5. Subjects under discussion will include: surface and physical chemistry; experimental methods; properties of skin; treatment of skin and mouth. Further information can be obtained from A. Herzka, Pressurized Packaging Consultants, Ltd., Ashbourne House, Alberon Gardens, London, N.W.11.

An international symposium on "Problems of Man in Space", organized jointly by the International Astronautical Federation and the International Academy of Astronautics and supported by Unesco, the International Atomic Energy Agency and the World Health Organization, is to be held in Paris during October 29–November 2. The programme will be devoted mainly to the problems of ecophysiology, psychophysiology and data acquisition, analysis and control, and there will be an exhibition showing the techniques used to study these problems and the equipment developed for survival in space. Further information can be obtained from Unesco, Place de Fontenoy, Paris 7e.

FIRST SCANDINAVIAN SYMPOSIUM ON CARCINOGENESIS

THE first Scandinavian symposium on "Carcinogenesis" was held at the Norsk Hydro's Institute for Cancer Research during November 16–18, 1961, being sponsored by the World Health Organization.

The symposium was intended as an informal meeting to create a closer contact between the Scandinavian research workers and to give them an opportunity to present their recent results and research projects, to co-ordinate the possible future work as well as to evaluate who is where doing what in Scandinavian carcinogenesis research. A total of 51 members participated: Denmark, 2; Finland, 3; Iceland, 1; Norway, 22; and Sweden, 23. There were 38 papers and 10 review lectures.

The symposium was divided into three parts. The first was a presentation of the present work and research projects of the various laboratories (38 papers). A short summary of these papers—arranged in alphabetical order after cities—follows first.

Copenhagen was represented by Dr. J. V. Spärck (the Tuberculosis Immunization Research Centre, the State Serum Institute), who reported investigations on transplanted tumours in mice treated with X-rays and with cortisone. It was shown that irradiation chimæras possess particular features within various growth facets, for example, an inhibition of isologous tumour implants. Treatment of mice with high dosages of cortisone results in a marked inhibition of the progressive growth of tumours that is obtained after implantation of spontaneous mammary tumours, isologous to the recipients.

Helsinki was represented by Prof. K. Setälä and Drs. E. E. Niskanen and L. Stjernvall (Department of Pathology, University of Helsinki). These investigators reported results from investigations on the mechanism of artificial skin carcinogenesis in the mouse obtained by different techniques—chemical, physicochemical, light-, polarization- and electron-microscopical, biophysical. Particular attention was paid to the fact that it is possible to visualize dormant cellular features in mouse epidermis correlated with skin tumour evolution.

Lund was represented by Prof. C. G. Ahlstrom and Dr. N. Jonsson (Institute for Pathology), Prof. A. Levan and Drs. Audrey Fjelde, Eva Hansen-Melander and G. Östergren (Institute for Genetics), and Dr. B. Källén (Institute for Embryology)—all from the University of Lund. Prof. Ahlström and Dr. Jonsson presented *in vivo* and *in vitro* studies with two variants of Rous sarcoma virus as well as the characteristics of the resulting tumours. Mice, rats, hamsters, guinea pigs and rabbits of various age-groups served as experimental animals. There were significant differences between the oncological effects of the two variants or mutants of the virological materials tested. Prof. Levan had analysed the chromosomes in sarcomas provoked by the Rous agent. Results were given indicating that the karyotypes had lost four chromosomes or gained one or three, respectively. It was concluded, for example, that there may be some similarity to the case of chronic myeloid leukæmia in man. Finally, the relations between carcinogenesis and chromosomal alterations were discussed. Dr. Fjelde had studied the different types of changes of cell populations of human cancer cell strains *HEp* 1, *HEp* 2 and *HS* 1 on the basis of tissue culture experiments. Dr. Hansen-Melander reported results of studies on the relation of chromosomes of the *MD* mouse lymphosarcoma to carcinogenesis. Dr. Kallén demonstrated tumour formation in the embryonic chicken brain, stimulated by surgically provoked disturbances in embryonic induction processes.

Oslo was represented by Drs. R. Eker, N. Arley, P. Fritzson and K. F. Nakken (Norsk Hydro's Institute for Cancer Research, the Norwegian Radium Hospital, Montebello), Prof. O. H. Lahelle and Dr. J. Jonsen (Virus Laboratories, the State Health Institute), Dr. J. Ulstrup (Ullevål Hospital), Prof. O. Torgersen and Dr. B. Öystese (Institute for Pathology, the State Hospital), and Prof. L. Kreyberg and and Drs. E. Evensen, O. H. Iversen and E. Mylius (Institute for General and Experimental Pathology, the State Hospital). Dr. Eker presented results from experiments on renal adenomas in rats. The results strongly support the view that the evolution of these tumours depends on a dominant gene. The effects on the tumorous growth of unilateral nephrectomy, castration, high dosages of 'Primoteston' and 'Estrafurin' were given. Dr. Arley gave a review of theoretical analyses of experimentally induced carcinogenesis, adding to the evidence that the evolution of both benign and malignant states can be started by a single gene-mutation, that is, a specific atomic substitution or rearrangement in a specific deoxyribonucleic acid (DNA) molecule. Dr. Fritzson had studied the effect of acetylaminofluorene (AAF) feeding on the uracil-degrading activity of rat liver. The results showed that addition of AAF to the diet caused a pronounced decrease in the activity of dihydrouracil dehydrogenase. The effect produced was dependent on the dosage of the carcinogen fed. It was concluded that the reduced activity of the uracil-degrading system should be a cancer-promoting factor. Dr. Nakken dealt with the role and mechanism of oxidation of aromatic amines to *o*-hydroxy-amines: *p*-amino-benzoacid reacted 3–6 times quicker with OH-radicals than the radiation-sensitive pyridoxine and cysteamine derivatives. Prof. Lahelle and Dr. Jonsen presented new refinements concerning production and cultivation of the polyoma virus. It was possible to produce viruses in media that did not contain glutamine or serum. Dr. Ulstrup, too, presented new techniques for quantitative determination of polyoma virus. Prof. Torgersen presented certain experimental results on precursors of gastric cancer in mice. Iron–dextran was administered intragastrically to animals having artificially induced gastric ulcers. This resulted in a marked penetration of the compound into the ulcerated area, vascular walls, etc., whereas normal gastric mucosa remained unaffected. Dr. Öystese gave results of studies on the pathogenesis of gastric cancer, carried out with fluorescence-antibody techniques. Dr. Evensen had studied the duration of cell division in the epidermis of hairless mice after exposure of the skin to methylcholanthrene and croton oil. It was shown that the carcinogen initially decreased both the mitotic duration and the observed number of mitotic cells. After the first two days there was a marked increase in the number of dividing cells together with an increase of the mitotic duration. On the other hand, exposure of the skin to croton oil increased the number of mitotic cells without affecting the duration of cell division. Dr. Iversen dealt with the effects of different carcinogens on the mouse epidermis. It was shown that carcinogens initially lowered the DNA synthesis, more or less inhibited the mitotic activity and destroyed the mitochondria. The damage to the mitochondria was demonstrated by means of a tetrazolium reduction method, which revealed increased amount of formazan deposits in carcinogen-treated epidermis. A blind test involving twenty substances gave support to the theory that the abovementioned changes in mitochondrial function is a specific effect of carcinogens. Dr. Mylius reported ultrastructural alterations of the epidermal mitochondria in hairless mice provoked by a single local application of methylcholanthrene. Electron micrographs were shown which indicated that mitochondrial changes occurred within 24 hr. after the exposure to carcinogen. The alterations were more pronounced after eleven days. It was concluded that the changes observed may interfere with the activity and functions of the mitochondria, altering the latter in a specific manner.

Reykjavik was represented by Prof. N. Dungal (Institute for Pathology, University of Iceland), who reported results from experiments concerning the correlation between the amount of polycyclic hydrocarbons in smoked food and development of various types of tumours in rats.

Stockholm was represented by Prof. L. Ehrenberg (Institute for Organic Chemistry), Drs. T. Gustafson and T. Hultin (the Wenner-Gren Institute) from the University of Stockholm, Prof. G. Klein, Drs. Ingegerd Hellström, K. E. Hellström, Eva Klein, L. Révész, H. O. Sjögren and Britta Slettenmark (Institute for Tumour Biology, Karolinska Institute), Drs. B. Lagerlöf and B. Thorell (Institute for Pathology, Karolinska Sjukhuset), and Dr. A. Nilsson (Defence Research Institute). Prof. Ehrenberg dealt with the effect on rat lymphocytes of free radicals in irradiated foodstuffs and discussed the necessity of testing the possible carcinogenicity of irradiated foodstuffs in general. Drs. Gustafson and Hultin reported, respectively, on studies concerning the formation of enzymes induced by the substrate in animal cells growing *in vitro*. and of some effects of liver carcinogenesis in short-time experiments. Prof. Klein reviewed some recent work on the antigenicity of tumours induced by polyoma virus. Dr. Ingegerd Hellström dealt with *in vitro* experiments with tumours provoked by polyoma virus. Dr. K. E. Hellström reported results from studies on interstitial testicular tumours in mice induced by œstrogens. Dr. Eva Klein dealt with the antigenicity of induced tumours. Dr. Révész reported on transplantation resistancy against induced tumours in isologous tumour-host systems. Dr. Sjögren had studied the interrelationship between transplantation characteristics of tumours provoked by polyoma virus. Dr. Britta Slettenmark reported on studies concerning the tumour-specific antigenicity of leukæmia induced by virus of the Gross type. Dr. Lagerlof gave some results of leukæmia transformation *in vitro*. It was shown that the cells of normal bone marrow, by the presence of leukæmia virus, are able to change into malignant cells: the shortest latency was fourteen days. Dr. Thorell had studied, by means of microspectrography, the chemistry of cells undergoing leukæmia transformation. Dr. Nilsson reported on results obtained during experiments with strontium-90 in mice. There developed various types of bone tumours in certain preferential sites of the skeleton.

Uppsala was represented by Drs. J. Hultén, L. Landerholm, J. Pontén and B. Stenkvist (Institute for Pathology, University of Uppsala). Dr. Hultén reported on studies of staining of normal and of malignant colon epithelium with fluorescein–protein conjugates. Dr. Landerholm had studied the various titres and morphology of the bone marrow during the development of virus-induced chicken erythroleukæmia. Dr. Pontén dealt with sex chromosomes as markers in transplanted chicken leukæmia cells. Dr. Stenkvist (together with Dr. Pontén) reported on relationship between virus-content, morphology and the phase of growth in progressing and in regressing Rous sarcoma.

The purpose of the second and third parts of the symposium was a general review and discussion of what is known and, especially, of what is not known to-day about the nature of experimental carcinogenesis, and to try, on the basis of these discussions, to plan to co-ordinate future research in the Scandinavian countries in this field. The following ten reviews were then given, followed by comprehensive discussions: the present situation in tumour virology (Prof. C. G. Ahlström); the role in carcinogenesis of purified nucleic acids and similar extracts (Dr. Audrey Fjelde); pyrimidine metabolism during rat-liver regeneration and liver carcinogenesis (Dr. P. Fritzson); fluorescent antibodies applied in carcinogenesis research (Dr. E. Glück); theoretical models of growth and their importance in theories of carcinogenesis (Dr. O. H. Iversen); the implications of variation and selection for carcinogenesis and for the continued progression of tumours (Prof. G. Klein); considerations on endocrine carcinogenesis (Dr. B. Källén); the chemistry and biochemistry of aromatic amines in relation to carcinogenesis (Dr. K. F. Nakken); the role of the chromosomes in carcinogenesis (Prof. A. Levan); mechanism of experimental tumorigenesis in the mouse skin (Prof. K. Setälä).

In the discussion that followed the last paper, Dr. Kirstine Borum (Copenhagen) presented a short communication on the importance of the hair cycle in epidermal carcinogenesis in mice.

Since the symposium was an informal contact meeting, during which only the Scandinavian languages were used, no papers or proceedings will be published. However, the review lectures will be translated into English and, together with the abstracts of the thirty-eight papers cited above, filed with the World Health Organization's head office in Geneva and its regional office in Copenhagen, where they may be studied by anyone interested.

It was decided to hold the second Scandinavian symposium on basic cancer research in 1963 in Stockholm.

The participants wish to thank the World Health Organization and its officers for the grant which made this inspiring gathering possible.

MATHEMATICS FOR PHYSICISTS AND ENGINEERS

MATHEMATICS FOR PHYSICISTS AND ENGINEERS is the fourth of the Organization for Economic Co-operation and Development's *New Thinking* series*. Its predecessor dealt with school mathematics, expressing some wildly revolutionary proposals. The present report is by comparison mild.

For the engineer and physicist, mathematics must be concrete at all levels, the syllabus must be motivated by technical relevance, exercises should be drawn from real-life applications, and, if necessary, breadth of coverage must yield to depth of understanding. Topics in modern mathematics will find a place as soon as their technical applications prove important; as for logical rigour, the truth must be told, but perhaps not the whole truth. To achieve these objectives, there must be much greater co-ordination between mathematical, scientific and engineering teachers at all levels. "If the teacher is a mathematician, he must know something about the problems and methods of the physicist and engineer, and vice versa."

So much is common ground; it is in the mode of implementing these suggestions that the report exhibits a variety of opinions. If new topics are to go in, must old and valued material go out, or can room be found by using improved teaching methods? How far up the school or university can a common course in mathematics be taken? Should the elementary topics be taught by the mathematician and the advanced subjects by the scientist, or vice versa? Is it true that the spirit of contemporary abstract mathematics "no longer concerns only those who used to be called geometers . . . but concerns in fact the whole scientific community"? Will engineers thrive on Bourbaki?

The papers and discussions are full of valuable information on conditions in Europe and North America, and on experiments that are being made; they also contain speculations and suggestions about what the teacher of to-morrow may need to know and to do. So far as Britain is concerned, it seems that the technical mathematical teaching is kept close to physical reality, but is slow in making use of advanced methods and techniques in pure mathematics.

MALARIA EPIDEMIC IN MAURITIUS

MALARIA was hyperendemic in Mauritius until a large-scale control programme was started in 1949. The programme was based on a general attack by residual insecticide (DDT) and was conspicuously successful within a short time. By 1953 malaria-rates were reduced to a negligible level and the principal vector, *Anopheles funestus*, was eradicated. Total coverage spraying was then abandoned, and, until 1960, antimalaria measures consisted only of a limited programme of case-finding and parasite surveys, which did not come up to the standards now universally accepted for surveillance operations in malaria programmes.

In 1959, the Government of Mauritius and the World Health Organization agreed on a plan for the complete eradication of malaria from the island. Under this plan, full-scale surveillance operations were started in a small district in March of that year, chiefly for training purposes, and a surprisingly high number of fresh cases of malaria was detected. Because of this alarming situation, active case detection was rapidly extended over the whole island, and, as a result, 1,001 cases were found during the period April–June. The majority of the cases occurred in limited areas with an over-all total of about 70,000 inhabitants, the incidence of malaria being approximately 14·2 per 1,000, which, in an area where malaria had been practically eradicated, had to be considered as an epidemic.

It is possible that a low degree of malaria transmission had been going on continuously since the withdrawal of total coverage spraying in 1953, and that a parasite reservoir—previously undetected owing to the limited degree of surveillance—was slowly building up until, by spring 1960, it had reached a sufficiently high level to start an epidemic. Although respraying of the foci was undertaken in an attempt to remedy the situation, it became obvious in 1961 that this measure was inadequate. In the first three quarters of 1961, 190, 702 and 83 cases of malaria were detected, mainly in areas adjacent to the foci treated in 1960. This has necessitated reverting to the attack phase in areas with a population of more than 200,000.

The work being carried out by the Government of Mauritius and the World Health Organization to combat these epidemics is reported in a recent issue of the *WHO Chronicle* (16, No. 2; February 1962).

ATTENUATED MEASLES VACCINE

DR. HUANG-CHEN-HSIANG, Chia Ping-yi, Chu Fu-T'ang, Kuo Ke-Ch'ien, Wang Hui-Ying, Wu Tsung-Lin and Wu Hsueh-Hsin have examined the clinical reactions of an attenuated measles virus of vaccine L_4 (37 passages in human amnion cells). They were considerably milder than those of vaccine M_{60-5} (5 passages in human amnion cells). The difference was chiefly limited to catarrhal symptoms and signs, rash and Filatov–Koplik's spots. There was, however, no appreciable difference if the average intensity and duration of fever were compared. Dr. Huang-Chen-Hsiang *et al.* report their findings in the

January issue of the *Chinese Medical Journal* (81, No. 1; 1961).

In a small number of cases, both vaccines gave 100 per cent antibody response even when the half tissue culture infectious dose ($TCID_{50}$) was as small as 6. The average titre of neutralizing antibody acquired from M_{60-5} vaccine was somewhat higher than that from L_4 vaccine.

There was no significant difference in the degree of temperature and duration of febrile reaction between the different doses of vaccine L_4 (600, 60, 6, 0·6, 0·06 and 0·006 $TCID_{50}$), but the percentage of children with febrile reaction decreased when the infective dose was lower than 0·6 $TCID_{50}$.

Studies on the influence of different infective doses on clinical reactions showed that man is at least 100 times more sensitive to the attenuated virus of vaccine L_4 than to that of the tissue culture system. The possibility of active immunization in infants below 6 months of age is suggested.

In another article in the same journal, Huang Chen-Hsiang, Chu Fu-T'ang, Chia Ping-Yi, Lin Ch'uan-Chia and Tseng Yi report their studies on the influence of placental globulin on the clinical and immunological response of 130 children previously inoculated with 6 $TCID_{50}$ virus vaccine L_4.

Experimental results indicate that the degree and percentage of febrile reaction to the vaccine decreased with increased dose of placental globulin. The average maximum temperature and the duration of fever showed regular decrease with increase in the dose of placental globulin. There was, however, no difference in the degree and extent of reactions when the same dose of placental globulin was given 1–4 days after inoculation of the vaccine.

The antibody-level 6–7 months after immunization was found to be about the same as when the vaccine was given alone or was followed by placental globulin. The average antibody titre of children with clinical reactions to the combined use of vaccine and placental globulin was found to be slightly higher than that of those showing no reactions, but the difference is not significant.

Twenty-eight immunized children had intimate contact with children with measles following immunization 1 day or 4 months previously. They lived and played together in the same room for a period of 3–5 weeks, but none of them had measles. Among these 28 immunized children, 4 received vaccine alone and 24 received both the vaccine and placental globulin. By contrast, living in the same environment, 39 out of 41 unvaccinated children caught the disease.

SIMPLE EXPERIMENTAL METHOD FOR VERIFICATION OF THE GIBBS ADSORPTION EQUATION

By E. S. SNAVELY, G. M. SCHMID and R. M. HURD

Texas Research Associates Corporation, Austin, Texas

THE derivation of the quantitative relation between adsorption and surface tension from thermodynamics by Gibbs[1] provoked attempts at an experimental verification of this equation. Such methods as the bubble method, the microtome method and, more recently, radioactive measurements have been used with varying but qualified success[2–8]. In general, those methods which attacked the problem directly, that is, skimming the surface layer from the bulk solution, followed by analysis of the surface-active components, have involved very elaborate apparatus and experimental procedures. In particular, McBain's microtome[4] involved a long trough with precision ground rails on which rode a catapulted microtome blade, automatic trap doors to permit passage of the blade through the controlled atmosphere surrounding the trough, and other complicated arrangements for collecting the skimmed solution. As described by Adam[9], " . . . the whole apparatus constitutes a triumph of mechanical skill."

The following describes a simple and inexpensive apparatus, using the same principle as McBain's microtome, but in which the solution, rather than the cutting edge, is the moving component. In addition to the simplicity, the design permits investigation of such parameters as time to reach equilibrium between surface and bulk, and the effect of electrostatic fields impressed across the interface. In fact, the apparatus was specifically designed for use in a programme for investigation of the effects of electrostatic fields on the surface properties of salt water[10].

The 'skimmer' (Fig. 1) consists of a small-diameter metal tube with one end carefully ground to a sharp edge. It is readily made from a stainless steel hypodermic needle. The hole is hit squarely by a jet of slightly larger diameter, flowing under pressure (~ 100 cm. of water) out of a rigidly fixed pipette. The hypodermic needle tip is joined to larger-diameter tubing to allow the liquid coming through the base of the needle to flow off freely. This tubing carries a collar to collect the liquid which flows down the outside of the apparatus. The needle assembly is mounted on a microscope stage so that its position relative to that of the pipette can be controlled precisely. The skimmer is enclosed in a lucite box in which 100 per cent relative humidity is maintained to prevent losses by evaporation.

The surfactant used was *n*-decylbenzene sodium sulphonate supplied by Continental Oil Co. This compound was selected because of its large $(\partial\gamma/\partial c)$ coefficient, and the existence of a strong absorption peak at 223 mμ, which permits accurate concentration determination by differential ultra-violet spectrophotometer measurements. The surface tension–concentration relationship was obtained for aqueous solutions from 5×10^{-6} to 1×10^{-3} molar, using the capillary rise method.

Theoretical surface excess values, Γ, were calculated, using the approximate form of the Gibbs equation:

$$\Gamma = \frac{c}{RT}\frac{\partial\gamma}{\partial c} \qquad (1)$$

where c = concentration of surfactant.

From the surface-tension measurement, $\partial\gamma/\partial c$ was found to be $-4{\cdot}2 \times 10^3$ dynes l./cm. mole. The

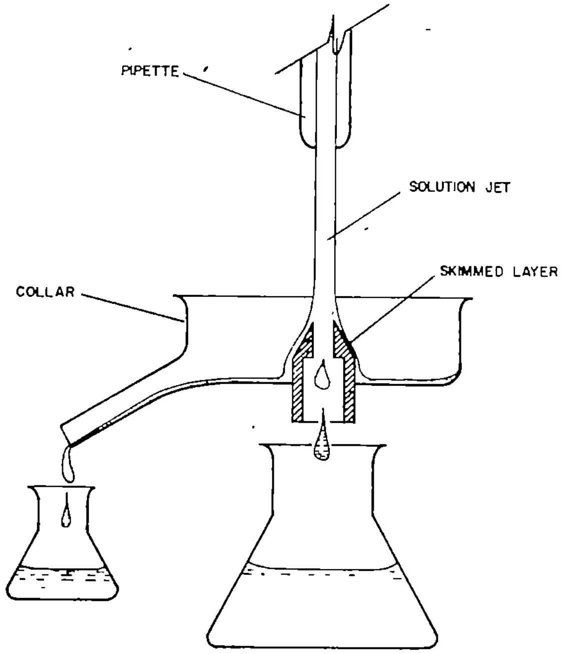

Fig. 1. Schematic diagram of skimmer

theoretical values of Γ calculated from equation 1 are represented by the line in Fig. 3.

Experimental Γ values were obtained in the following way: The flow of the jet was started and the ratio, R, of solution flowing through the hole to that flowing down the outside of the metal cone and collected by the collar was measured volumetrically. Since the diameter of the jet varies slightly with distance from the pipette tip, different values of this ratio could be obtained by simply varying the distance between the pipette tip and the ground edge of the needle. This distance was approximately 10 cm. in these experiments, with variations of less than 1 cm. to cover the ratios studied. The upper limit of distance between pipette tip and needle is that at which the jet of solution breaks up into droplets.

The thickness, x, of the skimmed layer, assuming the jet strikes the ground opening concentrically, is given in terms of the ratio, R, and the radius, r, of the opening by:

$$x \approx \frac{r}{2R} \tag{2}$$

which follows from the exact expression:

$$\frac{r^2 - (r - x)^2}{(r - x)^2} = \frac{1}{R} \tag{3}$$

when R is greater than 20 for $r = 0{\cdot}029$ cm., as used in these experiments. For ratios of 100, which could be obtained fairly easily, the thickness of the skimmed layer is $1{\cdot}5 \times 10^{-4}$ cm. It is believed that layers of 1000 Å. could be skimmed by a bit more sophistication in the construction of the apparatus.

It is not necessary for the jet to strike the opening concentrically in order to use the method. If it strikes off centre, provided only that the edge does not cut across or into the region where the concentration begins to deviate from that in the bulk (probably < 100 Å. from the surface), the value of x as obtained from equation 2, though an average, is here just as valid as if the jet would strike concentrically.

From the definition of surface excess, Γ, we can write:

$$\Gamma = (c_s - c_B)x \tag{4}$$

where c_s and c_B are the concentrations (in moles/cm.^{3}) of the skimmed layer and of the bulk solution. Equations 2 and 4 give:

$$(c_s - c_B) = \Gamma \frac{2R}{r} \tag{5}$$

so that a plot of $(c_s - c_B)$ versus $2R/r$ yields a straight line with slope Γ. Values obtained in this manner for one set of experiments are shown in Fig. 2. The scatter in the data is believed due to the edge cutting across the surface some fraction of the time during the course of the experiment.

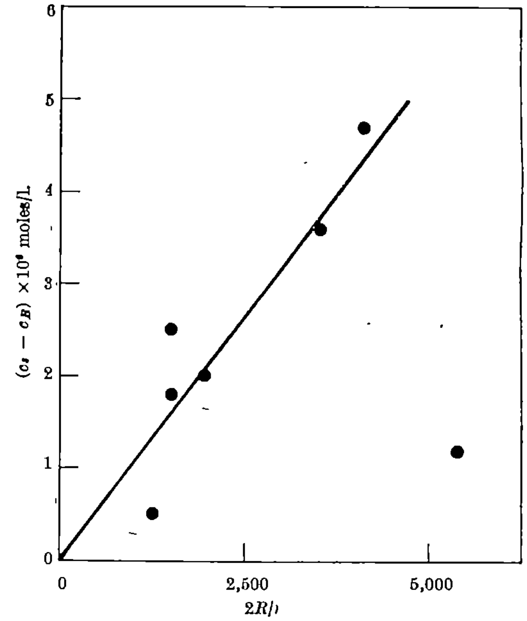

Fig. 2. Plot of $(c_s - c_B)$ versus $2R/r$ for n-decylbenzene sodium sulphonate
$c_B = 5{\cdot}5 \times 10^{-6}$ moles/l. $\Gamma = 10{\cdot}2 \times 10^{-13}$ moles/cm.^{2}; $\Gamma_{calc} = 9{\cdot}3 \times 10^{-13}$ moles/cm.^{2}

The agreement with theory is within less than 10 per cent over two decades of concentration-change. The experimental values are shown as points in Fig. 3, and are to be compared with the line which is calculated from the Gibbs equation. Appreciable deviation occurs for 10^{-3} M solutions. Here the limit of solu-

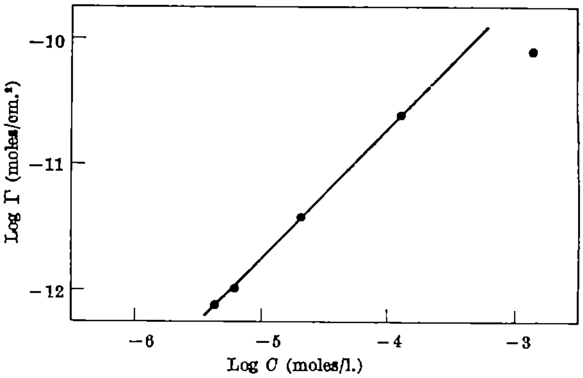

Fig. 3. Theoretical and experimental Γ values for n-decylbenzene sodium sulphonate
——, Calculated; ●, experimental

bility is almost reached, and one suspects micelle formation and/or surface film formation.

It has been implicitly assumed that the time during which the jet was in contact with air was sufficient to reach equilibrium at the jet-air interface. For 10 cm. distance between pipette and cutting edge, and 100 cm. of water pressure, this time is about 0·05 sec. The good agreement with theory indicates that, for these solutions, equilibrium is established in this interval, except possibly at 10^{-3} *M*, where the deviation may be in part due to a lack of equilibrium. However, the ability to vary the distance from capillary tip to cutting edge makes it possible to look for effects of time to equilibrium. Experiments to investigate these and effects of electrostatic fields on the surface excess concentrations are now in progress.

This work was performed as part of contract No. 14–01–001–200 with the Office of Saline Water, Department of the Interior.

SENSITIVE THERMAL ANALYSIS ESTABLISHING FORMATION OF THE INCONGRUENTLY MELTING COMPOUND $LiNaCO_3$

By E. J. CAIRNS and D. I. MacDONALD*

General Electric Research Laboratory, Schenectady, New York

THE liquid–solid equilibrium diagram for the system Li_2CO_3/Na_2CO_3 has been investigated at least four times[1–4], without general agreement among the investigators, except on the Na_2CO_3-rich side of the diagram. The point of greatest significance perhaps is that it has not been established whether or not a congruently melting compound, $LiNaCO_3$, forms. Eitel and Skaliks[1] determined the general shape of the phase diagram by cooling curves. On the basis of X-ray and index of refraction data at room temperature, they proposed the congruently melting compound $LiNaCO_3$ melting at 514° C., which was said to form eutectics with both Na_2CO_3 and Li_2CO_3. Both eutectics were found to melt at 510° C. The scatter in the cooling curve data was such that no definite conclusions could be reached about the phase diagram in the composition range 48–59 mole per cent Li_2CO_3.

Volkova[2] investigated this system by viewing the melt during cooling and noting the temperature of initial crystal formation, evidently without an atmosphere of carbon dioxide to prevent decomposition. The conclusion was reached that a compound was formed at a temperature of 501° C. The considerable uncertainty in the data did not lend much support to this proposal. Most recently, Janz and Lorenz[4] reported that this system is of the simple eutectic type based on cooling-curve evidence. However, Lorenz[5] suggested the possibility of the occurrence of an incongruently melting compound, based on the fact that X-ray results suggested the formation of another phase in the central region of the diagram. However, these X-ray results were not in complete agreement with those of Eitel and Skaliks, leading to additional uncertainty about the existence of a compound. Cooling-curve evidence was insufficient to establish the compound formation.

Because of the insensitivity of the thermal analysis equipment generally used in phase diagram determinations (± 2–3° C.) it has not been possible to detect the formation of small amounts of a new phase in a melt. This serious limitation has made it very difficult to obtain thermal analysis results in important regions (for example, eutectic, peritectic, compound formation) of phase diagrams. The usual procedure has been to obtain results well away from the region of interest, and then to extrapolate, leading to large uncertainty in the region of greatest interest.

An important object of the present work was to develop highly sensitive (± 0·003° C.) thermal analysis equipment capable of detecting very small heat effects associated with the formation of small amounts of new phases, or of phases limited to very narrow composition ranges. A recording potentiometer with zero suppression was constructed such that a full 10-in. chart deflexion could represent 5, 10, 20, 25, 40, 50, up to 10^4 μV. The highest sensitivity then corresponded to about 0·003° C., making possible the accurate measurement of previously insignificant thermal effects.

Platinum–platinum 10 per cent rhodium thermocouples were placed in a high purity alumina thermocouple well with a gold–palladium casing. The well was placed near the stirrer in order to minimize temperature lags. The thermocouples were used in pairs such that they could be checked against one another frequently. The differences never exceeded 0·025° C. at any temperature in the range investigated.

Reagent grade Li_2CO_3 and Na_2CO_3 were purified up to 99·99 per cent. The carbonates were dried at 440° C. under flowing dry carbon dioxide and stored over phosphorus pentoxide until used. All weighings were carried out to 0·1 mgm. so that composition errors were negligible (the total amount of each carbonate present was more than 100 gm.).

Cooling curves were taken at rates of 0·1–0·4° C./min. using an electrically heated furnace with a sealed quartz liner containing a crucible of 80 per cent gold–20 per cent palladium alloy. The charge of melt was in the range of 250 gm. (this large amount of melt increased sensitivity) and was always under a flowing stream of 'bone dry' carbon dioxide. Stirring was accomplished by a rotating gold–palladium alloy paddle running at 600 r.p.m.

---

* Present address: Direct Energy Conversion Operation, 1000 Western Avenue, West Lynn 3, Mass.

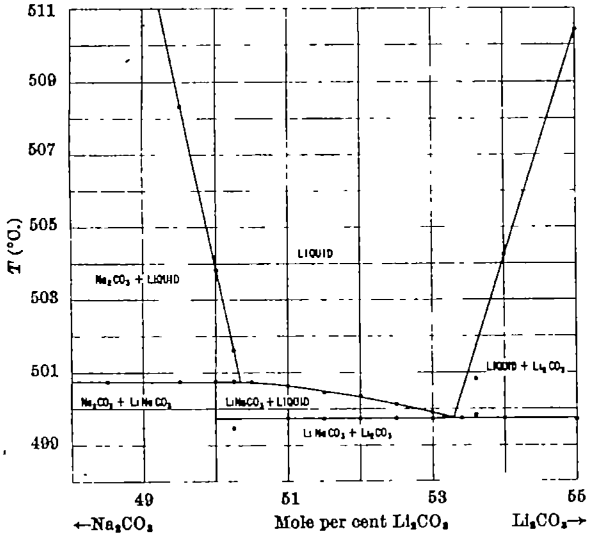

Fig. 1. Central region of the Li_2CO_3/Na_2CO_3 phase diagram showing compound formation

Cooling curve data were reduced by a modified method similar to that of Taylor and Rossini[6]. All data reported are corrected to zero impurity.

Fig. 1 shows the phase diagram in the range 48–55 moles per cent Li_2CO_3. It is clear that neither a simple eutectic nor a congruently melting compound is formed. An incongruently melting compound $LiNaCO_3$ occurs, which decomposes at 500·757 ± 0·005° C. The above limits express the repeatability of the result at various compositions of 48·5–50·25 per cent Li_2CO_3. The absolute accuracy of the results is not known precisely; however, Sigmund Cohn Corp. reference grade thermocouple wire was used, stated to be accurate to ± 0·4° C. at about 500° C. In addition, as stated above, pairs of thermocouples always agreed to within 0·025° C.

The products of the decomposition of $LiNaCO_3$ are solid Na_2CO_3 and a liquid of 50·34 moles per cent Li_2CO_3 (Fig. 1). A eutectic was found at 53·30 moles per cent Li_2CO_3, composed of $LiNaCO_3$ and Li_2CO_3, melting at 499·754 ± 0·057° C. (again, limits represent repeatability, in the range 50·5–55·0 moles per cent Li_2CO_3). The point for the liquidus at 53·6 per cent Li_2CO_3 is low because a cooling rate of 0·4° C. was too fast to allow thermal equilibrium to be established before the eutectic break was encountered. Data taken at a rate of 0·15° C./min. would surely fall closer to the line. The Li_2CO_3 liquidus line is further supported by many data taken at compositions above 55 per cent.

The three points at 50·25 moles per cent Li_2CO_3 are of special interest. They show definitely that there is formation of an incongruently melting compound via reaction between solid Na_2CO_3 (deposited starting at 503·6° C.) and the melt. After all the solid has been consumed, the remaining melt deposits additional $LiNaCO_3$ until the eutectic composition is reached, whereupon complete solidification takes place. These results rule out the formation of a congruently melting compound and simple eutectic behaviour. The fact that only two breaks were encountered in the cooling curves on the Na_2CO_3-rich side of the 50 per cent point eliminates the possibility of two enantiotropic forms of Na_2CO_3 being responsible for the behaviour encountered at 50·25 per cent. The present data thus conclusively establish the presence of the incongruently melting compound $LiNaCO_3$.

The small difference between the eutectic temperature and the decomposition temperature of $LiNaCO_3$, and the very narrow composition region for its separation from the melt (50·3–53·3 per cent) were the main reasons for the previous confusion as to the precise nature of the central region of the diagram. Extrapolations of data taken by others at 30 and 40 moles per cent Li_2CO_3 and at 60 and 70 moles per cent Li_2CO_3 with a repeatability of ± 2° C. could yield results showing behaviour anywhere between that of a simple eutectic and a gap of 5 moles per cent, indicating congruently melting compound formation.

The occurrence of $LiNaCO_3$, which melts incongruently, then shows that the X-ray[1,5] and index of refraction[1] data are not inconsistent with the conclusions which can be drawn from properly gathered thermal analysis data.

This work shows that it is possible to perform high-sensitivity (± 0·003° C.) thermal analysis experiments at elevated temperatures, allowing previously unattainable certainty in the determination of phase diagrams.

EXCIMER FLUORESCENCE OF AROMATIC HYDROCARBONS IN SOLUTION

By Dr. J. B. BIRKS and L. G. CHRISTOPHOROU

The Physical Laboratories, University of Manchester

THE fluorescence spectrum of pyrene in solution consists of two distinct components, a violet emission band *M* with vibrational structure, and a blue emission band *D* which is broad and structureless[1]. At low concentrations only *M* is observed, but as the concentration is increased *D* appears and increases in intensity, while the intensity of *M* decreases. At high concentrations and in the crystalline state[2], the fluorescence is almost exclusively *D*.

The effect was first observed by Förster and Kasper[1], who attributed *M* to the normal fluorescence of unassociated (monomer) molecules and *D* to the fluorescence of excited dimers (excimers), formed by the association of excited and unexcited molecules. This interpretation has been confirmed by Birks and Munro[3], who examined the dependence on time of the two emission components *M* and *D* following excitation by a pulsed light source. Typical results for a

5×10^{-3} *M* solution of pyrene in deoxygenated cyclohexane, showing the decay of *M* and the growth and decay of *D*, are plotted in Fig. 1. Detailed investigation[4] of the dependence on concentration, viscosity and temperature of the growth and decay times and fluorescence intensities of the two emission components have provided data about the kinetics of the diffusion-controlled photo-dimerization process. Stevens[5] has introduced the term 'excimers' to describe the photodimers in order to distinguish them from the excited states of dimers which are stable in the ground state. He has cited delayed fluorescence, self-quenching and sensitized delayed fluorescence as alternative evidence to the *D* emission for excimer formation in aromatic hydrocarbons.

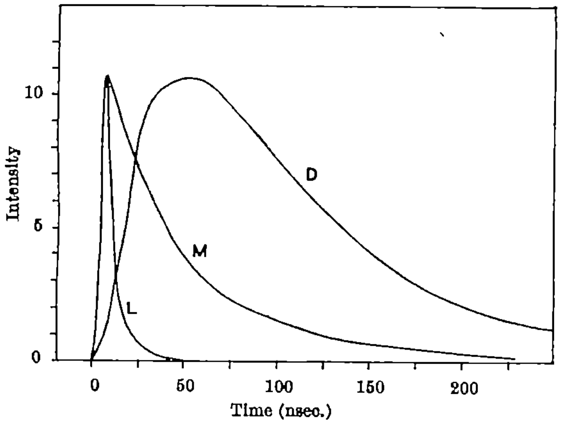

Fig. 1. 5×10^{-3} *M* solution of pyrene in deoxygenated cyclohexane (ref. 3). Growth and decay curves *M*, monomer emission ; *D*, excimer emission ; *L*, light pulse

In the present investigation studies have been made of the fluorescence and absorption spectra of a number of aromatic hydrocarbons in solution in cyclohexane or benzene, and of their dependence on concentration. In 10 of the 18 compounds studied so far a broad structureless emission band *D* is observed in the fluorescence spectrum at high concentrations. It is absent from the structured fluorescence spectrum *M* observed in dilute solutions. *D* lies at longer wave-lengths than *M*, and it increases in intensity relative to *M* as the concentration is increased. Typical fluorescence spectra observed for one of the compounds, 5-methyl 1 : 2-benzanthracene in cyclohexane, are plotted in Fig. 2. No change is observed in the absorption spectrum at high concentrations, showing that the molecular species responsible for the *D* emission are not present in the ground state. These results are consistent with excimer formation and emission. The absence of structure in the *D* emission is due to the dissociation which accompanies the emission.

The observations on the 10 compounds which exhibit excimer emission are summarized in Table 1. The wave-lengths of the first vibrational peak in the monomer emission M_1 and of the peak of the excimer emission D_1 are given. The energy difference ν' $(M_1 - D_1)$ in cm.$^{-1}$ between M_1 and D_1 corresponds to the energy of photo-association.

Two properties have proved useful in selecting compounds likely to exhibit excimer emission: (1) the molar extinction coefficient ε of the first absorption band[6]; and (2) the crystal fluorescence spectrum[2,7]. ε is approximately inversely proportional to τ_0, the natural lifetime of the first excited π-singlet state.

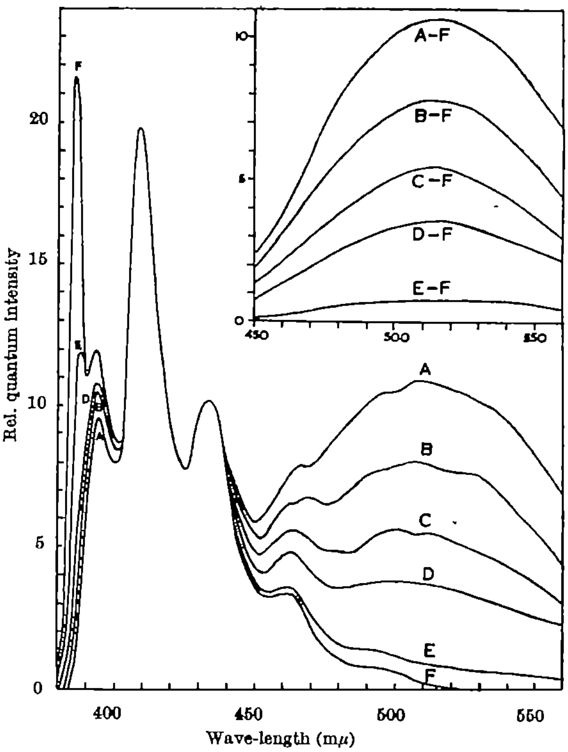

Fig. 2. Fluorescence spectra of 5-methyl 1 2-benzanthracene in cyclohexane at various concentrations. *A*, 10^{-2} *M* ; *B*, 7 5×10^{-3} *M* ; *C*, 5×10^{-3} *M* ; *D*, 3×10^{-3} *M* ; *E*, 5×10^{-4} *M* ; *F*, 5×10^{-5} *M*. Relative quantum intensities are normalized at $\lambda = 430$ mμ

Since a high value of τ_0 should favour excimer formation, the latter should be associated with a low value of ε. In all the compounds (Table 1) in which excimer emission has been observed $\log_{10} \varepsilon < 3{\cdot}5$. The radiative lifetime τ_M of *M* is reduced below τ_0 by internal quenching, excimer formation and oxygen quenching. These effects have been studied in pyrene solutions[3,4], and it is found that oxygen quenching reduces τ_M by a factor of ~ 20. This indicates that excimer emission might be more readily observed in solutions of other compounds if dissolved oxygen were removed. This has not been done in these preliminary studies.

The crystal fluorescence spectra of many of the compounds examined have been observed previously by Birks and Cameron[2]. Changes relative to the dilute solution fluorescence spectra, corresponding to a decrease in intensity of the structured emission *M* and the appearance of a structureless emission *D* at longer wave-lengths, were classified and attributed to molecular interaction. It is clear now that this interaction corresponds to excimer formation. The compounds the crystalline spectra of which are structureless and shifted to longer wave-lengths (pyrene, 3 : 4-benzpyrene, 5-methyl and 8-methyl 1 : 2-

3 : 4-Benzpyrene	403	480	3,980

benzanthracene) all exhibit efficient excimer emission in solution. However, other compounds the crystal spectra of which include much less of the component D (for example, 1 : 2-benzanthracene and its 2′-methyl and 3′-methyl derivatives) also show excimer emission in solution. These results indicate that partial or total excimer emission can occur from crystals which do not possess the 'dimeric' crystal structure of pyrene. It is possible that excimer formation occurs in crystals when excitons are trapped at dislocations.

Two of the other compounds studied, anthanthrene and perylene, also exhibit broad emission bands D at high solution concentrations, which are absent from the emission spectra M of dilute solutions. They are, however, accompanied by corresponding changes in the absorption spectra. At high concentrations a new absorption band D_0 appears at longer wave-lengths than the normal first absorption peak M_0. D_0 is approximately the mirror image of D, and in the case of perylene both D_0 and D show vibrational structure. It is clear that these two compounds form dimers in the ground state and that the D emission occurs from excited dimers. Excimer formation is excluded by the high value of $\log_{10} \varepsilon \sim 4\cdot5$ of the first absorption band, and the consequent low value of τ_0. Spectral data on the peaks M_1, D, M_0 and D_0 are summarized in Table 2. Both compounds exhibit broad structureless emission in the crystalline state[7,8].

Table 2. COMPOUNDS FORMING FLUORESCENT DIMERS

Compound	Emission M_1 (mμ)	Emission D (mμ)	Absorption M_0 (mμ)	Absorption D_0 (mμ)
Perylene	444	568, 620	438	558, 510
Anthanthrene	436	574	433	548

No dimer emission has been observed from concentrated solutions, containing dissolved oxygen, of the following compounds: anthracene, 9,10-dimethyl 1 : 2-benzanthracene, triphenylene, picene, coronene and fluoranthene. Crystalline fluoranthene and 9,10-dimethyl 1 : 2-benzanthracene have broad, featureless emission spectra, but so also do dilute solutions of these compounds, showing that the crystal spectrum is not an infallible guide.

A fuller account of these and related studies on other aromatic hydrocarbons will be published later. The fluorescence spectra were measured with a modified Unicam *SP*500 spectrophotometer. The absorption spectra were measured with a Unicam *SP*700 recording spectrophotometer, purchased with a grant from the British Empire Cancer Campaign.

ON THE VALIDITY OF THE EVIDENCE FOR SUB-UNITS OF HIGH MOLECULAR WEIGHT RIBONUCLEIC ACIDS

By H. BOEDTKER, W. MÖLLER and E. KLEMPERER

Department of Chemistry, Harvard University, Cambridge, Mass.

ALTHOUGH it is generally agreed that ribosomal ribonucleic acid (RNA) when first isolated consists of two components having sedimentation constants of approximately 16 and 23 *S*, several investigators have reported that these high-molecular-weight components represent aggregates of low molecular weight sub-units held together by magnesium ion interactions, hydrogen bonds or peptide links[1–3]. To understand both the structure and formation of ribosomes, it is clearly necessary to accept or reject the sub-unit hypothesis. For this reason we decided to study the methods which had been used to produce sub-units. We examined the effect of dialysis, interaction with bovine γ-globulin, reaction with trypsin, and the effect of heat on *E. coli* ribosomal RNA, tobacco mosaic virus (TMV) RNA and polyuridylic acid. The results summarized here cast serious doubt on the validity of the evidence which has been put forth in support of sub-units in RNA.

Dialysis experiments were carried out under the conditions used by Aronson and McCarthy[1], 2° and 0·01 M *tris*(hydroxymethyl)aminomethane, 0·004 M succinic acid, pH 7·6 (0·01 M *tris* buffer), and sedimentation constants were measured to determine changes in molecular weight. Both TMV RNA and *E. coli* ribosomal RNA were found to degrade after several days of dialysis, but the results were erratic and the degradation was less extensive than that observed by McCarthy and Aronson. The variability in these results suggested that the observed fall in molecular weight might be the result of ribonuclease contamination. We found that the addition of a ribonuclease inhibitor, polyvinyl sulphate[4], at a concentration of 1 per cent of the RNA concentration, stabilized RNA preparations so that the sedimentation constant remained unchanged even after one week of dialysis. Since such prolonged dialysis removes divalent cations, we conclude that RNA does not dissociate into sub-units in the absence of divalent ions provided the ribonuclease activity is suppressed.

Next we examined the interaction of RNA with a globular protein. Bovine γ-globulin was chosen because this was the protein which Brown, Ellem and Colter had reported to be most effective in dissociating RNA (ref. 2). In agreement with the results obtained by Brown *et al.*, we observed a significant drop in $S_{20\,w}$ when TMV RNA was incubated with protein at 5° in 0·15 M sodium chloride at pH 7. However, further studies revealed that the observed drop in sedimentation constant was dependent on time and the rate of degradation was proportional to the protein : RNA ratio. No limiting value of the sedimentation was found, when $(S^0_{20\,w}/S^t_{20\,w})^2$, a quantity roughly proportional to M_0/M_t, was plotted as a function of time. These results therefore suggest that the 'dissociation' reported by Brown *et al.* might be the result of nuclease contamination of the protein. To test the possibility that bovine γ-globulin contains trace amounts of ribonuclease, RNA was incubated with protein under conditions known to inhibit ribonuclease action. The results of incubating 100 γ/ml. bovine γ-globulin with 40 γ/ml. *E. coli* ribosomal RNA at neutral *p*H and low (10^{-4} *M*) magnesium ion concentration were compared with those obtained: (1) under identical conditions but in the presence of polyvinyl sulphate; (2) at *p*H 4·5, and (3) in 2 × 10^{-3} *M* magnesium. 12 hr. after RNA and protein were mixed at a ratio of 1 : 2, the sedimentation constant of both the mixture and a control were measured in 0·15 *M* sodium chloride. No change was found in the sedimentation constant or in the relative amount of the 16 and 23 *S* component under conditions which inhibit ribonuclease, but S_{20w} had fallen to 11 *S* at neutral *p*H and low magnesium ion concentration.

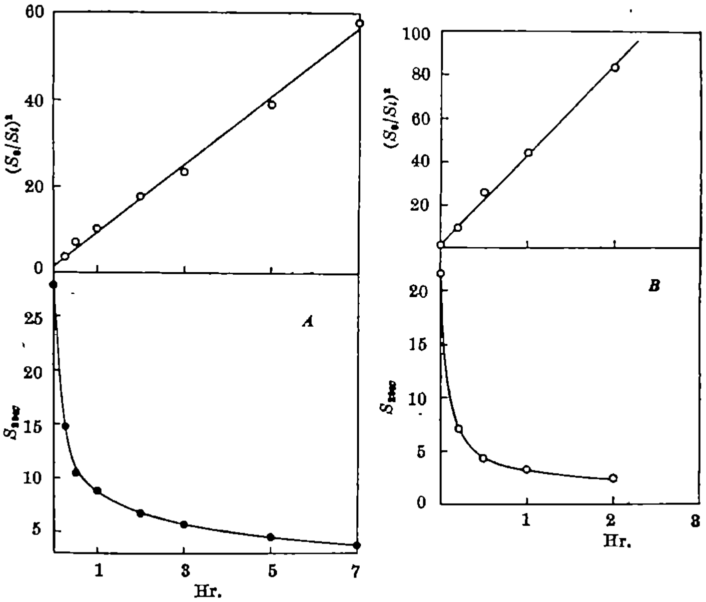

Fig. 1. *A*, hydrolysis of TMV RNA at 90° C. 0·15 *M* sodium chloride + 0·015 *M* sodium citrate; *B*, hydrolysis of *E. coli* ribosomal RNA at 90°. 0·01 *M tris* buffer, *p*H 7·6, plus 0·01 *M* magnesium chloride

Additional evidence for ribonuclease contamination of bovine γ-globulin was obtained by testing the effect of adding protein to both polyuridylic and polyadenylic acid. Ribonuclease readily degrades the former but not the latter. As expected, bovine γ-globulin had no effect on the sedimentation constant of polyadenylic acid but caused a marked decrease in S_{20w} of polyuridylic acid when the two were incubated at 5° for 24 hr. at a protein to RNA ratio of 3 : 1, S_{20w} decreasing from 5·8 to 3·3 *S*.

Our results with bovine γ-globulin made us suspect that the action of trypsin on yeast ribosomal RNA reported by Otaka, Oota and Osawa[3] might also be the result of ribonuclease contamination. For this reason we tested the 'activity' of native and alkaline denatured trypsin on polyuridylic acid. When 0·4 mgm./ml. trypsin was incubated with 10 × vol. of 11·3 mgm./ml. polyuridylic acid in 0·15 *M* sodium chloride, 0·01 *M* potassium phosphate, *p*H 6·3 at 2° for 12 hr. the protein–polyuridylic acid mixture sedimented with S_{20w} of 1·7 *S* while the control (measured simultaneously in a Spinco model *E* ultracentrifuge equipped with double optics) sedimented at 6·6 *S*. When the parallel experiment was carried out with trypsin which had been pre-incubated at *p*H 10 for 18 hr. at 25° (in the absence of divalent cations), the sedimentation constant of the trypsin–polyuridylic mixture was 1·0 *S* while that of the control was 5·2 *S*. As pure trypsin would not be expected to degrade polyuridylic acid and alkali-denatured trypsin should certainly be inactive, the results clearly indicate that an alkali-resistant contaminant is responsible for the observed degradation. Once again the most likely explanation was that trypsin was contaminated with ribonuclease. Naturally we cannot prove from these experiments that the trypsin used by Otaka *et al.* was similarly contaminated, but the fact that it was obtained from the same source (Worthington Biochemical) makes it likely.

Having found that the degradation of RNA as a result of dialysis, interaction with globular proteins and reaction with trypsin could all be attributed to ribonuclease action, it remained of interest to determine if exposure to high temperature, where enzymatic degradation could not be expected to play a major part, would result in the formation of sub-units. Several investigators, including Hall and Doty[5], Takanami[6], Osawa[7] and McCarthy[1], have reported that heating ribosomal RNA from widely differing sources results in a limiting value of S_{20w}. Unfortunately, with the exception of Hall and Doty, none of the reports included evidence that successive heating to the same high temperature would not further degrade the RNA. To clarify this point, several aliquots of both TMV and *E. coli* ribosomal RNA were heated to 90° for varying periods of time, whereupon the samples were quickly cooled and the sedimentation constant measured at 20°. The results obtained on TMV RNA and *E. coli* ribosomal RNA are shown in Fig. 1. It is clear that although a plot of S_{20w} against time appears to level off at about 4 *S*, a plot of $(S^0_{20w}/S^t_{20w})^2$ against time does not indicate a limiting value. The linear dependence observed in the latter case indicates that the molecular weight decay is proportional to time of heating to 90° and is characteristic of first order random degradation kinetics. Moreover, rate constants calculated from these data on TMV RNA are comparable with those reported previously[8] and hence of the same order of magnitude as those obtained for denatured single stranded DNA and for such model compounds as diethyl and dibenzyl phosphate. Thus, these data fail to provide any evidence for the existence of sub-units, for a non-random cleavage of phosphate diester bonds of RNA or for any exceptional instability of the RNA chain.

In conclusion, we find that the sub-unit hypothesis has not been successfully established by any of the evidence reported so far. Detailed time studies, properly interpreted, show that if degradation occurs, it is continuous and does not lead to a limiting value for the molecular weight. Furthermore, neither viral nor *E. coli* ribosomal RNA form low molecular weight sub-units if ribonuclease activity is absent or inhibited.

We thank Prof. Paul Doty for his help and criticism. We also thank Mr. Saul Rosenfeld for his assistance in measuring sedimentation constants. This work was supported by National Institutes of Health grants *C*-2170 and *A*–2396.

LOW CYST(E)INE CONTENT OF BACTERIAL EXTRACELLULAR PROTEINS: ITS POSSIBLE PHYSIOLOGICAL SIGNIFICANCE

By M. R. POLLOCK, F.R.S. and M. H. RICHMOND

National Institute for Medical Research, Mill Hill, London, N.W.7

A SCRUTINY of the published figures on amino-acid content of the five different bacterial extracellular enzymes[1–5] which have been successfully isolated during the past few years reveals that they all apparently lack cyst(e)ine. In order to discover whether this might be a general property of bacterial exo-proteins, we have determined the cyst(e)ine content of a number of other purified bacterial exo-enzymes that became available to us during the past eighteen months, and have repeated cyst(e)ine determinations on some of the exo-enzymes already analysed in other laboratories. The results, together with those (published and unpublished) from other laboratories, are summarized in Table 1, where they are expressed as the weight in grams of the exo-protein containing the equivalent of 1 gm.-molecule of cysteine. On comparing these values with the known molecular weight of the proteins, it is clear that, with the exception of the two toxins which appear to have four or more half-cystine residues per molecule, the maximum cyst(e)ine content never exceeds one half-cystine residue per molecule, and in many instances must be zero.

It is somewhat doubtful whether the toxin of *Clostridium tetani* should be included as a true exo-protein, since it alone, of all the proteins tabulated, is found attached to the cells in substantial proportions during the logarithmic phase of growth[27,28], and no critical tests have been done to determine the extent to which it might be liberated by cell autolysis. However, the evidence in favour of diphtheria toxin being a 'true' (that is, physiologically liberated) exo-protein is much better[28]. It is not yet known what number of disulphide bonds, if any, is present in the molecule of either of these two toxins. The thermo-stable α-amylase of the thermophilic organism *Bacillus stearothermophilus* (not included in Table 1), recently shown to contain four half-cystine residues and two disulphide bonds per molecule of mol.wt. 15,600 [29], is quite possibly extracellular, although it was isolated from the filtrate of a relatively old (36 hr.) culture and might therefore have been released by cell autolysis. Bearing in mind these three possible exceptions, the aforementioned generalization is supported by further work to the extent that ten different bacterial extracellular proteins (including five different functional types from six different species of bacterium) are now known to have a cyst(e)ine content so low that in no instance can there be a single disulphide bond present in the molecule, and in eight cases no cysteine is present at all.

The question arises, therefore, of the possible significance of the absence of —S—S— bonds in these bacterial extracellular proteins. The main possibilities appear to be as follows.

Table 1. CYST(E)INE CONTENT OF PURIFIED PREPARATIONS OF EXTRACELLULAR PROTEINS

Organism	Protein	Gm. of protein in preparation containing 1 gm. molecule of cyst(e)ine*	Known m w. of protein	Maximum apparent No. of ½-cystine residues/molecule
Pseudomonas myxogenes	Proteinase	∞[1]	77,000[1]	0
Pseudomonas saccharophila	α-Amylase	400,000[4,7]	40,000[4]	0
Streptococcus haemolyticus	Proteinase	120,000[8]	—	0
Bacillus subtilis	Proteinase ('subtilisin')	∞[9]	27,000[10,11]	0
Bacillus subtilis	Ribonuclease	∞[12] 20,000[8]	10,000–20,000[13] (S_{20} = 1 4)	0 1
Bacillus subtilis	Proteinase	100,000[8,14] 89,000[8]	30,000	0
,, ,,	α-Amylase	∞[8,15] 46,000[8]	49,000[16]	0 1
Bacillus cereus, strain 5/*B*	Penicillinase (constitutive)	∞[5]	35,000[17]	0
Bacillus cereus, strain 569	Penicillinase (induced)	92,000[8]	31,000[17]	0
Vibrio cholerae	Neuraminidase	77,000[8]	90,000[18] 10,000–20,000[19] (S_{20} = 1 3)	1 0
Corynebacterium diphtheriae PW 8	Toxin	18,000[20]	72,000[21]	4
Clostridium tetani	Toxin	approx. 5,000[22] 8,000–11,000[23]	67,000[22] 66,000–74,000[21]	14 9

The sources of the proteins analysed by us were as follows: *Streptococcus haemolyticus* proteinase: Dr. S. D. Elliott, Department of Animal Pathology, Cambridge University; *B. subtilis* ribonuclease: Dr. S. Nishimura, Cancer Institute, Tokyo; *B. subtilis* proteinase and α-amylase: Nagase Co. Ltd., Ohama, Amagasaki; *B. subtilis* α-amylase (recrystallized): Dr. Kakiuchi, Osaka University; *V. cholerae* neuraminidase: Dr. G. Ada, Walter and Eliza Hall Institute, Melbourne; *B. cereus*, strains 5/*B* and 569 penicillinases: crystalline specimens from this laboratory[25,26].

* Where ∞ is given as a value, the only information available was that no cyst(e)ine was detected by the method used, limits of sensitivity not being stated.

(1) *It may be characteristic of a particular catalytic type of enzyme.* However, in at least three instances catalytically similar enzymes from fungal, plant or animal sources are known to contain disulphide linkages in the molecule: (*a*) the α-amylases both of mammalian pancreas and *Aspergillus* have 4–8 half-cystine residues (all probably in the disulphide linkage) in each molecule, the size of which is identical with that of *B. subtilis* α-amylase[30]; (*b*) bovine pancreatic ribonuclease, having a molecular weight very similar to, and specific activity identical with, that of the *B. subtilis* enzyme[13] has four disulphide bonds[31]; (*c*) several animal proteases (for example, pepsin, trypsin and chymotrypsin) have two or more disulphide bonds per molecule[32].

(2) *It may be characteristic of bacterial proteins in general.* Only very few cell-bound bacterial proteins have been purified or analysed for cyst(e)ine; and in most cases they have been isolated from *Escherichia coli*, which does not liberate significant quantities of extracellular protein; they cannot thus be considered very satisfactory examples for comparison in this respect.

We have therefore determined the cyst(e)ine content of total cell protein in all the bacterial species from which individual exo-proteins have been previously analysed, and the results are summarized in Table 2.

Table 2. CYST(E)INE CONTENT OF BACTERIAL CELL PROTEIN

Organism	Weight of protein in gm. containing 1 gm. molecule of cysteine
1. *Escherichia coli*	7,600*
2. *Pseudomonas fluorescens KV* 2	14,200
3. *Pseudomonas saccharophila*	13,100
4. *Staphylococcus aureus* 524	7,000
5. *Bacillus subtilis* 6346	16,300
6. ,, ,, *H*	9,350
7. *Vibrio cholerae* 4 *Z*	11,300
8. *Streptococcus haemolyticus C* 748	8,250
9. ,, ,, *D* 58	9,500
10. *Corynebacterium diphtheriae PW* 8	9,150
11. *Bacillus cereus* 569	12,700
12. ,, ,, 5/*B*	10,100

McCarty, Rockefeller Institute, New York; No. 6: Dr. Iizuka, Applied Microbiology Institute, Tokyo; No. 10: Dr. G. C. Pope, Wellcome Research Laboratories, Beckenham; Nos. 2, 4, 5, 7, 11 and 12: lab. strains.

Media. For Nos. 2, 5, 11 and 12: casein hydrolysate medium + citrate (CH/C)[26]; for No. 3: a maltose + NH_3 + salts medium[33]; for No. 4: CH/C + 0·001 per cent nicotinic acid and 0·001 per cent thiamine; for No. 7: 0·05 *M tris* maleate buffer, *p*H 8·0 + 0·5 per cent L-glutamic acid, 0·9 per cent glycerol, 0·004 per cent adenine and 0·35 per cent KH_2PO_4; for Nos. 8 and 9: Hartley beef broth[34]; for No. 10: papain digest of beef + 0·08 per cent $MgSO_4.7H_2O$ and 0·25 per cent maltose.

The two species of *Pseudomonas* were grown at 30° in stationary culture. All other cultures were grown at 35° and aerated by shaking. Organisms were inoculated at a density corresponding to 0·02 to 0·05 mgm. dry wt./ml. and cropped after 16–18 hr. incubation.

* This figure, relating to *E. coli*, was calculated from results obtained by Roberts *et al.*[35].

So far as this analysis goes, the values agree well with those obtained by Mondolfo and Hounie[36] using a different (microbiological) technique. It seems clear that the mean cyst(e)ine content of cell-bound bacterial protein is very considerably higher than that of the extracellular proteins isolated from the same organisms. There does not, therefore, seem to be any good reason for supposing that bacteria in general, and exo-protein-forming bacteria in particular, produce protein which, regardless of whether it is cell-bound or liberated into the medium, is exceptionally low in cyst(e)ine. It would, of course, be interesting to know the cyst(e)ine content of the corresponding total extracellular protein produced by these organisms. But the proportion thus liberated rarely exceeds 3 per cent of the total cell protein, and is frequently much lower. Thus contamination with cell protein liberated by a very minor degree of cell autolysis (which is difficult both to estimate and to prevent) would invalidate any such analysis.

(3) *It may be characteristic of their extracellular location.* Little or nothing is yet known concerning the mechanism by which bacteria liberate enzymes and other proteins into the surrounding medium from apparently intact cells. But it seems almost certain that it will prove to be fundamentally different from processes occurring in mammalian tissues, such as the pancreas or salivary glands, where digestive enzymes appear first inside the cell, within zymogen granules which later move to the cell surface and discharge their contents outside[37,38]. The site of formation of bacterial exo-enzymes is not yet known; they may or may not have to pass through the cytoplasmic membrane in the process of liberation, though there is some evidence to suggest that the usually very small portion found still attached to the cell may be on the outside of the permeability barrier, and that the site of synthesis is the membrane itself[38,39]. However this may be, it seems certain that these enzymes have to pass through the rigid mucopeptide mesh and possibly other structures of the bacterial cell wall before they are finally liberated. The extent to which this cell-wall lattice acts as a barrier to the passage of protein molecules is not known; but there are suggestions that it may be far from negligible[40]. It is almost certain that no such rigid obstruction exists to the escape of pancreatic enzymes from the cell as soon as they have emerged beyond the limits of the cytoplasmic membrane. The presence, therefore, of disulphide bonds in pancreatic enzymes such as ribonuclease and α-amylase, which are later liberated into the duct lumen, does not mean that the absence of disulphide bonds in similar types of exo-enzyme of bacterial origin is unconnected with their property of 'extracellularity'. Indeed, this very fact may reasonably be taken as supporting the hypothesis that the absence of disulphide bonds might be directly related to the peculiar conditions associated with the passage of bacterial enzymes through a rigid cell-wall barrier.

It may be relevant to note in this connexion that other bacterial proteins of a partially extracellular nature appear also to lack disulphide bonds. Kobayashi, Rinker and Koffler[41] report that purified samples of flagella protein ('flagellin') from one *Proteus* and three *Bacillus* species in all probability contain only one half-cystine residue per molecule. The protein extractable with formic acid from cell-wall preparations of *E. coli*[42] gave completely negative tests for cysteic acid after oxidation and hydrolysis[43], which would indicate a cyst(e)ine content of not more than 0·2 per cent by weight. The extent to which such proteins might be regarded as 'extracellular' is obviously a matter of definition; more important, perhaps, is the degree to which they might possibly have certain characters in common with proteins that are released from the cell in a soluble state, by reason, perhaps, of peculiarities associated with their surface location. But even less is known about possible barriers to their penetration of surface structures than is the case with free extracellular proteins.

If the relationship between extracellularity and absence of disulphide bonds in bacterial proteins is a real one, it is tempting to speculate on its possible significance.

Disulphide linkages in a protein are the most important, if not the only, covalent (and, as such, the strongest and most important) bonds contributing to the stability and rigidity of the tertiary structure of the molecule[44]. A protein molecule lacking disulphide bonds would have to rely mainly on the weaker and more easily ruptured H-bonds and metal- and salt-linkages, for preserving its folded state. Bacterial exo-enzymes might therefore be expected to have more than the usual degree of flexibility and to be capable of more easily unfolding and refolding than proteins which contain —S—S— bonds. The possibility that these bacterial enzymes might have become adapted to pass more freely through a rigid cell-wall meshwork by evolving a degree of flexibility through elimination of disulphide bonds, seems at least worthy of consideration.

The value of such a speculation must depend in the first place on further information both on the cyst(e)ine and —S—S— bond content of a wider variety of bacterial proteins of all kinds and on the extent to which some of them may legitimately be classed as 'truly' (that is, physiologically) extracellular, and not liberated by cell damage. Without this, even the generalization on which this speculation is based can scarcely be considered as sufficiently well established.

At the same time it is important to know more about: (*a*) the detailed structure of the bacterial cell-wall and its permeability properties for large molecules; (*b*) the extent to which it is possible for the polypeptide chains of bacterial exo-enzymes to exist in an unfolded state, and subsequently to fold up without loss of biological activity, into the specific tertiary structures which they undoubtedly possess after liberation into the medium; (*c*) the factors which could stimulate or inhibit reversible unfolding of these enzymes (or maintenance of the unfolded state) under conditions existing in the cell, and their effect on exo-enzyme liberation; (*d*) alterations in the ability of proteins to penetrate through artificial and natural membranes of graded porosity, after treatment known to cause a partial or complete unfolding of the molecule. So far, however, the only work directly relevant to this possibility concerns the penicillinase of *B. cereus*, which Citri *et al.*[45] have shown to be capable of undergoing a limited degree of reversible unfolding; though there is no direct evidence relating this to the mechanism of its liberation from the cells. Further information would be valuable and interesting enough, quite apart from its relevance to a hypothesis which, though perhaps somewhat speculative, is nevertheless one which involves some fairly precise predictions, capable of experimental verification.

Cyst(e)ine Estimation

In view of the very low cyst(e)ine contents of the proteins being studied, the very small amounts (2–5 mgm.) that sometimes were available, and the well-known difficulty of preventing destruction of the amino-acid on hydrolysis, it was essential to devise a micro-method of maximal sensitivity, and to take special precautions to prevent loss, by prior oxidation to cysteic acid, and careful removal of excess acid.

For total bacterial protein, 1·0 ml. of 50 per cent (w/v) trichloroacetic acid (TCA) was added to 9 ml. of a washed cell suspension, from a log-phase culture containing about 50 mgm. dry bacterial wt. After standing 15 min. at room temperature, the mixture was heated to 95° for 30 min. and then left at 2° for 16 hr. The precipitate was washed twice with 5 per cent TCA, re-suspended in 10 ml. water, about 1 per cent of the total dissolved in *N* sodium hydroxide for estimation of protein[46], and the remainder evaporated to dryness and dissolved at a concentration of about 20 mgm./ml. in 98–100 per cent formic acid. With purified proteins, a known quantity was dried *in vacuo* and similarly dissolved in formic acid. These protein solutions were then oxidized by adding 2·5 ml. performic acid per mgm. protein and leaving for 4 hr. at room temperature. Samples were then evaporated to 5 ml. at 35°, redissolved in 50 ml. water, dried down, and the oxidized protein hydrolysed with 4 ml. 6 *N* hydrochloric acid in sealed ampoules at 105° for 16 hr. Most of the hydrochloric acid was then removed at 100° in a stream of air, and the remaining traces by repeated addition and evaporation of 3·0 ml. lots of water. The technique is based on that described by Schram *et al.*[47], with minor modifications.

The method used for separation of cysteic acid (CA) from other amino-acids present in the hydrolysates depended on whether or not diaminopimelic acid (DAP) was present in the preparation. DAP, which occurs in the cell walls of certain species of bacterium[48] and is, therefore, precipitated, by the technique used here, along with the amino-acids of true cell protein, does not easily separate from cysteic acid chromatographically. In its absence (that is, in all purified protein preparations, and in total cell protein from *Staphylococcus aureus* and *Streptococcus haemolyticus*), CA was isolated by loading up to 100 μl. of the hydrolysate, corresponding to 0·5–1·0 mgm. of protein, together with CA markers, on to Whatman No. 3 paper as a 3 cm. band, and allowing descending chromatography in *n*-butanol/acetic acid/water (63 : 10 : 27, by vol.) for three days. In the presence of DAP (that is, with all other cell protein preparations), preliminary separation of CA was achieved by ionophoresis. About 10 μl. of the hydrolysate (corresponding to 0·5–1·0 mgm. of protein) was loaded on to similar paper at the centre of a line drawn 10 cm. from the long side, after dipping into 2 *M* acetic acid (*p*H 2·4) and blotting off excess liquid. A potential gradient of 20 V./cm. was applied for 1¼ hr., the paper dried, and CA markers applied to the line so as not to overlie the partially separated amino-acids. Chromatography, similar to that already described, but for 18–24 hr. only, was then applied at right angles to the direction of the preceding ionophoresis. Since CA is the only amino-acid to move towards the anode on electrophoresis at *p*H 2·4, adequate separation from DAP and other amino-acids is thus achieved.

The CA thus isolated was estimated with ninhydrin according to the method used by Mandelstam and Rogers[49], by comparison with known 'marker' quantities of CA (1–20 μgm.) which were always run on each paper. The standard curve thus obtained gave extinction values at 570 mμ which were proportional to quantities of CA down to 2 μgm.

Protein hydrolysates tended to 'smear' slightly over the chromatography paper, so that weakly positive spots (equivalent, in ninhydrin colour, to up to 2 μgm. of cysteic acid out of a total load of 700 μgm. or more) were sometimes obtained with proteins (for example, α-amylase) that were known not to contain cyst(e)ine. Thus the recorded cyst(e)ine contents of 1 gm.-mole in 50,000 gm. or more of protein are consistent with complete absence.

Recovery of CA from oxidized and hydrolysed samples of insulin (World Health Organization standard) at loads of 100–150 μgm. gave yields of 75–80 per cent of theoretical. An artificially reconstituted low-cyst(e)ine protein made by oxidizing and hydrolysing a mixture of 2·9 mgm. of *B. subtilis* α-amylase + 250 µgm. insulin (that is, final cyst(e)ine content of 1·0 per cent) at a total load of 643 µgm. (having a theoretical CA content of 8·6 µgm.) gave a yield of 85 per cent. Smaller proportions of insulin gave somewhat lower yields (for example, with 44 µgm. insulin + 944 µgm. α-amylase, that is, a cyst(e)ine content of 0·51 per cent, the yield was only 60 per cent). Assuming that it might have been possible to 'lose' up to 50 per cent of about 4 µgm. of CA in a total load of 1 mgm. protein hydrolysate, the presence of a single half-cystine residue might have been missed in a protein with a molecular weight of 85,000 or more, and the possible presence of one disulphide bond might have been missed in proteins with molecular weight of 170,000 upwards. It seems, from the known molecular weights of the proteins investigated, that this eventuality is out of the question.

We thank those who co-operated in this work by sending us samples of purified exo-enzymes, as listed in Table 1, and those who sent us strains of bacteria, as recorded in Table 2.

LIQUEFACTION OF GELATIN BY SOME *STREPTOMYCES*

By Prof. A. CAPRIOTTI

Istituto di Microbiologia Agraria e Tecnica dell'Università di Perugia

THE cultural media used for the liquefaction of gelatin in taxonomic investigation of *Streptomyces* are often of different composition. In fact, Waksman and Curtis[1], Waksman[2], Millard and Burr[3], Frommer[4], Shinohu[5], use plain gelatin. Lindenbein[6], Corbaz *et al.*[7], Baldacci *et al.*[8], Kurtzner[9], Gause *et al.*[10], Hoffmann[11], Frommer[4], use gelatin with peptone and glucose. Shinohu[5] uses gelatin with peptone, beef extract and sodium chloride. Kzainsky[12], Jensen[13] and Taber[14] use gelatin with mineral salts and Gordon *et al.*[15] gelatin with agar, beef extract and peptone.

During a systematic study of several *Streptomyces* isolated from the soil and from other materials, I have performed many experiments in order to compare the media used by different authors on the production of melanoid-soluble pigments, and the liquefaction of the gelatin, and assimilation of carbohydrate and nitrogen compounds. The results obtained on the production of melanoid-soluble pigments have already been published[16].

This article reports the results on the gelatin liquefaction assay. The strains of *Streptomyces* were the same as those used in the investigation of soluble melanoid pigments[16]. The assay of gelatin liquefaction was performed by the stab method in test tubes of 150 × 15 mm., containing 20 ml. of gelatin (Difco) base medium, sterilized at 120° C. for 20 min. The inocula were made with a sterile needle using sporulate cultures obtained in tubes

N, no growth; —, growth but negative liquefaction; ·, beginning of liquefaction; S.T., sterilized together; figures, mm. of liquefied gelatin; plain gelatin, gelatin 15 gm. dist. water 100 ml.

with yeast extract malt agar[17]. After inoculation, the tubes were maintained at 20° C. and the observations were carried on each second day for a period of two months.

Table 1 shows the results obtained on 6 gelatin media with and without glucose and peptone, sterilized together or separately. The best results, regarding the rate of liquefaction, were obtained on plain gelatin and on gelatin with peptone and glucose. No liquefaction was observed for Strain 399 on gelatin and glucose sterilized separately and for the Strain 254 on gelatin and glucose sterilized together.

Table 2 records the results on gelatin with increasing doses of glucose. It may be deduced that the presence of glucose in the media influences the liquefaction especially if it is sterilized together with gelatin. Strains 399, 254, 328, 1 and *B*171, in fact, showed themselves incapable of producing liquefaction in gelatin 20 per cent and glucose 5 per cent. Strains 135 and 1 did not produce liquefaction in gelatin 20 per cent and glucose 10 per cent sterilized separately. On gelatin 20 per cent and glucose 10 per cent sterilized together 9 strains of the 10 studied did not grow. On this medium the growth of Strain 361 was only observed, but it did not liquefy.

As regards the rate of liquefaction, taking into account the technique used for the inoculum, I might add that it is very variable and inconstant. In plain gelatin some strains began even a month after the inoculum while when glucose was added to the gelatin some other strains liquefied even more slowly.

Table 3 shows the results in media with gelatin and different types of sugars and other compounds. It may be deduced that all the strains tested showed themselves capable of liquefying plain gelatin 15 per cent after 20 days from the inoculum. In gelatin 15 per cent and glucose 2 per cent sterilized together, liquefaction did not occur in Strains 64 and 254 even after 50–60 days from inoculum. Furthermore, Strain 64 liquefied very poorly gelatin with maltose and gelatin with lactose. On gelatin 15 per cent with D-xylose 2 per cent growth and liquefaction were observed with Strain 361 only. On gelatin 15 per cent with sodium nitrite 1 per cent sterilized together, Strains 135, 511, 512, and 64 did not grow at all; and Strains 135, 254 and 328 grew after 50 days from inoculation. On gelatin 15 per cent with sodium nitrate 1 per cent the results were like plain gelatin 15 per cent; but on gelatin 15 per cent with sodium nitrate 1 per cent and glucose 2 per cent, no liquefaction was observed with Strain 254 and a delay of liquefaction with Strains 512, 135 and 1.

In order to interpret the facts observed, some determinations of *p*H and redox-level were carried out before and after sterilization of the media prepared with three different types of gelatin (Difco, C. Erba and D.G.F.).

Redox potentials (by potentiometer and colorimetric methods) did not reveal appreciable variations in all media used, while the values of *p*H tended to become lower during sterilization.

This fact is in relation to the types of gelatin and to the types of sugars (greater with D- and L-xylose and with glucose than with sucrose, maltose, lactose, raffinose). On plain Difco gelatin 15 per cent the *p*H was 6·68 before the sterilization and 6·46 after the sterilization. On Difco gelatin 15 per cent and glucose 2 per cent, 6·59 and 6·02; on Difco gelatin 15 per cent and glucose 10 per cent, 6·52 and 5·54; on Difco gelatin 15 per cent and D-xylose (or L-xylose) 2 per cent, 6·67 and 5·62; on Difco gelatin 15 per cent and sodium nitrite, 1 per cent, 6·79 and 7·22. Similar results were also observed with C. Erba gelatin and with D.G.F. gelatin used as control. Moreover, gelatin sterilized together with D-xylose, or L-xylose, or glucose, become brown as a result of condensation of amino-acids and reducing sugars (Maillard theory) or because of a decomposition of sugars to furfuraldehydes or similar compounds (active-aldehyde theory)[18]. To these compounds and to the consequent reduced values of *p*H can also be attributed the lack of growth on gelatin 15 per cent sterilized together with glucose 10 per cent or with D-xylose 2 per cent.

No growth of some strains on gelatin 15 per cent plus sodium nitrite 1 per cent can be found in the real inhibitory effect of this salt[19]. The *p*H was not reduced after sterilization and the change of colour to brown-greenish in the medium reveals the reaction from amino-acids and sodium nitrite.

The facts observed lead to the conclusion that the presence of sugars in media may give completely negative results or may influence the rate of liquefaction. The rate of liquefaction depends on the technique of inoculation, the temperature of cultivation, the quantity of inoculum and also on the gelatin. Gelatin is a very complex organic substance, and its constituents change with materials and techniques used to obtain and to purify it.

With regard to the necessary uniformity of the methods of study of the Actinomycetes, the results obtained lead me to prefer the use of plain gelatin for a criterion of the identification. It must be added that this may give results which are not always constant because of the variable composition of gelatin, particularly in regard to the rate of liquefaction.

CARRAGEENIN AS A PROTEIN PRECIPITANT

By K. J. TURNER and B. J. MAGNUSSON

Commonwealth Serum Laboratories, Melbourne

SINCE the observation of Oncley[1] that dextran sulphate, under specific conditions, can be used as a precipitant for β-lipoproteins, increasing attention has been paid to reactions involving sulphated polysaccharides with serum proteins. After considering a range of polyanions, Bernfeld[2,3] concluded that sulphated amylopectin, with three sulphate groups per repeating unit, was the most satisfactory precipitant for β-lipoprotein. While the mechanism of the reaction is unknown, these lipoprotein–polysaccharide complexes may be broken by centrifugation in a saline gradient and the β-lipoprotein liberated from polysaccharide contaminant. Lipoproteins have successfully been assayed by this method and isolated for chemical characterization. Alternatively, direct nephelometric measurements of the turbidity of these complexes in dilute suspensions provides a measure of the β-lipoprotein concentration.

Serum proteins readily complex with certain sulphated polysaccharides, and the complexes so formed can normally be dissociated by high concentrations of salt. However, the subsequent removal of the polysaccharide from proteins of average density is difficult. Miller[4] precipitated an abnormal serum macroglobulin with heparin and dissociated the complex in concentrated saline. The macroglobulin was not chemically characterized presumably due to the incomplete removal of the liberated heparin.

The purpose of this article is to report the use of another sulphated polysaccharide, carrageenin, which, in addition to being an effective precipitant is readily removed from the protein carrageenin complex.

Carrageenin was extracted from the red alga *Chondrus crispus* by the method of Smith *et al.*[5]. Separation into the κ- and λ-fractions was accomplished by precipitation with 0·25 *M* potassium chloride, the former being insoluble, the latter soluble in this solvent. Three sub-fractions of κ- and five sub-fractions of λ-carrageenin were obtained by gradient addition of 95 per cent ethanol. The conditions of fractionation are given in Table 1, together with the intrinsic viscosities of the sub-fractions (labelled $\lambda 1$–$\lambda 5$ and κ_1–κ_3) measured in phosphate buffer μ 0·15 *p*H 6·8.

Table 1. FRACTIONATION OF CARRAGHEENIN

Fraction	Alcohol conc. vol. per cent	Amount precipitated per cent of total	$[\eta]$ dl./gm.
λ1	0–12	8·6	6·5
λ2	12–24	4·4	19·9
λ3	24–36	70·0	13·0
λ4	36–48	21 0	8·8
λ5	48–60	1 0	2·7
κ_1	0–30	34 0	8·8
κ_2	30–45	26·0	6·4
κ_3	45–75	40 0	9·7

Fetuin, isolated by ammonium sulphate precipitation of fœtal calf sera, has been shown to contain two α_1-glycoproteins[6,7], one of which is a macroglobulin[8]. The major glycoprotein ($S^0_{20w} = 3·2$) was separated from the macroglobulin ($S^0_{20w} = 20·2$) by high-speed centrifugation[8]. Physical characterization of these compounds[9] showed the major component to be isoelectric at pH 4·1 and the macroglobulin at pH 4·7. This difference suggested that the two components might be fractionated by precipitation with carrageenin over a pH range. Fetuin is readily soluble in 0·25 M potassium chloride whereas κ-carrageenin is not; hence κ-carrageenin–fetuin complex when dispersed in 0·25 M potassium chloride could yield a protein solution and a carrageenin precipitate.

1 ml. of a 0·5 per cent solution of κ_2-carrageenin was slowly added with stirring to 40 ml. of a 1 per cent solution of fetuin buffered at various pH values between 4·0 and 5·5. The buffers were mixtures of sodium acetate, acetic acid and sodium chloride at a total ionic strength of 0·1 and the carrageenin was dissolved in the appropriate buffer prior to addition. The precipitate, which formed after standing for 3 hr. at 0° C., was removed by centrifugation and dissolved in a minimal volume of pH 7·0μ = 0·1 buffer. The soluble complex and the original supernatants were then dialysed overnight with stirring against 0·25 M potassium chloride at 0° C. and the resulting precipitates were removed by centrifugation. The clear supernatants were examined in the Spinco model E ultracentrifuge and the composition of the components assayed by area computation corrected for cell dilution.

The results (Table 2) show that while both globulins were precipitated at each pH there was evidence of concentration of the macrocompound at specific pH values. This effect was optimal at pH 4·5 where a six-fold concentration of the macroglobulin was effected. Moreover, the macroglobulin was absent in the supernatant at this pH. Paper electrophoresis followed by selective staining with bromphenol blue and reduced Schiff's reagent showed that the precipitated material was a glycoprotein migrating as an α_1-globulin. Complete absence of contaminating carrageenin was indicated by negative staining with toluidine blue. Furthermore, the carrageenin removed from the complex with 0·25 M potassium chloride, when hydrolysed with acid, was shown to be ninhydrin negative. Thus, glycoprotein was absent, thereby confirming the efficiency of the potassium chloride partition. We have used κ-carrageenin as above to isolate β-lipoprotein from human serum and have found that 0·25 M potassium chloride is likewise effective in breaking the polysaccharide–lipoprotein complex.

Table 2. EFFECT OF pH ON GLYCOPROTEIN PRECIPITATION BY κ_2-CARRAGEENIN

pH	Percentage $S^0_{20w} = 3·2$ glycoproteins	 $S^0_{20w} = 20·2$ glycoproteins
4·0	75	25
4 5*	63	37
4 7	85	15
5·0	68	34
5·5	87	13
Control fetuin	94	6

* Precipitate formed at pH 4·5 redissolved and reprecipitated to give the composition 66 per cent $S^0_{20w} = 3·2$ and 34 per cent $S^0_{20w} = 20·2$ glycoproteins.

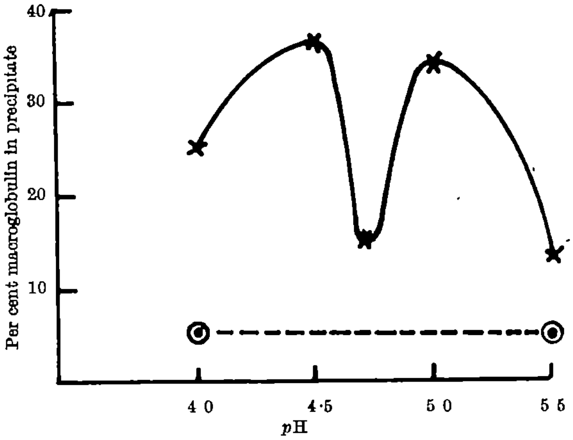

Fig. 1. Percentage of macroglobulin in the κ_2-carrageenin–fetuin precipitate as a function of pH. The dotted line shows the percentage of macroglobulin in the original fetuin sample

If the concentration of the macroglobulin (Table 2) is plotted against the pH of precipitation (Fig. 1) a trough is shown at pH 4·7, the isoelectric pH of the macroglobulin. Were the reaction to be ionic one would expect a rapid decline in the percentage of the macroglobulin precipitated on the alkaline side of the isoelectric pH. Since this did not occur the reaction mechanism is probably first ionic followed by a second stage of more complex nature.

Further work is planned to cover more completely the pH-range in the region of 4·1 the isoelectric pH of the major glycoprotein fraction. Attention will also be paid to the physical characteristics of the polysaccharide used since κ_1- and κ_3-carrageenin, both of which have higher intrinsic viscosities than κ_2, gave precipitates containing proportionally less of the macroglobulin. By inference, λ5-carrageenin of low intrinsic viscosity (2·7 dl./gm.) might be a more satisfactory fraction to use as a protein precipitant, but λ-carrageenin is soluble in 0·25 M potassium chloride. This limitation could be overcome by the use of the enzyme carrageenase[10]. The application of these observations to a study of both normal and abnormal serum macroglobulins is apparent since it may provide a mechanism for the isolation of these important proteins.

We thank Mr. G. Wilson for the ultracentrifuge analyses, Mr. C. Guthrie for the preparation of the carrageenin fractions, Miss C. M. Gilbo for the paper electrophoresis studies, and Dr. J. F. O'Dea for advice.

COLCHICINE-INDUCED POLYPLOIDY IN *MUSA*

By NADER G. VAKILI

Division of Tropical Research, Tela Railroad Co., La Lima, Honduras

PREVIOUS work on bananas has shown that: (*a*) in Nature the polyploid seedlings are formed by the union of a haploid pollen gamete ($n = 11$) with a restituted polyploid egg cell[1]; (*b*) the edible bananas of commerce are triploid plants which have descended from parthenocarpic diploids and seeded species by means of hybridization, mutation, and selection by man throughout centuries past[2]. A method of obtaining tetraploids from diploids could have practical advantages in a banana-breeding programme involving polyploid plants, and where there are problems of male and female sterility in some of the diploid parents[3]. This article describes a method of colchicine application to diploid *Musa* seedlings and the effect of the colchicine treatment on the growth of the resulting polyploid seedlings.

Seeds were obtained from an open-pollinated bunch of *M. balbisiana* Colla and from a hand-pollinated cross between *M. balbisiana* × *M. acuminata* Colla sub-sp. undetermined. After harvesting, seeds were dried and stored in polyethylene bags. Stored seeds were soaked in water for 5 days at 35° C. before being placed between layers of cheese cloth buried in a mixture of equal parts of clay loam, sand and vermiculite. Germination, as indicated by the displacement of the micropilar plug, commenced 9–10 days after planting. Soaking and planting dates of three groups of seeds were distributed over a period of three days so that seedlings of varying age could be selected for colchicine treatment.

The seedling stages used in this work were: (I) intact seed; (II) seeds with dislodged micropilar plugs, the first visible stage of seed germination; (III) seeds with emerged seedlings showing epicotyl and the beginning of a primary root; (IV) seedlings with coleoptile-like first leaves 1–2 cm. long[4] and with 3–5 adventitious seminal roots 1½–3 cm. long (Fig. 1).

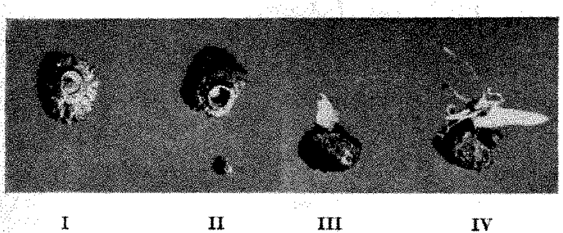

Fig. 1. Stages of seedling development in *M. balbisiana* Colla: (I) intact seed; (II) first visible stage of seed germination with dislodged micropilar plug; (III) seedling showing epicotyl and the beginning of a primary root; (IV) seedling with coleoptile-like first leaf and adventitious seminal roots

The treatments consisted of submerging the seeds or seedlings, at different stages of growth, in various concentrations of aqueous colchicine solution for given times. After treatment, seedlings were washed with water and transplanted to flats. Each treatment included 100 seeds or seedlings which were planted in four replicates in a randomized block design. Observations on the emergence of the first leaves above the soil-level were made at 2–3-day intervals. After two months, the seedlings were transplanted into black plastic pots, and chromosome counts were made by root-tip smear in aceto-orcein stain. Chromosome counts were made sporadically until seedlings were 10 months old and before transplanting to the field for further observations. (I thank Dr. M. O. Thomas for help in counting the chromosomes.)

Colchicine treatment increased mortality, retarded growth and induced doubling of the chromosome complement in *M. balbisiana*. These responses depended on the developmental stage of the seedling, the concentration of the colchicine solution and the duration of exposure of the seedlings to the solution (Tables 1 and 2). At emergence, the tetraploid and the octaploid seedlings were easily distinguished from the diploids. The coleoptile-like first leaf-sheath of the polyploid seedlings was short and thick, giving the emerging seedlings a much greater diameter than the diploids. The lamina of the second, third and sometimes the fourth leaf was either absent or was greatly reduced in size. The treated seedlings were slow to emerge; but after emergence the unaffected diploid seedlings resumed their normal growth while those which had been induced to polyploidy remained retarded. The length and the abundance of roots also declined as ploidy was increased. The reduction in, or the absence of, a root system seemed to be one of the factors responsible for the death of the octaploid-appearing seedlings.

The colchicine-induced tetraploids resembled tetraploid seedlings obtained by hybridization. The tetra-

	20	1·1	21·5	6·1	61·3

* Two months after emergence.

† See text and Fig. 1 for seedling stages.

ploids had drooping thick leaves with short petioles, but appeared sturdier than the diploids (Fig. 2). The surviving octaploids either retained their higher ploidy, with characteristic brittle, deformed and thick leaves (Fig. 2) or reverted to tetraploids. The reversion from tetraploid to diploid was easily recognized by the changes in shape and thickness of leaves, length and thickness of petioles, and the degree of bending of petioles. Root-tip smears of some of the tetraploid-appearing seedlings showed a diploid chromosome number suggesting a chimera of tetraploid aerial parts with diploid root system; however, after a month or two the newer leaves of these plants displayed diploid characteristics (Fig. 3). This fact indicated that the root-tip chromosome counts had shown reversion before it could be detected in the aerial parts of the plants.

The unsoaked intact seeds were less affected by colchicine treatment than seeds in early stages of germination (stages II and III in Table 2). This was most likely due to the presence of the thick seed coat and the quiescent state of the embryos. Seeds at their earliest visible stage of germination (stage II, Fig. 1) were the most susceptible to the effects of colchicine. Furthermore, treatment at this stage produced comparatively more octaploid- than tetraploid-appearing seedlings. As seedlings grew through stages III and IV (Fig. 1), mortality decreased while the percentage of tetraploids formed increased. When seedlings slightly older than those of stage IV were treated, the effect of the colchicine was superficial and the ploidy of the growing point was unchanged. The great majority of these seedlings remained diploid.

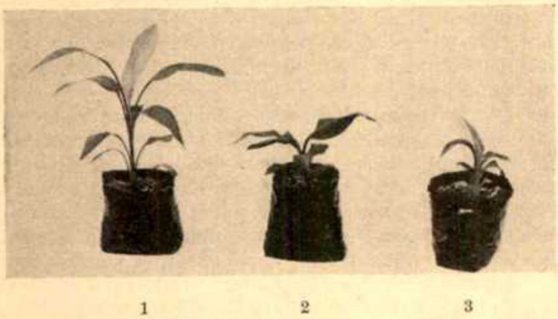

Fig. 2. Four-month-old seedling from a cross between *M. balbisiana* × *M. acuminata* : (1) diploid ($2n = 22$); (2) tetraploid; (3) octaploid

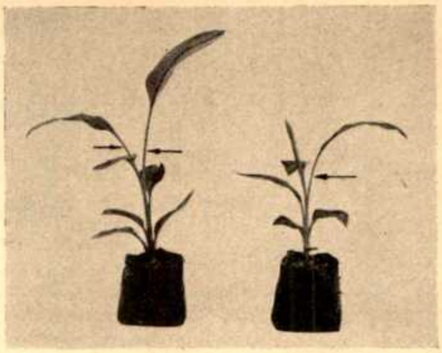

Fig. 3. Reversion from tetraploid characteristics to that of diploid in *M. balbisiana* seedlings. Arrows indicate leaves displaying diploid features

These investigations show that colchicine treatment of diploid *Musa* seedlings at certain stages of development results in the formation of a high percentage of tetraploids having thick leaves, short petioles and a drooping habit. The growth-rate of the tetraploid seedlings was much slower than that of the diploids. Many of the octaploid and tetraploid seedlings reverted to tetraploids and diploids respectively as the plants grew. This reversion could be detected in the appearance of the aerial parts of the plants and was substantiated by the root-tip chromosome counts.

GENETIC HETEROGENEITY OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

By Prof. PAUL A. MARKS and JULIA BANKS
Department of Medicine, Columbia University, College of Physicians and Surgeons, New York City
AND
Prof. RUTH T. GROSS
Department of Pediatrics, Albert Einstein College of Medicine, Yeshiva University, New York City

THE inherited deficiency of glucose-6-phosphate dehydrogenase among human subjects is widespread in occurrence and varies markedly in frequency among different population groups[1-6]. There is evidence to suggest that the enzyme defect may not reflect the same genetic alteration in all affected persons (the term 'affected persons' refers here to those with glucose-6-*P* dehydrogenase deficiency). The activity of the enzyme in red cells and leucocytes of affected males of Greek and Southern Italian extraction has been compared with American Negro males, and found to be significantly lower among the Caucasians[7]. The decreased thermostability of glucose-6-*P* dehydrogenase activity in lysates of erythrocytes and leucocytes prepared from the affected Caucasian males is more marked than that from affected Negro males[8]. Studies of the properties of the dehydrogenase purified from red cells of normal subjects and affected Negro males failed to reveal any differences in the characteristics of the catalytic site, electrophoretic mobility or thermostability[9,10]. Kirkman[11] has reported that glucose-6-*P* dehydrogenase purified from red cells of a Caucasian subject with chronic non-spherocytic hæmolytic anæmia differed in the properties of its catalytic site from the enzyme of normal subjects. We report in this

Table 1. COMPARISON OF THE PROPERTIES OF GLUCOSE-6-*P* DEHYDROGENASE OF NORMAL SUBJECTS AND AFFECTED MEMBERS OF THE B. FAMILY

* A unit of enzyme activity is defined as the change of 1·00 optical density unit/min./gm. of hæmoglobin for erythrocytes (*RBC*) or per 10^9 cells for leucocytes (*WBC*) or per mgm. protein for purified enzyme.

† Stability of glucose-6-*P* dehydrogenase (G6*PD*) during incubation of hæmolysates was determined according to previously described procedures (ref. 8) and is expressed in terms of the per cent of the initial activity remaining after incubation for 1 hr. at 37°.

‡ These properties refer to the fraction prepared by the first technique. For detailed description of the procedures used to obtain these data see ref. 10. 2DG6*P* is 2-deoxyglucose-6-phosphate.

§ Values for enzyme-levels in red cells and white cells of control subjects represent the mean ± one standard deviation of 85 determinations. All other values are the mean of 7 determinations (ref. 7). For comparison with values indicated in the table, the following represent the average ± one standard deviation for red cell enzyme-levels in various groups of affected subjects: Negro males, 2·7 ± 1·5 units; Negro females, 6·9 ± 2·3 units; Caucasian males, 0·4 ± 0·4 units, and Caucasian females, 6·8 ± 3·2 units; and for white cell enzyme-levels: Negro males, 38·1 ± 11·6 units; Caucasian males, 14·0 ± 5·9 units; values for Caucasian and Negro females are within the normal range (ref. 7).

‖ For the B. family each value represents the average of at least two separate determinations.

article our investigations on the occurrence of glucose-6-*P* dehydrogenase deficiency in a Caucasian family of northern Italian origin in which the expression of the defect among males differs from previously observed affected male subjects. Furthermore, the enzyme purified from erythrocytes of three members of this family has characteristics of its catalytic site and electrophoretic mobility which are different from those of the enzymes of normal and other affected subjects studied.

In the course of studying the incidence of glucose-6-*P* dehydrogenase deficiency in northern Italy, a male, A. B., was found to have a moderate decrease in the level of the red cell enzyme comparable with that generally encountered among affected females and higher than that characteristic of affected males. Sex chromatin studies on leucocytes and buccal mucosa of this subject indicated a normal male pattern. In seven members of the family of A. B., blood was obtained for determination of red cell glucose-6-*P* dehydrogenase activity. The defect appeared to be inherited from the mother. The father and a paternal uncle had normal enzyme-levels. Moderately deficient levels of red-cell glucose-6-*P* dehydrogenase were present in the mother (M. G.), a maternal uncle (Q. G.), a maternal aunt (A. G.) and the sister (G. B.) of the propositus (Table 1). Another maternal aunt had normal enzyme-levels and there were no other siblings. While the findings in the B. family are compatible with sex-linkage as the mode inheritance of glucose-6-*P* dehydrogenase deficiency[1-6], the data are too meagre to permit any conclusions on this point. All subjects tested had normal values for hæmoglobin, red and white cells and reticulocytes and no history of anæmia.

The leucocyte glucose-6-*P* dehydrogenase activity was tested in the two affected males (A. B. and Q. G.) and one affected female (G. B.) and were within the normal range (Table 1). Previous investigations of leucocyte glucose-6-*P* dehydrogenase-levels have revealed a marked reduction among affected Caucasian males, slightly reduced to normal values among affected Negro males, and normal levels among affected females of both Negro and Caucasian origin[7].

The stability of glucose-6-*P* dehydrogenase activity during incubation of hæmolysates prepared from subjects A. B., G. B. and Q. G., was found to be comparable with that of subjects with normal levels of the enzyme (Table 1). No evidence was found for an activation of the enzyme on addition of stroma prepared from normal red cells. The methods used to test for stromal activation of glucose-6-*P* dehydrogenase were similar to those described by Ramot *et al.*[12].

Sufficient blood for purification of red cell glucose-6-*P* dehydrogenase was obtained from A. B., G. B. and Q. G. In addition, preparations of the enzyme purified from erythrocytes of normal and various other affected subjects were studied concomitantly. The method used in purification of glucose-6-*P* dehydrogenase has been described in detail[10], and yields an ammonium sulphate fraction which is a 300- to 500-fold purified preparation of the enzyme in a yield of 35–45 per cent of the initial activity (first technique). A further purification was achieved by treating this ammonium sulphate fraction with 'Sephadex', diethylaminoethyl cellulose (DEAE) column chromatography, and precipitating the enzyme from the eluate of the DEAE column with ammonium sulphate. These additional steps provide a preparation 3,000- to 5,000-fold purified in a yield of 15–20 per cent of the original enzyme activity (second technique). All the studies with purified glucose-6-*P* dehydrogenase were performed with the original ammonium sulphate preparation unless otherwise indicated. In the course of the preparation of glucose-6-*P* dehydrogenase from erythrocytes of A. B., G. B. and Q. G., no apparent differences from the enzyme of normal subjects were noted with respect to the fractionation of the enzyme at various stages in the purification procedure[10] (Table 1).

The enzyme preparations from A. B., G. B. and Q. G., have Michaelis constants for triphosphopyridine nucleotide (TPN), and for glucose-6-*P* (measured at *p*H 7·6 and *p*H 8·4) which are higher than normal (Table 1). The decreased affinity for TPN is more striking than that for glucose-6-*P*. The enzyme preparations from these subjects did not appear to be significantly altered in affinity for nicotinamide, a competitive inhibitor of TPN, or 2-deoxyglucose-6-*P*, which can serve as a substrate for the enzyme (Table 1). No differences from the normal enzyme were noted in the *p*H optima curves.

The electrophoretic mobility of the purified preparations of glucose-6-*P* dehydrogenase in starch gel, in 0·025 *M tris* buffer, *p*H 7·6 were studied using the methods described in detail elsewhere[10]. The electrophoretic mobility of the A. B. and Q. G. preparations were indistinguishable, and both migrated

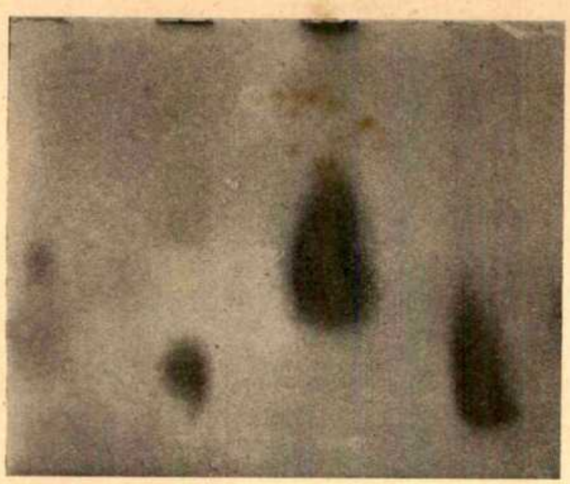

Fig. 1. Difference in electrophoretic mobility in starch-gel of glucose-6-*P* dehydrogenase of normal subjects (Nos. 1 and 5), and O.G. (No. 3) and A.B. (No. 7). The origin is at the top of the figure and migration proceeded towards the anode. The location of the dehydrogenase was identified by specifically staining for the enzyme (ref. 10). The larger size of spots Nos. 5 and 7 reflect a greater amount of enzyme applied

at a faster rate than the enzyme from normal subjects (Fig. 1). (The G. B. preparation of glucose-6-*P* dehydrogenase was not available in sufficient amount for the electrophoretic studies, and only the A. B. preparation was obtained in sufficient quantity to permit purification through to the second technique.) The rate of migration of the fraction from A. B., prepared by the second technique, was slower than that prepared by the first technique and approached, but was still faster than, that of the normal enzyme. The fractions of normal enzymes prepared by the two techniques had identical rates of electrophoretic mobility. Michaelis constants for TPN and glucose-6-*P* of the fractions of A. B. prepared by the two techniques were similar. There are several possibilities that could account for the faster rate of electrophoretic migration of the fractions of A. B. and Q. G., prepared by the first technique, including a difference in molecular weight or an alteration in net charge resulting from either a difference in amino-acid composition or an associated small charged molecule. No results have been obtained that permit conclusions on this point.

This study provides evidence for a variant of glucose-6-*P* dehydrogenase deficiency which differs from that observed in other subjects in respect to the level of the enzyme in affected males, and to the properties of the catalytic site and the electrophoretic mobility of the enzyme. These results suggest that glucose-6-*P* dehydrogenase deficiency in man is genetically heterogeneous and can be explained by one of several genetic mechanisms. Glucose-6-*P* dehydrogenase deficiency in the B. family might be due to a non-sex-linked gene and all the affected subjects studied are heterozygotes. Alternatively, the difference in the enzyme defect in the B. family and that of other affected subjects might reflect different mutations on the *X*-chromosome locus for glucose-6-*P* dehydrogenase or differences in genes which affect various quantitative aspects of the formation and function of this enzyme.

AN ASSOCIATION BETWEEN SOIL CONDITIONS AND DENTAL CARIES IN RATS

By T. G. LUDWIG and R. S. MALTHUS

New Zealand Medical Research Council

AND

W. B. HEALY

Soil Bureau, Department of Scientific and Industrial Research, New Zealand

REPORTS have previously been given of a variation in prevalence of dental caries which occurred between children resident in the adjacent towns of Hastings and Napier in Hawke's Bay, New Zealand[1,2]. It was suggested that the lower caries in Napier children may have been related to the consumption of vegetables grown on the recent marine soils on which the city is largely situated. Detailed analyses have shown that notable differences occur in the mineral content, and particularly in the molybdenum content, of vegetables grown on Napier and Hastings soils, and these differences are such that it seems possible they could influence the caries susceptibility of local children.

To test this hypothesis, an experiment has been undertaken to determine the effect on prevalence of

Table 1. CARIES PREVALENCE IN RATS FED A CARIOGENIC OR CARIOGENIC ASH-SUPPLEMENTED DIET

Group	Diet fed	No. of animals	Mean body-weight (gm. per animal*)	Mean No. of carious lesions per animal	Mean caries severity score per animal

Results on oven-dry basis

caries of the ash of vegetables grown on soils of Napier and Hastings when added as supplements to a cariogenic control diet fed to albino rats. The vegetable chosen was the French bean (*Phaseolus vulgaris*, var. The Prince) since this best reflected the characteristic differences between Napier and Hastings vegetables. Approximately a half-ton of French beans was grown on market gardens in Napier, and a similar quantity in Hastings. The beans (green pods with seeds) were dried at 100° C. and then ashed as required at 500° C.

Analysis of these beans confirmed the mineral differences previously found[2]. The molybdenum content of Napier beans was 12·3 p.p.m. (180 p.p.m. on ash basis) and of Hastings beans 1·0 p.p.m. (15 p.p.m. on ash basis).

The present experiment involved the comparison of prevalence of caries in four groups of albino rats (Wistar strain), each group initially containing 20 male animals. Diets were as follows:

Group 1: Control diet.
Group 2: Control diet 99 per cent, plus Napier bean ash 1 per cent.
Group 3: Control diet 99 per cent, plus Hastings bean ash 1 per cent.
Group 4: Control diet 99 per cent, plus Hastings bean ash 1 per cent, the molybdenum content of this ash having been increased to a concentration equivalent to that found in Napier bean ash.

The cariogenic control diet consisted of: sucrose, 68 per cent; casein, 25 per cent; salt mixture, 185 (ref. 3), 3 per cent; soybean oil, 3 per cent; and vitamin mixture, 1 per cent. The type of salt mixture used in the diet was selected because it contained no additions of minor elements.

The addition of molybdenum to the Hastings ash in Group 4 was made because this element gave the most pronounced difference in the Napier and Hastings ashes, and there is evidence which suggests that it may have a caries-reducing effect[4-6]. This additional molybdenum was added to the Hastings ash in the form of an aqueous solution of ammonium molybdate, the ash afterwards being re-dried.

The experimental animals in the four groups were born to mothers fed since mating the same diet afterwards fed to their offspring, because it was considered important that the groups of experimental animals should be exposed both pre- and post-natally to any mineral influences from the diet. Allocation of animals to groups had therefore to be made on the basis of the mothers rather than of the offspring. This was done by taking 40 virgin does and dividing them by the use of random numbers into four equal groups. Each group was placed in a galvanized cage with two bucks of known fertility and fed from the day of mating the appropriate experimental diet. For the second half of pregnancy each doe was isolated in a stainless steel breeding box with shredded paper added for nesting. Throughout the experiment the animals were given distilled water for drinking via stainless steel drinking tubes. Reproductive performance was good in all groups. The litters were weaned at 27 days, and at 31 days twenty male offspring were drawn from each of the four groups of mothers to form the various experimental groups. Twenty male offspring drawn from mothers fed the control diet only formed Group 1; twenty male offspring drawn from mothers fed the control diet plus the Napier bean ash formed Group 2, and so on. The selected offspring were transferred to individual polyethylene cages with stainless steel grids (Malthus, R. S., unpublished results) and each group was maintained on the appropriate diet for a further period of 12 weeks. Animals were weighed at weekly intervals. At 8 and 12 weeks after weaning examinations of the teeth of the animals were made using a mouth prop with ether anæsthesia. At 8 weeks no carious lesions were seen, but at 12 weeks all groups had developed lesions and the experiment was terminated.

The animals were killed with coal gas, the heads removed, autoclaved and cleaned of soft tissue. The jaws and teeth were stained by Keyes's method[7] and scored for caries by Davies's method[8]. The teeth were afterwards ground and caries scoring verified by a method corresponding to Carr's[9].

At the termination of the experiment it was found that the body-weights of animals in Group 1 receiving the control diet only were significantly lower than those in the other three groups receiving the ash-supplemented diets. This may have been due to the marginal levels of calcium and phosphorus in the control diet. During the experiment two animals in Group 1 died under ether anæsthesia, and one was found dead, the cause of death being unknown.

Table 1 shows the caries scores for the four groups of animals. It was found that animals receiving the control diet only (Group 1) had more caries than those in the other three groups receiving the ash-supplemented diets. The most interesting finding was that animals receiving the control diet supplemented with the Napier ash (Group 2) had significantly less caries than those receiving the control diet supplemented with Hastings ash (Group 3). It was found also that animals receiving the control diet supplemented with Hastings ash (Group 4), the molybdenum content of which had been increased, had less caries than those receiving the Hastings ash supplement alone (Group 3).

It will be noted from Table 1 that while caries prevalence was reduced in the animals receiving the supplement of Hastings ash plus molybdenum (Group 4), the caries score for these animals was somewhat higher than for those receiving the supplement of Napier ash (Group 2). The reason for this difference is not clear and may involve a number of factors including interactions between molybdenum and other elements.

Analyses of diets are shown in Table 2. As would be expected, the levels of various elements in the ash-supplemented diets are higher than in the control diet. No differences occur in the levels of major elements in diets supplemented with Napier or Hastings ash. Some differences occur in the levels of aluminium, titanium and manganese; but the most striking difference in micro-elements is still in the molybdenum content. As the molybdenum in the control diet is low, the molybdenum content of the diets supplemented with Napier or Hastings ash closely reflects the molybdenum differences originally shown for the beans.

The experiment has shown that the mineral ash of a vegetable grown on the marine soil at Napier reduces caries prevalence in rats, and that this effect is likely to be related to its relatively high content of molybdenum possibly in association with other elements. This result supports our hypothesis that the lower caries prevalence in Napier children as compared with Hastings children is the result of soil differences in these areas which are reflected in the mineral composition of vegetables.

This investigation was supported in part by a U.S. Public Health Service Grant (*D*965-C2). We also thank Glaxo Laboratories and Roche Products, Ltd., for their support.

CROP YIELDS IN EXPERIMENTS AND ON FARMS

By BRUCE DAVIDSON

Division of Land Research and Regional Survey, Commonwealth Scientific and Industrial Research Organization, Canberra

WHEN attempts are made to assess the agricultural potential of new areas of agricultural land, or when a new crop is introduced into a region where agriculture is already practised, the results of experiments are often used to establish the general yield-level of the crop.

In any strict comparison between farm yields and experimental yields the following features must be common to both the experiment and the farm crop: (1) they must be grown in the same climatic region on similar soils in the same season; (2) the species and varieties of the crop must be the same; (3) cultivation and fertilizer practices should be similar.

As a preliminary investigation of the relationship between farm yields and experimental yields it was decided to select two dissimilar crops for which the relevant information was available, the extensively grown Victorian wheat crop and Queensland sugar cane, which is cultivated intensively.

In Victoria, wheat variety trials have been carried out for a number of years at Dookie and Longeronong Colleges on 1/40 of an acre plots, using standard farm cultural practices and quantities of phosphate fertilizers (Sims, H., private communication). The area of each variety of wheat grown on farms in the counties (Moria and Lowan) in which the trials are located can be obtained, and the results of the variety trials, weighted for variety, can be compared with the average yields of the farm crops in these counties over a period of eighteen years (Arnold, V. H., private communication).

In Queensland, the Bureau of Sugar Experiment Stations has carried out a large number of trials of different varieties of sugar cane for many years in plots located in farmers' fields in all major sugar-growing areas[1]. As the area of each variety and of plant and ratoon crop for each mill district are known, the experimental yields weighted for variety, and plant and ratoon crop areas can be compared with the average farm crop yield for the mill district in which the trial is situated over a period of six years for eight districts (Young, H. E., private communication).

When farm yields were plotted against experimental yields it was found that the data for both crops lay along a Mitscherlich curve of the formula :

$$y = A(1 - e^{-bx})$$

where y = farm yield, x = experimental yield, A = the maximum farm yield obtainable with infinitely high experimental yields.

The curves and formula for each crop are shown in Figs. 1 and 2.

The most striking feature displayed by this relationship is that in years of low yield, farm yields approach experimental yields more closely than in years when yields are high. This relationship applies to both crops, although wheat is a temperate annual and in Australia is cultivated on an extensive basis, while sugar cane is a tropical perennial, and in Queensland is intensively cultivated on relatively small farm allotments.

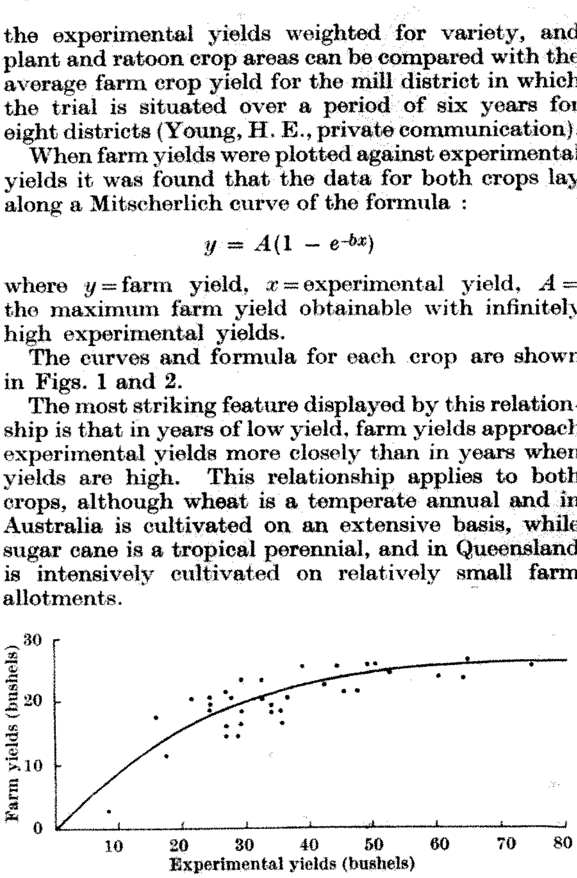

Fig. 1. Victorian wheat, 1940–59. $y = 26{\cdot}93\,(1-e^{-0.0444x}) \pm 2{\cdot}8$ bushels

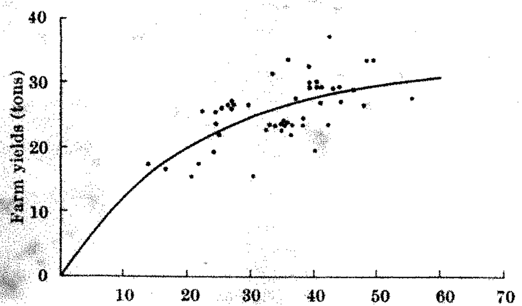

Fig. 2. Queensland sugar cane, 1954–59. $y = 32{\cdot}976\,(1-e^{-0{\cdot}0461x}) \pm 3{\cdot}8$ tons

Mean weighted farm yields as a percentage of experimental yields for the two crops were :

Victorian wheat	57
Queensland sugar cane	76

As climatic conditions, soil, fertilizer and cultural practices are the same in the experimental plots and on farms, the lower farm yield must be associated with the larger scale of farming operations or with the managerial ability of farmers. In an experiment, cultivation, sowing and harvesting are normally carried out at the correct time.

The managerial skill of farmers will vary over a wide range in any area; but even a skilled farmer, working a large area of land, is unable to carry out cultural operations over the whole area at the right time or with optimum efficiency. In favourable years the optimum timing and efficiency of operations for the experiment give exceedingly high yields which are not reflected on farms. In unfavourable years the correct timing of operations is less beneficial to the experiment because yield is largely determined by climatic conditions and experimental yields approximate to farm yields.

The exact proportion which mean farm yields form of the mean of experimental yields over a period of years will depend on the number of favourable and unfavourable years included in the period examined. The ratio will be high if there are many unfavourable years and low if there are many favourable years. In addition, the proportion is probably affected by the intensity of cropping. The smaller the area of a farm crop, the more closely experimental conditions and experimental yields are approached.

From the evidence obtained from these two crops it would seem unwise to assume that commercial crops will produce more than two-thirds of the mean yield of experiments using the same varieties, cultural practices and levels of fertilizer. Further work covering a wide range of crops and climatic conditions is necessary before a definite relationship between farm and experimental yields can be established.

EFFECTS OF X-RAYS ON THE AGEING OF SEEDS

By Dr. KARL SAX*† and Dr. HALLY J. SAX†

School of Botany, University of Oxford

It has long been known that ageing, storage at high temperatures or exposure to X-rays decreases the viability of seeds and increases the frequency of chromosome aberrations and mutations in the resulting plants[1–3]. Storage of seeds following irradiation augments the radiation effect[4–7]. The radiation effect is reduced if the seeds are stored at low temperatures[8]. Old seeds are more sensitive to X-ray than are fresh ones[9,10]. The following experiments were carried out to determine the nature of the ageing of seeds induced by irradiation.

The onion seeds used in the first tests were provided by the Charter Seed Co., from their 1960 crop. The seeds were divided into two lots. One lot was exposed to 1,000 r. of X-rays on February 15, 1961. The other lot was used as the control. Both lots were stored in an oven at 42° C. to hasten the ageing process. At intervals samples of 100 seeds of each lot were germinated on moist filter paper in a Petri dish. Root tips of the first seeds which germinated were fixed as soon as they reached the stage of the first nuclear divisions, since subsequent divisions have a lower frequency of chromosome aberrations due to the retardation or prevention of divisions in many of the progeny of cells with a high frequency of aberrations[11]. In most cases root tips were also taken from the seeds, which germinated the second day, to see if delay in germination is associated with a greater frequency of chromosome aberrations.

The root tips were fixed in alcohol acetic acid and stained in aceto-orcein. Anaphase figures were scored for chromosome bridges and acentric fragments. The early tests, based on an analysis of about 100 cells in each of four slides, gave rather uniform results as indicated by the standard errors. But as the seeds aged the variability increased with increasing aberration frequencies. The variance was also higher in the root tips of seeds which germinated the second day, due to the smaller number of division figures available —about 50 per slide. The results are presented in Table 1.

The artificial ageing did not increase the aberration frequency during the first three weeks, but with subsequent ageing the aberration frequency increased rapidly and at an accelerated rate in the control seeds. The aberration frequency in the X-rayed seeds seemed to increase earlier with ageing, but not so much as would be expected if the irradiation had simply aged the seeds to the level that the controls had reached

Table 1. CHROMOSOME ABERRATIONS PER 100 CELLS IN FIRST DIVISION OF ONION ROOT TIPS AT SUCCESSIVE DATES OF GERMINATION FOLLOWING IRRADIATION WITH 1,000 R. OF X-RAYS ON 2/15

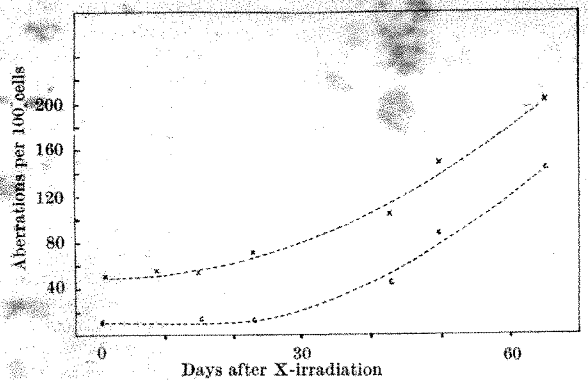

Fig. 1. The frequency of chromosome aberrations in root tips of control and X-rayed seeds germinated at intervals after storage in an oven at 42° C. to hasten ageing

after about six weeks of ageing. Although the differences between the aberration frequencies of the X-rayed seed and the control seed increases with ageing, the relative increase on the X-rayed seed with ageing is less than that of the controls. But when the aberration frequencies of the X-rayed and the control seeds are plotted against the duration of ageing the two curves are essentially parallel after the initiation of the increase in aberration frequency (Fig. 1). The same trends were found for the root tips fixed on the first day of germination ($X1$–$C1$) and those which germinated the following day ($X2$–$C2$), although variance in the latter was higher due to fewer division figures and higher aberration frequencies.

Although the individual differences are often of doubtful significance there is a consistent difference in the aberration frequencies of the root tips from seeds which germinated the first day and those which germinated the second day. This was true for the control ($C2$–$C1$) and the X-rayed ($X2$–$X1$) seeds. For each of the two series a t test showed that the differences are significant. Subsequent tests showed that further delay in germination was associated with an increasing aberration frequency. In another lot of seed tested the aberration frequency per 100 cells was 36 for the seeds which germinated the first day and 54, 59, 77 and 85 respectively for each of the following days. After the fifth day very few seeds germinated and the root tips had few division figures. Delayed germination of onion seed is associated with a higher frequency of chromosome aberrations.

Seed germination shows little correlation with the frequency of chromosome aberrations. There was no significant difference in the germination of the control and X-rayed seeds. During the 10 weeks of artificial ageing the aberration frequency of the control seeds increased from 10 to 141. Germination was 94 per cent at the start of the experiment and had dropped to 74 per cent at the end of the test. As Gustafsson[4] has shown, barley seeds exposed to a very high dose of radiation (75,000 r.) will still germinate even though every cell will contain many chromosome aberrations. Such seedlings soon die due to chromosome damage. At lower doses of irradiation the seedlings may continue to grow, but many are retarded in their development.

A second experiment was done with seeds of the onion variety Ailsa Craig, obtained from a local source. It was apparently older than the variety Silver Skin used in the first experiment, since the spontaneous chromosome aberration frequency exceeded 40 per 100 cells before the artificial ageing began. Although the aberration frequency was high and there were fewer division figures per slide, the results were very similar to those obtained in the first experiment. There was, however, no lag-time in the increase of aberrations with ageing. The control seeds had an aberration frequency of 35 per 100 cells at the beginning of the experiment, and had apparently already reached the stage of accelerated ageing when the test was started.

These results indicate that ageing of seed, as measured by the frequency of chromosome aberrations, is not a uniform process, but accelerates with time. The irradiation only increases the level of ageing. Lindop and Rotblat[12] find similar results with mice. Irradiation shortens the life-span in proportion to X-ray dose, but the survival curves of irradiated and control mice are parallel. The irradiated mice behave like the controls at an older age. Radiation simply adds a deleterious effect, but does not accelerate the subsequent rate of ageing.

Ageing of seeds, however, does appear to make seeds more sensitive to X-rays[9,10]. Similar differences have been found in mice by Sacher[13]. He found little difference in the sensitivity of mice to X-rays with increasing age between 100 and 600 days, but after the mice pass the age of 600 days the sensitivity to irradiation increased rapidly. Natural ageing also increases more rapidly towards the end of the normal life-span.

The differences between natural and X-ray induced ageing have been beautifully demonstrated by Clark and Rubin[14]. They found no difference in the life-span of diploid and haploid male wasps. When the adult wasps were given an X-ray dose of 50,000 r. the life-span was greatly reduced, but the diploids lived much longer than the haploids. Since somatic mitosis does not occur in the adult wasps the radiation damage cannot be attributed to chromosome loss at mitosis. The shorter life of the irradiated wasps is attributed to the induced deleterious mutations, which would be expected to be more lethal in the haploid than in the diploid. Since there is no difference in the life-span of the non-irradiated diploid and haploid wasps, natural ageing cannot be attributed to the accumulation of deleterious mutations or gross chromosome aberrations. Radiation induced ageing differs from natural ageing.

Since irradiation does not significantly decrease seed germination the ageing effect of X-rays differs from natural ageing. Chromosome aberration frequency is not highly correlated with seed germination, indicating that death of the dormant seed is not due to chromosome aberrations. Nor does the ageing of X-rayed seed increase the 'rate' of aberration any faster than ageing of non-irradiated seeds. These results would seem to support the conclusions of Harrison and McLeish[15] that chromosome aberrations are the result, not the cause, of ageing,

LETTERS TO THE EDITOR

GEOPHYSICS

Dependence of the Ionospheric *F* Region on the Solar Cycle

THE general increase of ionospheric critical frequencies with sunspot number is well known, but the corresponding changes in ionospheric structure are not obvious from the critical frequency data alone and have not been extensively discussed in the literature. It is therefore interesting and instructive to examine a sample of ionospheric electron density distributions from different latitudes, seasons, and phases of the solar cycle.

Three stations—Huancayo, Peru; Washington, D.C. (Belvoir); and Anchorage, Alaska—were selected to represent low, medium, and high latitudes, respectively. Each of these stations has operated for more than one solar cycle. Winter and summer months were then selected, for which the mean Zurich sunspot numbers were, as nearly as possible, 0, 100 and 200. Within these months magnetically quiet days were selected for which noon f_0F-2 was as nearly as possible equal to median noon f_0F-2. Thus, it is hoped, these noon observations are representative of the solar, seasonal, diurnal, and latitudinal conditions from which they were selected.

The ionograms for these dates and times were converted to electron density profiles, using Budden's method[1]. Each profile was extrapolated above $h_{\max}$ *F*-2 by the process described by Wright[2], but with one important difference, as discussed in the following section.

Several workers (for example, Hirono[3]) have demonstrated that an ionospheric layer approaches an equilibrium shape under the combined influences of diffusion and attachment-like loss which is formally identical with the well-known Chapman distribution. Although electron production cannot be ignored in the daytime, it is still reasonable to expect that the *F*-2 peak and higher regions are strongly influenced by these processes, and that at the *F*-2 peak and above the quiet ionosphere approaches the Chapman form. To this extent, then, the characteristic thickness at the *F*-2 peak becomes a measure of the scale height and is usable for extrapolation of the profile above $h_{\max}$ *F*-2. Each of the profiles discussed here has accordingly been extrapolated above $h_{\max}$ *F*-2, using their individual thickness parameters. This differs from the constant scale height suggested earlier[2] as being appropriate to sunspot maximum conditions.

The result of this analysis is shown in Figs. 1–3. The most striking characteristic of all these profiles is that an increase in sunspot number adds additional ionization at greater heights, leaving the electron densities at lower heights comparatively unchanged. While the electron densities above the *F*-2 peak are the result of the extrapolation described here, it is important to note that they are more probably under-estimates than over-estimates, since the latter would imply a negative scale height gradient near the *F*-2 peak.

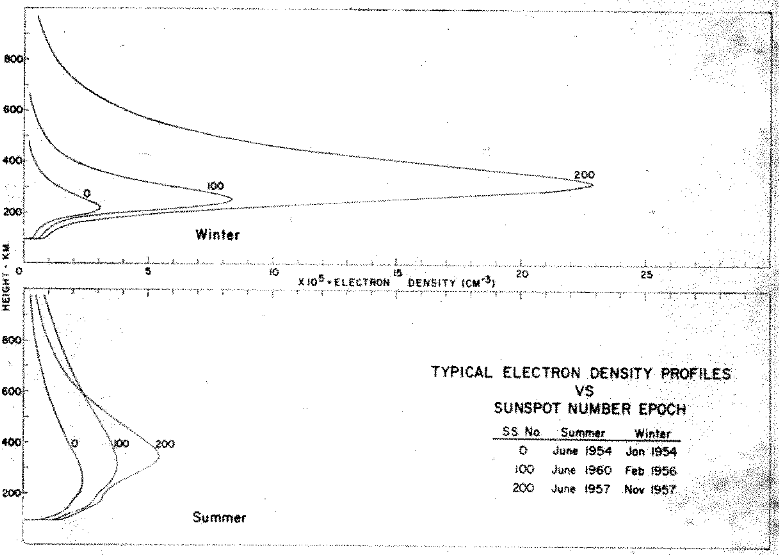

Fig. 1. Typical electron density profiles at three sunspot epochs for winter and summer noon conditions at Anchorage

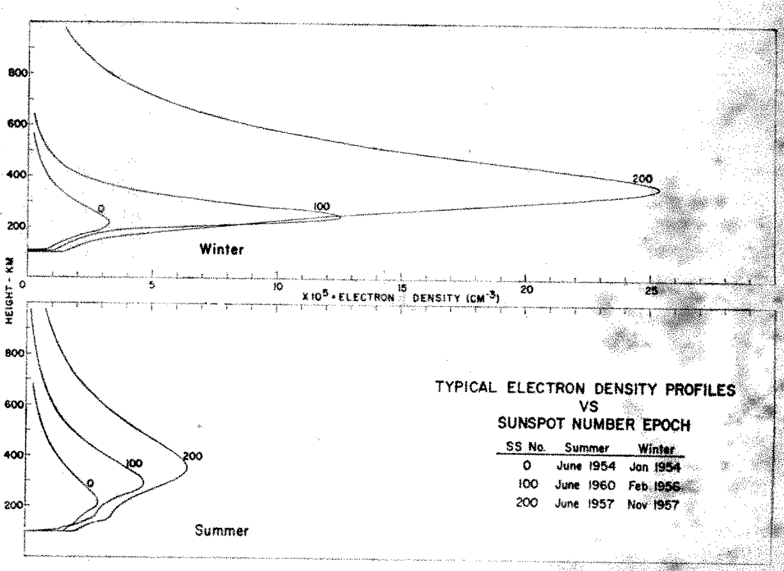

Fig. 2. Typical electron density profiles at three sunspot epochs for winter and summer noon conditions at Washington

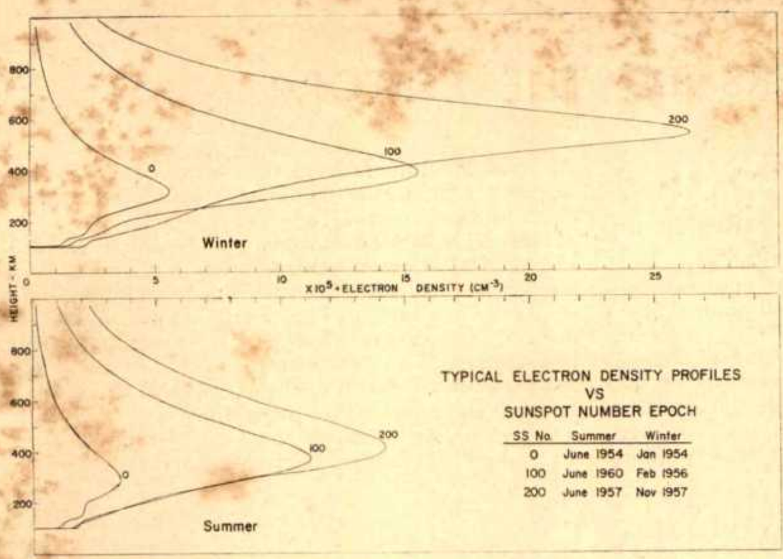

Fig. 3. Typical electron density profiles at three sunspot epochs for winter and summer noon conditions at Huancayo

The seasonal anomaly, by which the winter electron densities greatly exceed those in the summer, is very prominent at high sunspot number but is scarcely discernible during the solar minimum period. Elsewhere[4], it is shown that for sunspot maximum conditions and mid-latitudes, this seasonal anomaly is in fact a summer anomaly in the sense that the diurnal variation of summer electron content is anomalously low while the winter electron content follows a consistent 'Chapman' law over a wide range of latitudes. At Huancayo, the seasonal variation is doubly curious: since this station is slightly south of the equator, the 'winter' anomaly is more properly termed the 'December anomaly'[5]. It is present even at sunspot minimum.

A more extensive analysis of the sunspot cycle dependence of the ionosphere is being investigated in this laboratory.

Direct Observation of Correlation between Auroræ and Hiss in Greenland

AT the Ionosphere Station in Godhavn, located at 69° 16′ N., 53° 30′ W. geog. and 79·9° N., 32·6° E. geomagnetic, routine recordings of very-low-frequency-phenomena for 2 min. every hour were made since the beginning of the International Geophysical Year in July 1957. In order to undertake a more detailed study of hiss, a selective amplifier and a pen recorder were added to the existing equipment in October 1960.

It is now possible to record noise continuously at selected frequencies. 825 c./s. and 8 kc./s. were chosen as measuring frequencies. The 8 kc./s. records were used for carrying out an investigation of the correlation between hiss and auroræ similar to that reported by Martin *et al.*[1].

Contrary to the findings from the 825 c./s. recordings, the 8 kc./s. results indicate a close correlation between strong noise and the occurrence of auroræ.

In order to examine this correlation more closely the apparatus was so constructed that one could listen to hiss through a loud-speaker and at the same time observe auroræ visually.

Observations carried out during January and February 1961 gave the following results: the 8 kc./s. hiss read on the pen recorder can be regarded as a steady background-hiss without greater diurnal variations. It has a shallow minimum at local noon and a maximum in the early night hours. Superimposed on this background noise there appear strong outbreaks lasting from a few minutes to about 1 hr. The hiss outbreaks are of an intermittent character,

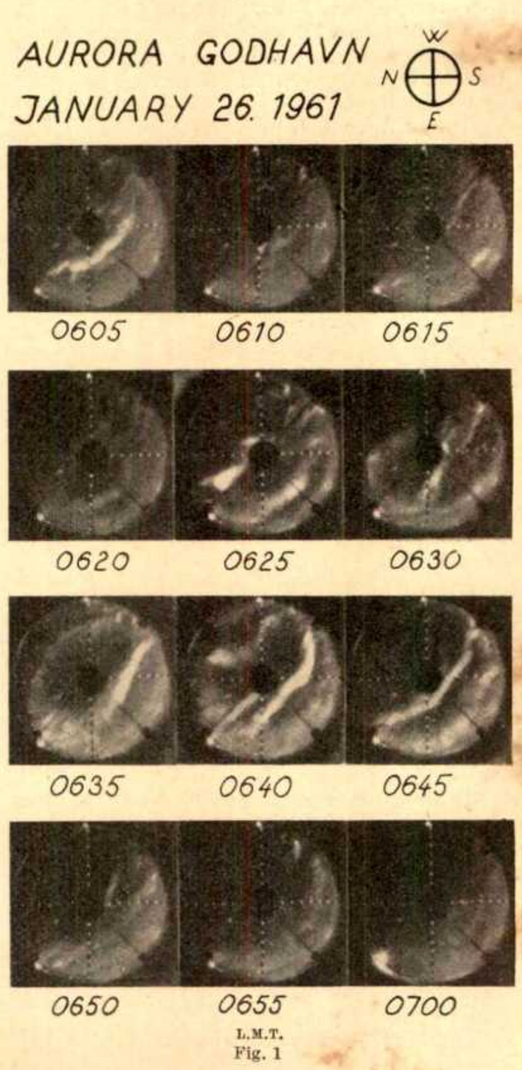

Fig. 1

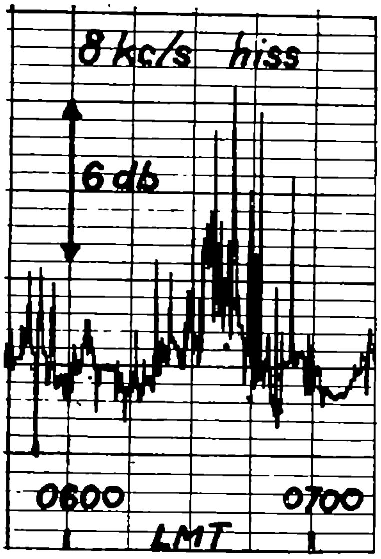

Fig. 2

sounding in a loudspeaker almost as the noise of a shower hitting a metal roof.

In the 30 cases of simultaneous hiss-listening and observations of auroræ there has been a clear correlation between the two phenomena. The strength of the hiss has shown second-to-second and minute-to-minute variations similar to those of the intensity of light in, and the activity of, the auroræ. Great activity of auroræ has never been observed without recording a strong hiss, and a strong hiss has never occurred when auroræ were missing.

Hiss was recorded both when the auroræ were low and high in the heavens, while ionospheric absorption and magnetic disturbance were recorded only when auroræ were present, near the zenith.

As an illustrative example, an 8 kc./s. hiss recording and all-sky-camera recordings of auroræ on January 26, 1961, are shown (Figs. 1 and 2).

We thank Mr. Knud Lassen for advice and inspiring discussions.

PHYSICS

Law for the Composition of de Broglie's Velocities

The application of the special theory of relativity in physics, and especially in mechanics, is still very incomplete. The treatment of the various laws associated with different kinds of pendulums in different circumstances is of great importance, because—from a purely kinematic view—all kinds of clocks and watches are, theoretically speaking, equally affected 'through their movement'. However, from a physical point of view this is not proved. I am at the moment working on this problem and my full results will be published elsewhere. However, to test the point other relativistic collision laws were required. This has been my main field of investigation and has been outlined elsewhere[1]. So far when dealing with de Broglie's velocities, I have taken no consideration of any oscillators. In this communication I shall consider these enormous velocities.

Let us first consider three co-ordinate systems $S_1(x_1, t_1)$, $S_2(x_2, t_2)$ and $S_0(x_0, t_0)$, origins of which 0_1, 0_2 and 0_0 move with uniform velocities along a straight line. The system S_1 moves, with respect to the system S_2, with uniform velocity v_1 and the system S_2 moves, with respect to the system S_0, with uniform velocity v_2. Then the system S_1 will move, with respect to the system S_0, with uniform velocity v_0, and if we take Poincaré's fundamental law for the starting point, we have:

$$v_0 = \frac{v_1 + v_2}{1 + \frac{v_1 v_2}{c^2}} \tag{1}$$

where c is the uniform velocity of light[2]. If we suppose that at 0_1 there is an oscillator (particle) with a frequency ν_1, then it will be—considered from system S_2—accompanied by a plane series of waves. This series of waves vibrates with a phase-velocity u_1 (ref. 3). Similarly we find an oscillator (particle) with a frequency ν_2 at 0_2 which, considered from system S_0, is accompanied by a plane series of waves with a phase-velocity u_2. On the other hand, the oscillator (particle) with frequency ν_1 at 0_1—considered from system S_0—also appears accompanied by a plane series of waves with a phase-velocity u_0. It is known that:

$$u_i = \frac{c^2}{v_i}, \quad (i = 0, 1, 2) \tag{2}$$

Therefore from equation (1):

$$u_0 = \frac{c^2}{v_0} = c^2 \Bigg/ \frac{v_1 + v_2}{1 + \frac{v_1 v_2}{c^2}} = \frac{c^2 + v_1 v_2}{v_1 + v_2} \tag{3}$$

But

$$\frac{c^2 + v_1 v_2}{v_1 + v_2} = \frac{\frac{c^2 + v_1 v_2}{v_1 v_2}}{\frac{v_1 + v_2}{v_1 v_2}} = \frac{\frac{c^2}{v_1 v_2} + 1}{\frac{1}{v_2} + \frac{1}{v_1}} = \tag{4}$$

$$\frac{\frac{c^4}{v_1 v_2} + c^2}{\frac{c^2}{v_1} + \frac{c^2}{v_2}} = \frac{c^2 + u_1 u_2}{u_1 + u_2}$$

and from equation (3) we have:

$$u_0 = \frac{c^2 + u_1 u_2}{u_1 + u_2} = c^2 \Bigg/ \frac{u_1 + u_2}{1 + \frac{u_1 u_2}{c^2}} \tag{5a}$$

The relation (5*a*) is a new law for the 'composition' of de Broglie's velocities. This can be rewritten:

$$u_0 = \frac{u_1 + v_2}{1 + \frac{u_1 v_2}{c^2}} = \frac{\frac{c^2}{v_1} + v_2}{1 + \frac{v_2}{v_1}} = \tag{5b}$$

$$\frac{c^2 + v_1 v_2}{v_1 + v_2} = c^2 \Bigg/ \frac{v_1 + v_2}{1 + \frac{v_1 v_2}{c^2}} = \frac{c^2}{v_0}$$

On the other hand we have from equations (4) and (5):

$$\frac{u_1 + u_2}{1 + \frac{u_1 u_2}{c^2}} = \frac{v_1 + v_2}{1 + \frac{v_1 v_2}{c^2}} = v_0 \qquad (6)$$

but such an addition of velocities u_i ($i = 1,2$) would be nonsensical from the physical point of view—unlike the equations 5*a* and *b*.

Does Matter have a Half-Life?

IN a recent book Prof. R. O. Kapp[1] has suggested that atoms of matter disappear spontaneously in a statistically random manner with a half-life of about 4×10^8 years and that it is this extinction of matter which causes gravitational attraction. It is the purpose of this communication to point out that there is no reason why the confirmation or disproof of this suggestion should not be established by means of existing techniques.

The gravitational constant G is usually reported[2] as $(6{\cdot}670 \pm 0{\cdot}005) \times 10^{-8}$ dyne. cm.^{2}gm.$^{-2}$ and it is not unreasonable to assume that the sensitivity of the apparatus used for the determination of G can be made somewhat better than the stated error of 5 parts in 6,000 and may well be 0·04 per cent or even less. It is difficult to estimate the speed with which such an apparatus would respond to a change of this magnitude, but it is not unlikely that a change of half-sec. duration or possibly even less would be detectable.

Assuming that G is determined by a Cavendish–Boys type of apparatus and that the weight of the attracting lead spheres is about 1,000 gm., the number of lead atoms involved would be $(1{,}000 \times 6{\cdot}023 \times 10^{23})/207{\cdot}2$ or about 3×10^{24}. Now, if the half-life of matter is taken as 4×10^8 years, the number of lead atoms which would cease to exist in every half-sec. interval must be about $(3 \times 10^{24} \times 0{\cdot}693)/(4 \times 10^8 \times 6 \times 10^7)$ or 1×10^8.

Assuming a normal Gaussian distribution it follows that there is 1 chance in every $1{\cdot}6 \times 10^4$ that the actual number of atoms which disappear in any given half-sec. interval will differ from this value by a detectable 0·04 per cent (which is 4 times the standard deviation)[3].

In other words, provided the deflexion of the beam is monitored continuously for a month at a time, the apparatus should spontaneously record a value of G which is either high or low for about 300 of the half-sec. intervals during such a one month period (which involves 5×10^6 half-sec. intervals). A control experiment would, of course, have to be carried out with an otherwise identical beam in the absence of lead weights.

The feasibility of monitoring the apparatus for a month on end may seem somewhat far-fetched, but R. H. Dicke *et al.* have successfully monitored their apparatus in a repeat of the Eotvos experiment for a period of several months[4].

Moreover, only a slight increase in the assumed sensitivity or the speed of response of the apparatus would produce a marked increase in the frequency of detectable deviations of G from the average value. It is even conceivable that the half-life of matter may be somewhat greater than the value suggested by Kapp and that the uncertainty in the currently accepted value of G may be partly due to statistical variations in the rate of disappearance of matter and not wholly the result of extraneous causes.

Provided an apparatus with sufficient sensitivity and speed of response can be constructed, it should thus be possible, by an analysis of the frequency and magnitude of such apparent variations in G, not only to verify that matter does have a half-life (if it in fact does disappear spontaneously) but to estimate the magnitude of such a half-life as well. The importance of a positive result for such an experiment on our understanding of gravitational attraction can scarcely be over-emphasized.

[4] Dicke, R. H., *Sci. Amer.*, **205**, 84 (1961).

DR. SWART makes an interesting suggestion which is theoretically sound. He shows himself aware of the three main practical difficulties, and it may be worth while to emphasize these for the benefit of anyone who might wish to translate the proposal into an experiment.

The first difficulty is that the Cavendish–Boys type of apparatus is at present not quite sensitive enough. One could perhaps hope to increase its sensitivity by the requisite factor of about 3; but this would only add to the second difficulty, which is that of securing a sufficiently quick response. Apparatus of this type measures in effect the time-integral of power; hence the well-known inverse ratio between sensitivity and speed of response. However, the technique of measurement has improved enormously since the year when Boys determined the value of G. It is not unreasonable to hope that Dr. Swart's proposal may soon become feasible, if it is not so already. Perhaps a technique using a differential method would be more promising than that used by Cavendish and Boys.

The third difficulty is the effect of Earth tremors which would shake the apparatus. Adequate isolation from these may not be possible; but Dr. Swart's proposed control experiment with an otherwise identical beam in the absence of lead weights might provide means of distinguishing between the effect of shaking the apparatus (noise) and the effect of fluctuations in the gravitational field.

The suggested test mass, namely, 1,000 gm. serves to illustrate the magnitudes entering into the problem. For an actual experiment, however, the optimum mass would have to be determined. This would, of course, be a function of the constants of the experimental apparatus.

METALLURGY

An Anti-ferromagnetic Heusler Alloy, Cu_2MnSb

In the course of a comprehensive examination of the Heusler alloys it has been found that the alloy Cu_2MnSb, previously reported as ferromagnetic[1], shows some of the properties of an antiferromagnet. The alloy was prepared by melting at 1,000° C., homogenizing at 650° C. for 50 hr., and quenching in water. The composition of the specimen was $Cu_{2\cdot000}Mn_{0\cdot998}Sb_{1\cdot026} \pm 0\cdot001$. X-ray diffraction analysis showed the presence of Heusler structure similar to that of the alloy Cu_2MnAl, with a lattice parameter 6·097 ± 0·004 Å., which is intermediate between the values of 5·95 Å., and 6·20 Å. for Cu_2MnAl and Cu_2MnIn respectively, both of which are ferromagnetic.

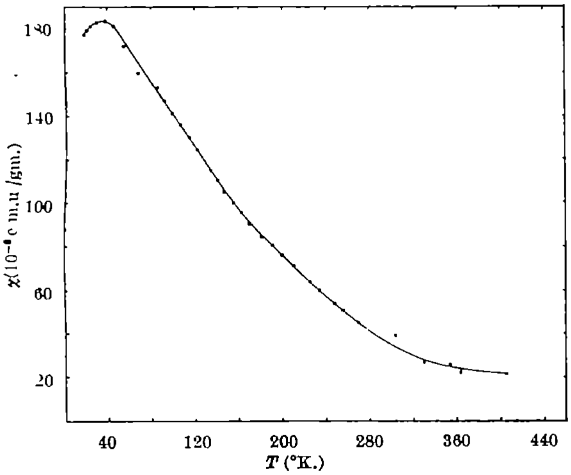

Fig. 1. Variation in magnetic susceptibility (χ) with temperature of Cu_2MnSb

No lines other than those attributable to the ordered Heusler phase were observed. The variation in magnetic susceptibility with temperature is shown in Fig. 1. Below 38° K., the susceptibility χ decreases with decreasing temperature, indicating the presence of antiferromagnetic order; above this (Néel) temperature the alloy is paramagnetic in that χ decreases with increasing temperature, but there is no indication that a Curie–Weiss law is followed within the range of temperature investigated. A specimen with slightly different composition showed the same characteristics.

Crystal Structures of $ThRh_2$, ThRu and ThIr

An investigation of the constitution of alloys of thorium and the platinum metals is in progress, and the structures of five intermetallic compounds of the type Th_7X_3 have been reported previously[1]: the structure of Th_7Rh_3 has since been confirmed by Ferro and Rambaldi[2]. Dwight, Downey and Conner[3] have established that the compound $ThRh_3$ has the Cu_3Au structure ($L1_2$). This communication presents the structure of three new compounds $ThRh_2$, ThRu and ThIr.

Alloys were prepared by arc-melting 1-gm. samples of the component metals in a zirconium-gettered argon atmosphere. The alloys were brittle and powders for X-ray studies were prepared by crushing in air; powder patterns were obtained with a Guinier-type focusing camera using mono-chromatized copper radiation.

Phase relationships in thorium–rhodium alloys of 60–75 at. per cent rhodium are complex, compounds having been identified by metallographic and X-ray methods at approximately 63, 65, 66·6 and 75 at. per cent rhodium. The structure of $ThRh_3$ is given in par. 1 and X-ray patterns of the compounds at 63 and 66·6 at. per cent rhodium were complex and have not been indexed, but the film of the compound at 65 at. per cent rhodium was indexed on the basis of a hexagonal lattice $a = 4\cdot629 \pm 0\cdot002$, $c = 5\cdot849 \pm 0\cdot003$ Å. $c/a = 1\cdot264$. Systematic extinction of the $000l$ and $hh2\bar{h}l$ reflexions were noted when l was odd and of $hkil$ lines when $h-k = 3n$ and l was odd. The observed intensities showed excellent agreement with those for the Ni_2In structure ($B8_2$) space-group D^4_{6h} P $6_3/mmc$.

The $B8_2$ structure proposed for $ThRh_2$ is related to the $B8_1$ NiAs lattice by filling up the trigonal positions in the latter structure, the completely filled-up version having the composition A_2B. If the trigonal positions are incompletely filled it is possible for this structure to occur over a range of compositions or at the non-stoichiometric composition. The effect of temperature on the relationship between the complex structure in alloys of 66·6 at. per cent rhodium and the comparatively simple Ni_2In structure of 65 at. per cent rhodium has not yet been established.

ThRu and ThIr are formed directly from the melt: their X-ray patterns were indexed as orthorhombic with the following lattice parameters:

	'*a*' (Å.)	'*b*' (Å.)	'*c*' (Å.)
ThRu	3·878 ± 0·002	11·29 ± 0·01	4 071 ± 0·002
ThIr	3·894 ± 0·003	11·18 ± 0 01	4·266 ± 0·003

No hkl reflexions were observed unless $h+k$ was even and $h0l$ lines were present only when l was even. The lattice parameters and systematic extinctions suggested that ThRu and ThIr might be isostructural with ThCo (ref. 4) space group D^{17}_{2h} Cmcm. Line intensities calculated on the basis of this structure with $y_{Th} = 0\cdot14$ and $y_X = 0\cdot41$ where X is Ru or Ir gave good agreement with the observed intensities; other compounds reported to have this structure include ThAl (ref. 5), CeNi (ref. 6), PuNi (ref. 7) and DyGa (ref. 8).

I thank Prof. J. G. Ball under whose supervision this work was carried out; also the Atomic Energy Research Establishment, Harwell, for financial support and for allowing me to make use of some of their experimental facilities.

RADIATION CHEMISTRY

Estimation of the Levels of Cæsium-137 in Sea-water by the Analysis of Marine Organisms

It is necessary to know the levels of cæsium-137 in sea-water which has been released by nuclear explosions or waste disposal, although the sampling of a large volume of sea-water, usually 100 litres or more, is not always easy or convenient.

Since the weight of marine organisms equivalent to the sea-water with respect to potassium or natural cæsium content is only one-thirtieth or less, the analysis of the former in place of the latter might supply convenient means of estimating the oceanic level of cæsium-137 if an equilibrium is assumed between them.

We have analysed various marine organisms collected in the vicinity of Japan for both natural cæsium-133 and radioactive cæsium-137; the former being analysed by a neutron activation method (to be described elsewhere) and the latter by a radiochemical separation followed by low-background β counting[1]. The results obtained are shown in Table 1.

Table 1. Estimates of Concentration of Cæsium-137 in Sea-water

Time of sampling	Locality	Organisms	^{137}Cs/^{133}Cs (× 10^8)	Estimate of ^{137}Cs in sea-water* (μμc./l.)
Dec. 1958	Suruga Bay	*Sergestes lucens* (shrimp)	2·5	1·3
March 1959	Sagami Bay	Diatoms	3 7	1 9
June 1959	Tokyo Bay	*Neomysis japonica* (zooplankton)	1·2	0 6
Aug. 1959	Sagami Bay	*Eisenia bicyclis* (brown seaweed)	1 6	0 8
Aug. 1959	Tokyo Bay	*Tapes japonica* (littleneck clam)	2·0	1 0
March 1960	W. Pacific	*Sardinops melanostica* (Japanese sardine)	0·8	0 4
March 1960	Japan Sea	*Euphausia pacifica* (zooplankton)	1·4	0·7
Oct. 1960	W. Pacific	*Cololabis saira* (Pacific saury)	3·3	1 7
Oct. 1960	W. Pacific	*Sphyraena* sp. (barracuda)	3·3	1 7
Oct 1960	W. Pacific	*Lateolabrax japonicus* (Japanese sea bass)	1·6	0 8
Oct. 1960	W. Pacific	*Trachurus japonicus* (jack mackerel)	1 5	0 8
Oct. 1961	W. Pacific	*Cololabis saira* (Pacific saury)	0·8	0·4
Oct. 1961	W. Pacific	*Sphyraena* sp. (barracuda)	1 0	0 5
Oct. 1961	W. Pacific	*Lateolabrax japonicus* (Japanese sea bass)	2·3	1 2
Oct. 1961	W. Pacific	*Trachurus japonicus* (jack mackerel)	0·7	0 4

* On the basis of the concentration of cæsium-133 in sea-water being 0 5 μgm./l.

When an equilibrium has been attained between sea-water and marine organisms, the ratio of cæsium-137/cæsium-133 in the former should be equal to that in the latter. On the basis of the concentration of cæsium-133 in sea-water being 0·5 μgm./l., as given by Smales and Salmon for the Atlantic[2], and assuming this value is also valid for the Pacific and coastal waters, we have estimated the levels of cæsium-137 in sea-waters as given in the last column of Table 1.

The estimate indicates somewhat higher values for coastal waters in 1959 than those given by one of us previously for 14 samples of surface waters, namely, 0·38 μμc./kgm. on the average[3]. The estimate in the Western Pacific in October 1961 from 4 species of fish, 0·6 μμc./l. on the average, is approximately half that in the same month of the preceding year, 1·3 μμc./l. These values are much higher than those in the Atlantic or the Eastern Pacific, as already mentioned by Miyake *et al.*[4].

It is interesting to note that the concentration of cæsium-133 is fairly constant, as shown in Table 2, in several fish species which are popularly consumed in Japan. Presumably, this will be caused by the homogeneous distribution of cæsium-133 in the ocean and the biological insignificance of the chemical element. The standard deviation of the cæsium-133 content in different species around the mean value of 21 μgm./kgm. is ± 12 per cent. Accordingly, the analysis of cæsium-133 will not be necessary in the rough estimation of the levels of cæsium-137 in sea-water so far as those fishes are used as monitor.

Table 2. Cæsium-133 Content of Some Fishes

Fish	Cæsium-133 μgm./fresh kgm. (whole body)
Cololabis saira (Pacific saury)	19
Sphyraena sp. (barracuda)	22
Lateolabrax japonicus (Japanese sea bass)	19
Trachurus japonicus (jack mackerel)	25
A kind of flatfish*	21
Average	21 ± 2·5

* Japanese name, 'karei'.

Thus, it may be concluded that the estimation of the levels of cæsium-137 in sea-water can conveniently be made by analysing approximately 100 gm. fresh weight of the whole body of some kind of fish for cæsium-137, although it should be kept in mind that the estimate does represent the concentration of cæsium-137 in sea-water of not a fixed point but an average in space, depth and time, reflecting the life-history of an organism.

'Hot'-Atom Chemistry of Radiocobalt in Hexamminecobalt(III) Hexacyanocobaltate(III) and Hexamminecobalt(III) Hexacyanoferrate(III)

Behaviour of cobalt-60 recoils arising from thermal neutron capture and isomeric transition on cobalt atoms in either hexamminecobalt(III) complex salts or hexacyanocobaltate(III) complex salts has already been investigated[1-6]. However, the system which contains both NH_3 and CN groups together has not yet been investigated. In order to elucidate the role of CN groups in recoil reactions, we selected, as such a system, two complex salts of the formula $[Co(NH_3)_6][M(CN)_6]$, where M = Co or Fe, since no hexamminecobalt(III) cyanide is known at present.

Solid complex salts $[Co(NH_3)_6][Co(CN)_6]$ and $[Co(NH_3)_6][Fe(CN)_6]$, were prepared by the methods described in literature and were subjected to neutron irradiation in an experimental hole in the *JRR*-1 reactor for 5–6 hr. at pile temperature. Thermal neutron flux was approximately 3 × 10^{11} n./cm^2. sec. After varied storage time following the irradiation the irradiated salts were dissolved in 0·3 M hydrochloric acid and species labelled with cobalt-60 were separated by procedures involving ion exchange, paper electrophoresis, recrystallization, or a combination of these. Essentially the same distribution of

	2·5 months	20·3	3·8	1·0	6·8	4·0	5·1	8·7	41·3
	4 months	22·7	5·3	1·7	8·5	4·1	3·2	9·2	38·1

* A denotes an NH_3 group and X a CN group in most cases. However, it is also possible that some of A's may be water and some of X's may be chlorine or other anions present in the solution.

† Summation of percentage does not amount to 100 because of the presence of unidentified species (3–6 per cent)

labelled species was obtained even if different separation procedures were used.

The results are shown in Table 1. Major components labelled with cobalt-60 in the solution of the irradiated salt were CoA_6^{3+}, Co^{2+}, and CoX_6^{3-} (A = mostly NH_3, X = mostly CN). On the storage of the irradiated salts at room temperature, CoA_6^{3+} was increased, Co^{2+} was decreased and CoX_6^{3-} remained almost unchanged. It is worth while to mention that appreciable amounts of ^{60}Co-labelled cyanocobaltate ions were found in the solution of irradiated $[Co(NH_3)_6][Fe(CN)_6]$. The distribution was not altered at all when the irradiated salt was dissolved in 0·3 M hydrochloric acid containing macroscopic quantity of Co^{2+} beforehand. It should also be mentioned that the distribution of ^{60}Co-labelled species in $[Co(NH_3)_6][Fe(CN)_6]$ was essentially similar to that in $[Co(NH_3)_6][Co(CN)_6]$. The latter salt contains cobalt atoms in both cationic and anionic components, whereas the former salt contains cobalt only in cationic component. Therefore, comparison of distributions of species labelled with cobalt-60 in these salts might afford clues for elucidation of the nature of recoil reactions, especially, for estimation of the size of 'hot' zone involved in such reactions.

CHEMISTRY

Distribution Patterns of Isotopic Peaks in the Mass Spectrum of Stannic Bromide

ONE of the problems in high-molecular-weight mass spectrometry is to establish unambiguously the definite mass to be assigned to the fragmentation peaks in the higher mass (200–800) range. A suitable calibrating material is stannic bromide. It has a vapour pressure at 25° C. of a little less than 1 torr, and from its elementary isotopic constitution the relative peak heights can be calculated for the molecular parent ion and its fragments.

For simplicity the abundance fraction of bromine-79 and bromine-81 can be taken each as 0·50, and the lower abundance isotopes tin-112, tin-114 and tin-115 omitted from the calculation. The fractional abundance of the tin isotopes 116, 117, 118, 119, 120, 122 and 124 were taken as: 0·143, 0·077, 0·238, 0·087, 0·328, 0·047 and 0·060, respectively[1].

In the mass spectrometer there appear the ions $SnBr_4$, $SnBr_3$, $SnBr_2$, SnBr, Sn and Br, in the approximate relative intensities 42, 100, 24, 68, 24 and 29 respectively. These relative intensities cannot be calculated, but in a given ion, the complex isotopic peaks which constitute it can be.

This is done as has been shown for other materials[2,3]. If the fractional bromine-79 and bromine-81 abundances are taken as a and b, the ion group peak heights for a single tin isotope of abundance S is given by the distribution equation $S(a + b)^n$, where n takes the values 4–1 for the various bromine-containing ions. This is calculated and weighted for each tin isotope

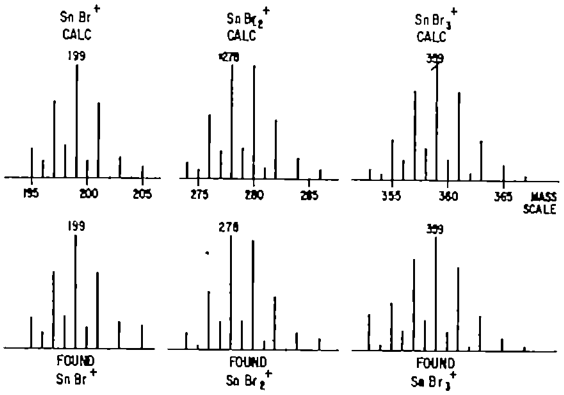

Fig. 1. Isotopic peak distribution for ion fragments of stannic bromide

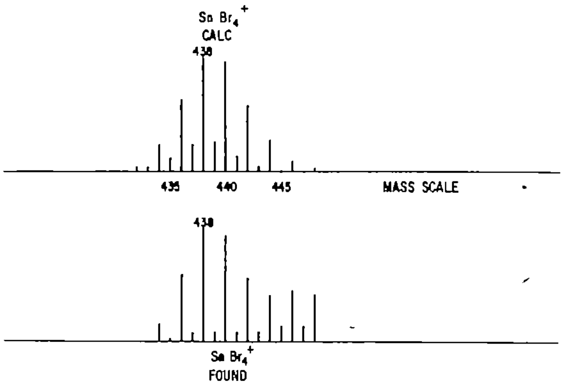

Fig. 2. Isotopic peak distribution for molecular ion $SnBr_4^+$

and the totals summed for each mass in the group. The distributions calculated and found are shown in the graphs of Figs. 1 and 2. Particularly useful are the maximum peak heights at 440, 438, 359, 280, 278. The peak 199 appears among the mercury isotopes. The main discrepancy between the distributions calculated and found just above mass 444 is probably due to an impurity.

Some of the peaks are quite complex. For example, the highest peak of mass 359 in the $SnBr_3$ ion is made up of: $^{116}Sn^{81}Br_3$, $^{118}SnBr_2{}^{79}Br$, $^{120}Sn^{81}Br^{79}Br_2$ and $^{122}Sn^{79}Br_3$.

If pure, stannic iodide, even though less volatile, would furnish excellent mass markers. Since iodine is monoisotopic, all the ions would exhibit the tin isotopic distribution pattern, with masses of the highest peak in each group at 628, 501, 374 and 247. These are for the iodine containing ions formed with tin-120. However, any slight bromine contamination in the iodide yields a great number of mixed iodide-bromide peaks, due to the large number of such combinations possible.

Absorption Spectra of the D-State Ions $TiCl_6^{-3}$, $TiCl_4^-$, $CrCl_4^{-2}$, $FeCl_4^{-2}$ and $CuCl_4^{-2}$ in Chloride Melts

THE absorption spectra of dilute solutions of the ions $TiCl_6^{-3}$, $TiCl_4^-$, $CrCl_4^{-2}$, $FeCl_4^{-2}$ and $CuCl_4^{-2}$ in chloride melts have been obtained. Of particular interest is the magnitude of *Dq*, the crystal field splitting parameter, deduced from the locations of the near infra-red absorption bands. In the present communication, a detailed discussion of the spectra and their interpretation in terms of distortions of the complexes will not be given. The salient results of the investigation are, however, listed in Table 1, this constituting the first report of the tetrahedral spectra of a number of these ions.

Table 1. ABSORPTION SPECTRA OF *D*-STATE IONS IN CHLORIDE MELTS*

Ion	Electronic configuration	Energy at absorption maxima (cm.⁻¹)	Width at half-maxima (cm.⁻¹)	Transition	*Dq* (cm.⁻¹)
$TiCl_6^{-3}$	d^1 ^2D	10,000 13,000	4,000 3,500	T → E	~1,150
$TiCl_4^-$	d^1 ^2D	8,000 6,000	3,500 3,000	E → T	~700
$CrCl_4^{-2}$	d^4 ^5D	9,800	4,600	T → E	980
$FeCl_4^{-2}$	d^6 ^5D	5,100	3,100	E → T	510
$CuCl_4^{-2}$	d^9 ^2D	9,500	3,400	T → E	950

* The solvent was LiCl–KCl eutectic and the temperature 400° C. in all cases except $TiCl_4^-$ where the solvent was $CsGaCl_4$ and the temperature 750° C.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Absorption and Afterglow Spectra of Selenium Dioxide

IN a report now in the press[1] we have attempted to interpret the continuous emission and absorption spectra of sulphur dioxide by assuming a photo-dissociation and recombination process.

In this report, we extend the examination to the selenium dioxide molecule, which has an electronic configuration similar to that of sulphur dioxide (and also tellurium dioxide). As with the other diatomic oxides, the energy of the excited levels decreases as one goes to heavier molecules: that is to say, from sulphur dioxide to selenium dioxide and then to tellurium dioxide. One would expect a corresponding shift in the respective continuous and discrete band spectra.

In studying this molecule, we used the same photometric method as for sulphur dioxide. To stabilize the concentration of selenium dioxide, we connected two furnaces (F_1 and F_2) so that F_1 had the solid oxide contained in a side tube while the other, F_2, operating at a higher temperature, contained the absorption vessel connected to the small tube in F_1

The range of temperature in the F_1 furnace was quite limited because at less than 250° C. the vapour pressure was too low for adequate absorption measurements, while, near 300° C., the absorption was almost complete in the region between 2600–3000 Å. This use of two furnaces allowed the investigation of the influence of the temperature on the absorption spectra.

The absorption band spectrum has been examined by Evans[2], Choong-Shin-Piaw[3] and Duchesne and Rosen[4]. Most of the bands have been classified in three distinct groups, corresponding to the spectral regions: (*A*) 2070–2210 Å.; (*B*) 2210–3300 Å.; (*C*) 3400–3800 Å.

As in the case of sulphur dioxide, raising the temperature has a double effect: (1) the rotation structure of the individual bands is made to disappear progressively into a continuous absorption spectrum; (2) a new continuous spectrum appears which is associated with the increase of the total absorption.

It is this last absorption which was measured. For a given temperature in the F_1 furnace—that is to say, for a given value of pressure—we measured the optical density $d(T_1)$ and $d(T_2)$ corresponding to the two different temperatures of the furnaces F_1 and F_2.

In the regions where there was no new absorption, $\frac{d(T_2)}{d(T_1)} \approx 1$. This was indeed the case for the bands located in the 2500–3000 Å. spectral region. In other spectral regions, the excess density:

$$d_c = d(T_2) - d(T_1) \quad T_2 > T_1$$

was arbitrarily assumed to be equal to that of the continuous absorption.

Fig. 1 shows our results for $T_1 = 250°$ C. and $T_2 = 370°$ C. With rising temperature, two regions of continuous absorption appear: one between 3000–3350 Å. and the other less than 2600 Å. The maximum absorption cross-section was of 8×10^{-21} cm.² at 250° C.

As is well known, for diatomic molecules, the absorption spectrum may be continuous in one spectral region and discrete in another when both the electronic states of the transition are stable. The absorption is entirely continuous, or shows broad intensity fluctuations, when one of the potential curves is of a repulsive type. In the first case, the

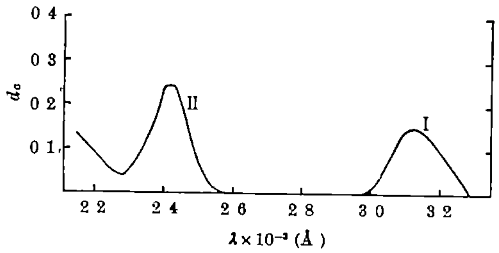

Fig. 1. Optical density d_c of the continuous spectrum obtained by the subtraction of the optical density at 250° C. from that at 370° C.

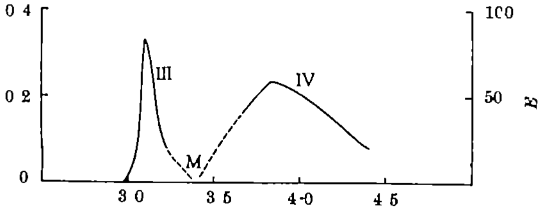

Fig. 2. Comparison between the intensity distribution E of the continuous afterglow spectrum and the optical density d_c of the continuous absorption spectrum. The wave-length of the point M, obtained by extrapolation, corresponds to the dissociation energy of selenium dioxide into selenium monoxide and oxygen. Curve III: The scale on the left represents the optical density of selenium dioxide at 360° C. (pressure = 250 mm. mercury). Curve IV. The scale on the right gives the distribution of relative intensity of the new afterglow spectrum of selenium dioxide

continuous absorption is located on the shorter wave-length side of the band spectrum. One can wonder whether the continuous absorptions shown in Fig. 1 are associated with the band systems (A, B, C) mentioned above. If that were the case, the continuous band I of Fig. 1 would correspond to C system and the continuous band II to B system.

If the upper electronic state of the transition giving the continuous absorption were unstable and the lower state stable (fundamental level), one would expect to have a continuous emission located on the longer wave-lengths side of the continuous absorption. This would be the result of a recombination process transforming selenium and oxygen into selenium dioxide with radiation.

Continuous Spectra in the Afterglow. To choose between the two possible interpretations, we sought to excite and photograph the afterglow spectrum of selenium dioxide. The excitation was produced by a 50-cycle high-frequency pulse generator and the observation made with the aid of a synchronous rotating disk. Under these conditions, we observed a continuous afterglow spectrum between 3400 Å. and 4900 Å. The intensity is considerably weaker and less extensive than the continuous afterglow spectrum of sulphur dioxide (under similar conditions). Fig. 2 shows curve III of continuous absorption at 360° C. and 250 mm. mercury pressure, and alongside curve IV, which gives, in arbitrary units, the relative intensity distribution, E, of the continuous afterglow spectrum. It is seen that the relative position of these two curves, III and IV, is much like those of sulphur dioxide, with the exception that the spectral region is much more restricted. The common spectral limit of the two curves near 3400 Å. corresponds to the dissociation energy of 29,400 cm.$^{-1}$ = 3·64 eV. This value seems likely as the dissociation energy of selenium dioxide into selenium monoxide and oxygen.

It seems that we have to conclude that the continuous absorption and emission of Fig. 2 are due to the two inverse processes of molecular dissociation and recombination:

$$SeO_2 + h\nu \longrightarrow SeO + O \text{ and}$$
$$SeO + O \longrightarrow SeO_2 + h\nu$$

Silver/Silver Oxide Electrodes for Fuel Cells

Many laboratories active in the field of fuel cell research have adopted the silver/silver oxide electrode as the oxygen electrode in conjunction with strong alkali (generally 20–40 per cent potassium hydroxide) electrolyte. There have been many investigations of the fundamental operating characteristics of such an electrode under current drain conditions, and various theories have been advanced to account for its behaviour. Although various polarization mechanisms have been considered, as in the work of Dirkse[1], it is remarkable that the significant solubility of silver in strong potassium hydroxide has been systematically ignored. This solubility is adequately recorded in the work of Mathur and Dahr[2], and of Johnston, Cuta and Garrett[3] for room-temperature operation under quiescent conditions and a synopsis of these authors' results is given in Table 1.

Table 1. Solubility of Silver/Silver Oxide in Potassium Hydroxide at 25° C.

Normality	Mathur and Dahr gm. Ag/l		gm. equiv. Ag_2O/l. × 10^{-4}	Johnston Cuta and Garrett gm equiv. Ag_2O/l × 10^{-4}
0·002	0·0093	—	0·87	—
0·001	0·0016	—	0·15	—
0·0012	—	0·00355	—	0·329
0·01	0·0010	—	0·10	0·076
0·02	—	0·00067	—	0·062
0·05	—	0·0012	—	0·110
0·10	0·0032	—	0·30	—
0·117	—	0·0028	—	0·26
0·40	—	0·0216	—	2·00
1·03	0·0162	—	1·50	—
2·26	0·0309	—	2·86	—
2·33	—	0·040	—	3·70
5·20	0·0457	—	4·23	—
6·60	—	0·0583	—	5·40

Although the results of Johnston *et al.* are somewhat higher, they are in reasonable agreement and confirm a minimum solubility at about 0·02 normal with solubility rising sharply in strong potassium hydroxide solutions such as used in typical fuel cells.

No direct information is available for higher temperatures in strong caustic, but a factor of four obtains for dilute solutions. Using this factor, a solubility in the range 0·18–0·25 gm./l. of silver as a complex anion can be anticipated for fuel cells operating in the temperature-range 60–80° C.

This solubility of silver is fully adequate to account for the polarization effects observed, and, in experiments in this laboratory on hydrox and methanol cells, a silver transport as high as 20 mgm./cm./hr. for a fuel cell under load has been confirmed by spectrographic, X-ray fluorescent and chemical analyses. It is, however, very probable that the quiescent solubility of silver in potassium hydroxide will be greatly exceeded in fuel cells operating at high current density. All previous data should, therefore, be reviewed in the light of this information, which should afford a better understanding of the electrochemistry of fuel cells.

Intermolecular Energy of Benzene-Cyclohexane

Bottomley and Coopes[1] have recently measured the second virial coefficients of mixtures of benzene and cyclohexane vapours. They derive the values of B_{12}, the virial coefficient for the interaction of one molecule of benzene (1) with one of cyclohexane (2), at 35, 50 and 70° C. They say that these values do not confirm the deduction from measurements of the critical temperatures of these mixtures[2] that the characteristic energy of interaction ε_{12} is smaller than both ε_{11} and ε_{22}. This conclusion appears to be unwarranted and disguises the fact that their measurements of B_{12} are in much better accord with the measurements of the critical temperature than were either of the two earlier measurements of B_{12}.

It is impossible to deduce accurately even the relative sizes of the energies from the virial coefficients since benzene and cyclohexane do not conform exactly to the same reduced equation of state. This is shown in Fig. 1, where B/V^c is plotted as a function of T/T^c (benzene, V_1^c = 260 cm.^{3} mole^{-1}, T_1^c = 561·9° K., cyclohexane, V_2^c = 308 cm.^{3} mole^{-1}, T_2^c = 553·4° K.)[2,3]. The two curves are not coincident. An estimate of the hypothetical critical temperature T_{12}^c (and so of the relative size of ε_{12}) can be made from B_{12}, as follows. Choose a value of V_{12}^c from the familiar equation:

$$(V_{12}^c)^{1/3} = \tfrac{1}{2}(V_1^c)^{1/3} + \tfrac{1}{2}(V_2^c)^{1/3}$$

calculate (B_{12}/V_{12}^c) at each point, and find what value of T_{12}^c is needed for the graph of (B_{12}/V_{12}^c) as a function of (T/T_{12}^c) to fall between the lines for benzene and cyclohexane. This temperature is 550° K., as is shown in Fig. 1. The variation permitted in this value of T_{12}^c is ± 4° K. (subject to the correctness of B_{12} and V_{12}^c) if the points for (B_{12}/V_{12}^c) are not to lie outside those for benzene and cyclohexane. This mean value of T_{12}^c is well below the arithmetic means of T_1^c and T_2^c (557·7° K.), and, in fact, even below T_2^c. It compares very well with the value determined directly from the critical temperatures[2], namely, 548·9° K.

The extent of the agreement between our results and the new values of B_{12}, and the extent of the disagreement with earlier values of B_{12} is shown by tabulating the difference $(T_{12}^c - \frac{1}{2}T_1^c - \frac{1}{2}T_2^c)$, which is a measure of the amount by which ε_{12} falls below the arithmetic mean of ε_{11} and ε_{22} (Table 1).

Table 1

Measurements	$(T_{12}^c - \frac{1}{2}T_1^c - \frac{1}{2}T_2^c)$ deg.
Critical temperatures (ref. 2)	−8·9
B_{12} (Waelbroeck, ref. 4)	−0 5
B_{12} (Cox and Stubley, ref. 2)	>0
B_{12} (Bottomley and Coopes, ref 1)	−8 ± 4

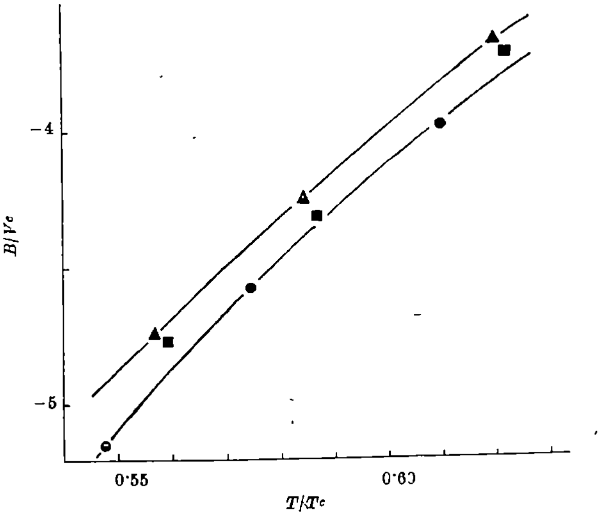

Fig 1. Reduced second virial coefficients for benzene (circles) and cyclohexane (triangles). The squares are (B_{12}/V_{12}^c) for a reduced temperature determined by T_{12}^c = 550° K.

Confirmation of the relative weakness of ε_{12} for aliphatic-aromatic interactions is provided both by the excess thermodynamic functions of the liquid mixtures[5] and by measurements of the solubility of vapours of volatile hydrocarbons in solvents of high molecular weight[6]. However, none of these results can show whether the relative weakness of ε_{12} is caused by a real weakness of the 1–2 forces or by an unusual strength of the 1–1 forces.

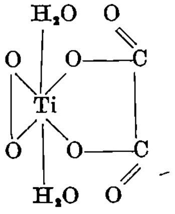
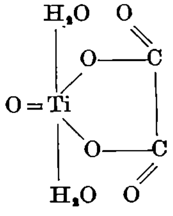
Infra-red Absorption Bands of Co-ordinated Water in Titanium Complexes

ORANGE red and amorphous peroxy-titanium complexes of oxalic, malonic and maleic acids[1–3], when vacuum-dried, have co-ordinated water molecules firmly bonded to the central titanium atom as shown in formula (I).



(I)



(II)

The peroxy-oxygen from these compounds is slowly lost even at room temperature because of the strained peroxy-group[3,4]. The compounds, when kept at 95°–100° C. for about three days, give deperoxygenated compounds of the type (II). However, a sample of peroxy-titanium oxalate sealed in a glass tube lost all its peroxy-oxygen in about four years and gave a white crystalline basic oxalate (II). The amorphous nature of the compounds may be due to random hydrogen bonding in the complexes. The crystallinity observed in one of the deperoxygenated titanyl oxalates may be due to the rearrangement of the molecules during ageing for more than four years. The infra-red absorption of these compounds was studied to find out the effect of co-ordination and hydrogen bonding on the infra-red bands of the free water.

Very little is known about the stretching and bending frequencies of co-ordinated water of transition metal complexes[5]. Fujita *et al.*[6] assigned the co-ordinated water bands in the region 800–1,000 cm.$^{-1}$; but these bands are only due to the rocking motion of the entire water molecule[5]. In the free water molecule, the oxygen moves very little during vibration because of its linkage to two light hydrogen atoms. Even on its co-ordination with a metal atom very little effect is expected on its fundamental modes of vibration.

The infra-red absorption spectra of the first two compounds (Table 1) were taken with a Perkin–Elmer single-beam spectrometer, model 112, and of the rest with infra-cord double-beam spectrophotometer, model 137, using sodium chloride prisms. The observed frequencies for the co-ordinated water are listed in Table 1. In all the compounds, the anti-symmetric and symmetric stretching vibrations of water overlapped in the region around 3,200 cm.$^{-1}$ This band was broad and strong in the amorphous compounds, while it was sharp and strong in the crystalline deperoxygenated oxalate. By elimination of the dicarboxylate group bands, the weak band in the region 850–870 cm.$^{-1}$ was attributed to the rocking mode of vibration of co-ordinated water. This assignment is complicated and at times uncertain because of the presence of strong absorption bands due to the ligands of the complexes.

Table 1. INFRA-RED FREQUENCIES OF CO-ORDINATED WATER

Compounds	Frequencies in cm.$^{-1}$ Stretching	Bending	Rocking
Peroxy			
Oxalate	3,250 (*s*, *b*)	1,640 (*s*)	850 (*w*)
Maleate	3,190 (*s*, *b*)	1,658 (*s*)	854 (*w*)
Malonate	3,125 (*s*, *b*)	1,660 (*s*)	865 (*w*)
Deperoxygenated			
Oxalate	3,185 (*s*, *b*)	1,668 (*s*)	860 (*w*)
Maleate	3,175 (*s*, *b*)	1,664 (*s*)	869 (*w*)
Malonate	3,180 (*s*, *b*)	1,664 (*s*)	870 (*w*)
Oxalate (crystalline)	3.448 (*s*)	1,610 (*s*)	856 (*w*)

s, strong ; *b*, broad ; *w*, weak.

The results in Table 1 show that in the crystalline deperoxygenated oxalate sample, the stretching band for co-ordinated water occurs at 3,448 cm.$^{-1}$ and the bending one at 1,610 cm.$^{-1}$. The stretching band of the co-ordinated water is lowered by a few hundred cm.$^{-1}$ and the bending one is raised by 15 cm.$^{-1}$ from the fundamental vibrations of free water molecule (ν_1 = 3,652, ν_2 = 1,595, ν_3 = 3,756 cm.$^{-1}$). This finding conforms to the theoretical expectations of Sartori *et al.*[7], who concluded that the stretching frequency of co-ordinated water would be lowered by 300–400 cm.$^{-1}$, while the bending would be raised by some tens of cm.$^{-1}$ from the fundamental frequencies of free water. The stretching band of co-ordinated water in the amorphous compounds occurs between 3,175 and 3,250 cm.$^{-1}$, and the bending one around 1,650 cm.$^{-1}$. These frequencies are influenced by the hydrogen bonding in the molecules, showing that hydrogen bonding further lowers the stretching frequency by about 250 cm.$^{-1}$ and the bending is raised by about 40 cm.$^{-1}$ from those of the co-ordinated water of the crystalline oxalate, which may be relatively free from hydrogen bonding.

Significance of Experimental Rate Constants

THERE are difficulties in defining rate constants for the reactions of solids[1]. Since a rate constant describes a rate it must have the dimension (time)$^{-1}$. Constants with other dimensions with respect to time may exist in an empirical relation between extent of reaction and time, but they should never be wrongly identified as rate constants.

Consider the following relation as defining an experimental rate constant:

$$r = kf(x) \qquad (1)$$

where x is a measure of the extent of the reaction. r is the reaction rate (dx/dt); $f(x)$ is a function of x which is independent of temperature and time; k is the experimental rate constant defined by $f(x)$.

Such a rate constant is defined in terms of a particular $f(x)$ and contains an arbitrary constant, since any function $g(x) = cf(x)$ will satisfy the definition if c is independent of temperature. The experimental activation energy is not affected by this constant factor of the rate constant.

For Gomes's example, $x = a\,t^{1/2}$

$$r = a\,t^{-1/2}/2 = a^2/2x$$

(a^2) is the rate constant for $f(x) = (1/2x)$ and the experimental activation energy is unambiguous.

In order to interpret an experimental rate constant a hypothesis as to the mechanism is needed. A rate constant has a simple significance if the rate is proportional to the concentration of a single activated complex which is formed directly from the reactants If the rate-determining activated complex (or complexes) is not formed directly from the experimental reactants as measured by x, then it may still be possible to interpret the experimental rate constant in terms of a number of simple rate constants.

Experimental rate constants may contain one or more of the following complications. The first three are combinations of simple rate constants and the fourth is due to a temperature-dependent factor (of the rate constant) which can be interpreted as some property of a solid phase in the system.

(*a*) The product of a simple rate constant and one or more equilibrium constants (provided the equilibrium constants can be expressed as a ratio of simple rate constants, otherwise see (*c*) below). Such a compound rate constant will obey the Arrhenius relation, and the experimental activation energy will be the heat of formation from the experimental reactants of the rate-determining activated complex.

(*b*) A compound rate constant containing as a factor the product of several simple rate constants each one to a fractional power so that the compound rate constant has the dimension (time)$^{-1}$, for example, $(k_1 k_2)^{1/2}$. Such a rate constant will obey the Arrhenius relation and the experimental activation energy is the mean heat of formation from the experimental reactants of the several activated complexes.

(*c*) A compound rate constant containing as a factor the sum of several simple rate constants. Such a rate constant will not obey the Arrhenius equation exactly; the apparent activation energy will vary with the temperature. Consider, for example, the first-order consecutive reactions:

$$A \underset{2}{\overset{1}{\rightleftharpoons}} B \xrightarrow{3} C$$

Suppose k_1, k_2 and k_3 are simple rate constants obeying the Arrhenius relation. For steady-state conditions, the concentration of B changing slowly compared with the overall rate, the compound rate constant is $k_1 k_3/(k_2 + k_3)$ and the apparent activation energy is $(E_1 k_3 + E_3^1 k_2)/(k_2 + k_3)$. This is a mean between E_1 and E_3^1 weighted by the relative magnitudes of k_2 and k_3. E_1 is the activation energy of reaction one and $E_3^1 = E_3 + E_1 - E_2$ is the (compound) activation energy for the formation of activated complex three from the experimental reactant A.

(*d*) A rate constant as defined here may contain a temperature-dependent factor which a hypothetical mechanism may ascribe to some property of a solid phase in the system, for example, the permeability of a coherent layer of product. The presence of such a factor may be suspected if the experimental rate constant deviates greatly from the Arrhenius relation but its presence is generally not detected except from knowledge of the mechanism.

On the other hand, similar temperature-dependent constants may appear explicitly in an empirical relation between the extent of reaction and time. In these instances it may be necessary to include the constant as a factor of the measure of the extent of the reaction in order to define a rate constant, for example, the logarithmic law:

$$mx = \ln(kt + 1)$$

(m) is not a rate constant as it does not have the dimension (time)$^{-1}$. If it varies with temperature an experimental rate constant can be defined in terms of $y = mx$ since $r = dy/dt = ke^{-y}$

The major difficulties in defining rate constants for the reactions of solids are:

(*a*) The presence in the experimental rate constants of factors which can be interpreted as the temperature-dependent property of a solid phase but which cannot be expressed in terms of simple rate constants.

(*b*) For powdered solids it is usually difficult to measure particle shapes, sizes and positions sufficiently accurately to test fully the often complicated rate equations predicted by quite simple reaction mechanisms.

(*c*) Rate equations for the reactions of solids rarely approximate to the form needed to define a single experimental rate constant. It would seem better to discard the concept of an experimental rate constant than to generalize equation (1) and define several experimental rate constants although this can be done sometimes by writing the rate equation as

$$\sum_n \sum_m [r/k_m f_m(x)]^n = 1 \qquad (2)$$

BIOCHEMISTRY

Phenethyl Alcohol in Wines

PHENETHYL alcohol has been found in fusel oils in but a few cases[1,2], and only in trace amounts. Probably for this reason it has been assumed that it is not formed in fermentation of natural substrates[3-5]. However, it is well known in the perfume industry that in steam distillation phenethyl alcohol is mainly left in the pot residue[6]. The low volatility of phenethyl alcohol thus explains its absence in fusel oil fractions.

The recent discovery of phenethyl alcohol in beer[7-9], sometimes in amounts approaching to those of isoamyl alcohol[7,10], raises the question of whether this substance is to be regarded as peculiar to beer, or whether it is a common product of yeast fermentations. I have therefore attempted to estimate the content of this alcohol in several different wines, using a method developed especially for the analysis of this substance in beer[11]. The method involves extraction of wine with ether, removal of interfering substances with alumina, chromatography of the concentrated extract on a silicic acid column, and ultra-violet spectrophotometric estimation of phenethyl alcohol in the appropriate fraction. The method is not ideal for wine, and the values obtained are probably somewhat too low. The application of the method to wines with a high alcohol content is especially difficult. Thus it was necessary to subject the extract of a South African muscatel wine (with 18 per cent alcohol, v/v) to repeated chromatography on silicic acid before the characteristic fine structure spectrum of phenethyl alcohol could be observed. The recovery in such cases is probably far from quantitative.

Table 1. AMOUNT OF PHENETHYL ALCOHOL IN SOME WINES

Origin of wine	Type of wine	Mgm. phenethyl alcohol/l.
French	red, Bordeaux	51
French	red, Burgundy	37
Hungarian	red, sweet	27
French	white, Bordeaux, dry	34
French	white, Bordeaux, sweet	20
South African	muscatel wine, sweet	> 7

The results are shown in Table 1. All the wines contain phenethyl alcohol, and the concentration-range is the same as was found in beers[7], that is. 10–50 mgm./l. In this respect phenethyl alcohol differs from the common fusel alcohols, isoamyl alcohol and isobutanol, which are present in wines in amounts several times higher than in beers.

As some fruits are known to contain phenethyl alcohol, a sample of grape must from fresh Spanish green grapes was subjected to the same analytical procedure, but no traces of phenethyl alcohol could be detected.

According to the classic theory of Ehrlich[12], phenethyl alcohol might be formed from phenylalanine on fermentation. The concentration of phenylalanine in seven different Californian grape musts lies between 30 and 80 mgm./l.[13], and in five different French wines 0–4 mgm./l.[14]. If these figures can be taken as representative for musts and wines in general, the disappearance of phenylalanine and formation of phenethyl alcohol during fermentation is in very good quantitative accord with Ehrlich's theory. On similar grounds, I have expressed the opinion that the Ehrlich mechanism would explain the presence of phenethyl alcohol in beer[7].

However, this accordance with Ehrlich's theory may be only apparent and accidental. Recently, Stevens has found small amounts of phenethyl alcohol (1–2 mgm./l.) in fermented substrates free of amino-acids, together with tyrosol (*p*-hydroxy-β-phenylethanol)[15]. Independently, I have carried out fermentations in substrates free of phenylalanine, but with otherwise widely different sources of nitrogen, using a brewery strain of *Saccharomyces carlsbergensis*. In them I have always found phenethyl alcohol in amounts of the same order of magnitude (14–29 mgm./l.) as formed by the same yeast in the normal fermentation of malt wort (21–23 mgm./l.) (to be published later).

The present view is that fusel alcohols are either overflow products of amino-acid synthesis within the cell or by-products derived from the deamination and decarboxylation of amino-acids found in the fermentation medium[5,15,16]. They are considered to be formed from the corresponding keto acids which constitute a common intermediate step in both processes. Thus the initial precursors of fusel alcohols may be carbohydrates as well as amino-acids, depending on the factors which influence the supply and withdrawal of each particular keto acid pool. Guymon *et al.*[5] suppose that this theory is limited to the metabolism of leucine, isoleucine, and valine; but Stevens's and my results seem to imply that it may be extended at least to tyrosine and phenylalanine metabolism.

I thank Dr. L. Enebo, Stockholm Brewing Co., for advice, and Mr. B. Risberg, director of AB Vin- och Spritcentralen, for the samples of wine.

Red Proteins from Bovine Milk

SEVERAL workers have reported the isolation of a red coloured protein ('red protein') from bovine[1–3] and human[4–8] milk. The occurrence of a similar red protein in serum, responsible for transport of iron (transferrin), is now well established[9]. It has been suggested[10] but not always accepted[11] that serum transferrin occurs to some extent also in milk. In the work reported here an attempt has been made to isolate the different red proteins occurring in bovine milk and to compare them with one another and with bovine serum transferrin.

During the chromatographic fractionation of the 'albumin fraction'[12] of a pooled bovine whey on diethyl amino-ethyl (DEAE) cellulose, two similar salmon-pink coloured fractions, F_1 and F_2, were obtained[13]. Removal of slow sedimenting impurity from the fractions was achieved by the use of 'Sephadex *G*.75'. Purified bovine serum transferrin was kindly provided by Dr. J. Williams.

Although similar in colour and spectrum, the two fractions, F_1 and F_2, behave quite differently on examination by starch gel electrophoresis in 0·0088 *M* borate − 0·022 *M* sodium hydroxide buffer at *p*H 9·2. Though F_1 gives a single protein band at the origin which spreads slightly (Fig. 1*a*), F_2 gives a distinctive pattern (Fig. 1*b*) comprising several adjacent bands of similar intensity with a trace of more rapidly moving material. Bovine transferrin gives a very similar pattern without the fast impurity. Immunoelectrophoretic comparison[14] of F_2 and bovine serum transferrin against rabbit antisera (anti-bovine colostrum and anti-bovine serum) suggests a close antigenic relationship (Fig. 2*a*). This is confirmed by the combination of gel diffusion and immunoelectrophoresis[15] shown in Fig. 2*b*. Thus with transferrin in one of the troughs, the precipitation line

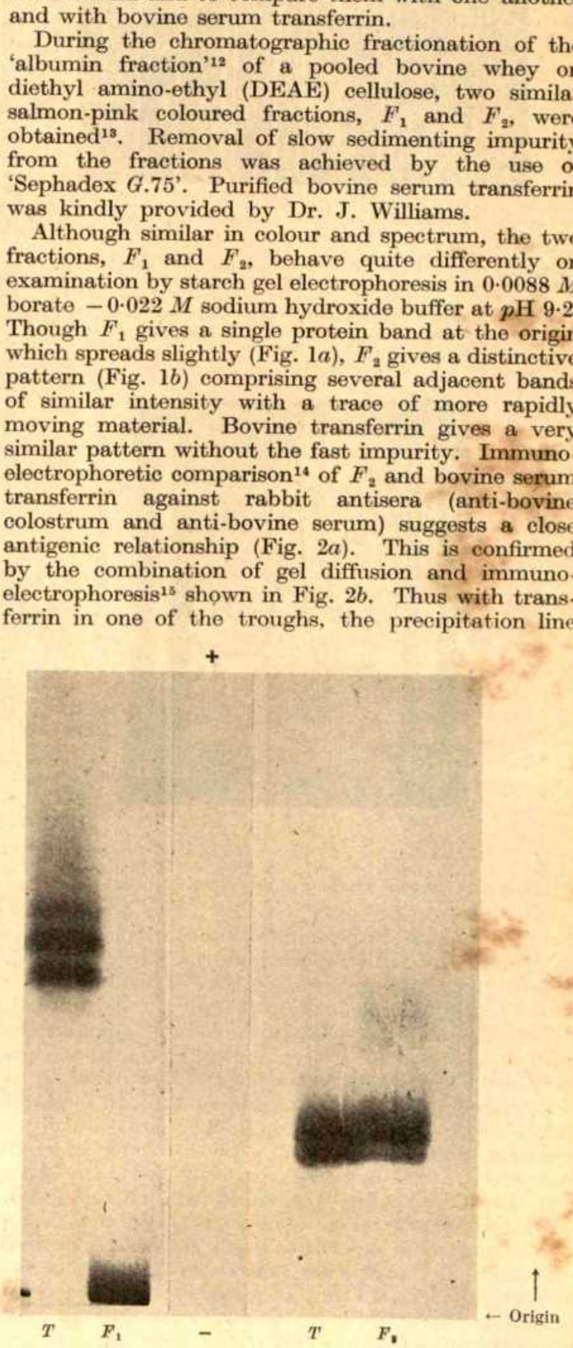

Fig. 1. Starch-gel electrophoretic comparison of *a*, Fraction F_1 with bovine serum transferrin (*T*); 6 V./cm. applied at 18 ± 2° C. for 8½ hr.; *b*, Fraction F_2 with bovine serum transferrin (*T*); 6 V./cm. applied at 18 ± 2° C. for 6 hr.

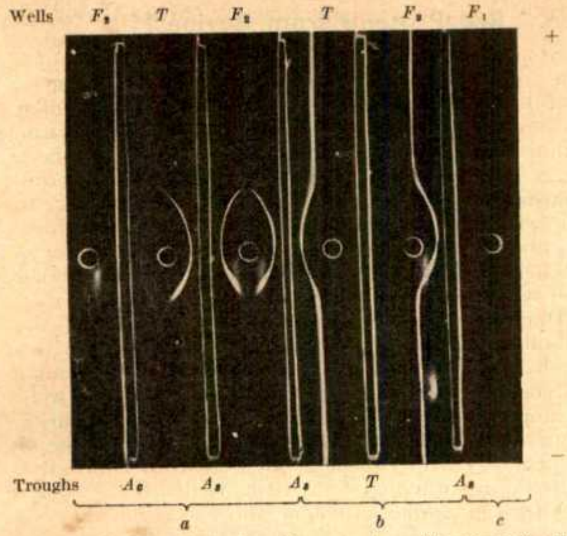

Fig. 2. Immuno-electrophoretic comparison of fractions F_1, F_2 and bovine serum transferrin (T) in 0·05 M veronal buffer at pH 8·6. Wells contain F_1, F_2 and T, as shown. Troughs contain rabbit anti-bovine colostrum (Ac), rabbit anti-bovine serum (As) or T, as indicated. Approximately 10 V./cm. applied parallel to trough direction for 2 hr.

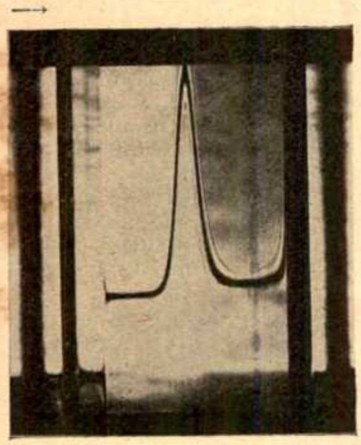

Fig. 3. Sedimentation pattern for fraction F_1 in phosphate–sodium chloride buffer, I = 0·1, pH 7·8 after 80 min. at 59,780 r.p.m. protein concentration = 1·5 gm./100 ml.

formed against anti-bovine serum in an adjacent trough, merges with the precipitation arc due to F_2, against the same antiserum. Hence F_2 and bovine serum transferrin are closely related if not identical.

Solutions of F_1 are salmon-pink in colour and the absorption spectrum is very similar to that described for Groves's red protein[3]. Fig. 2c shows that F_1 is not related to any serum component. It migrates as a single well-defined boundary in the ultracentrifuge (Fig. 3) giving $[S_0]_{c=0} = 5{\cdot}65\,S$ in close agreement with Groves's reported value (5·55 S). The isoelectric pH is established as $8{\cdot}0 \pm 0{\cdot}2$. Although at neutral or acid pH it migrated as a single component with only slight asymmetry in free boundary electrophoresis, at more alkaline or at extremely acid pH's it was resolved into two components. An attempt was made to separate the latter by refractionation on DEAE cellulose. Three, and possibly five, components having different electrophoretic behaviour on starch were obtained. All have the salmon-pink colour of the starting material and a very similar absorption spectrum. Slight differences in the extinction coefficients both at 280 mμ and 460 mμ occur, but these may result from incomplete purification. One of the fractions tends to precipitate on exhaustive dialysis against distilled water. The others are highly soluble. The sedimentation constants of two of the fractions are somewhat higher than for the mixture at comparable concentration.

In view of the multiple character shown to exist for several well-defined proteins emerging from chromatographic columns[16,17] or detected by starch-gel electrophoresis[18] and similar methods, the occurrence of several F_1 fractions is not surprising; but the possibility that the different components are transformation products of a single protein, induced by the method of fractionation, cannot at present be excluded.

We are grateful to Dr. A. E. Pierce for the supply of bovine milk and rabbit anti-bovine sera, and to Mr. A. Feinstein for performing the immuno-electrophoresis experiments.

Metal Ions as Stabilizers or Destabilizers of the Deoxyribonucleic Acid Structure

RECENTLY there has been considerable interest in the interaction of metal ions with nucleic acids and polynucleotides, primarily as a consequence of the fact that the hydrogen-bonded structure of these macro-molecules collapses in solution in the absence of metallic salts[1–4]. It is perhaps of equal importance that some metal ions are as effective in destroying the native structure of deoxyribonucleic acid (DNA) as others are in maintaining it. Such destabilization has previously remained largely undetected because investigations of metal interactions with DNA have generally been carried out in approximately 0·1 M solution of an electrolyte such as sodium chloride, in which the destabilization effects are masked[5]. However, the double-stranded helical configuration of DNA is stable in solutions containing as low as 10^{-3} M concentration of electrolyte[6]. In the present work, various divalent metal ions have been added in 10^{-4} M concentration to solutions of calf-thymus

DNA (5×10^{-5} *M* in phosphate) in 5×10^{-3} *M* sodium nitrate. Changes in optical density at 260 mμ are then observed in a Beckman *DU* spectrophotometer on heating these solutions at the rate of 1° per min. to 90° and then cooling at the same rate[7]. The conversion of the low optical density solution to the high optical density solution is correlated with the transformation of the double-stranded helix to single strands, and the mean temperature of transition (T_m) is a measure of the stability of the molecule[7].

The various divalent metal ions examined fall into three categories in their effect on the DNA 'melting curves', and these are illustrated in Fig. 1. Curve *A* is obtained in the absence of divalent ions. In the presence of Mg^{+2} (curve *B*), T_m is increased from 63° to 80°, and there is a greater decrease in optical density on cooling. In contrast, in the presence of Cu^{+2} (curve *C*), T_m is decreased to 42°, and there is essentially no decrease in optical density on cooling. Fe^{+2} (curve *D*) combines features of Mg^{+2} and Cu^{+2} in that it increases T_m but causes the retention of the maximum optical density when the solution is cooled.

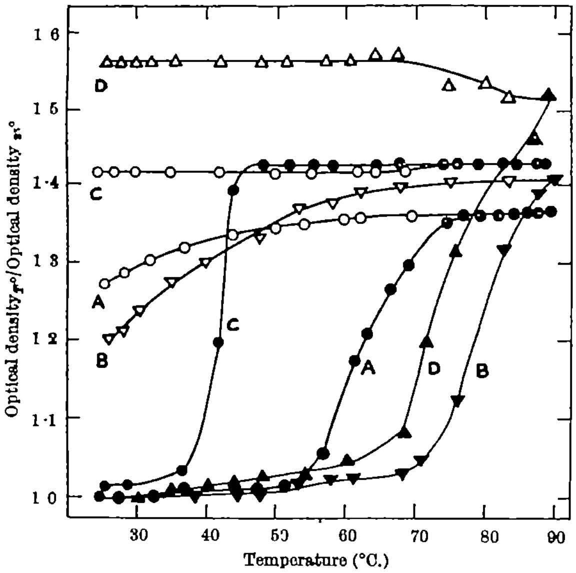

Fig. 1. Closed symbols represent heating curves and open symbols cooling curves for solutions of DNA which are 5×10^{-5} *M* in phosphate containing 5×10^{-3} *M* sodium nitrate and 10^{-4} *M* concentrations of the following: *A*, no divalent metal added; *B*, Mg^{+2}; *C*, Cu^{+2}; *D*, Fe^{+2}

In line with the previous interpretation of DNA melting curves, the effect of Mg^{+2} is considered as stabilizing the molecule. Such stabilization would be achieved by binding to the phosphate groups, and neutralizing the negative charges; the greater decrease in optical density on cooling may be explained by assuming that Mg^{+2} ions hold single chains of DNA in close proximity after the hydrogen bonds are split during heating, so that more of the hydrogen bonds can reconnect during the cooling process. Other metals that behave like Mg^{+2} are Ca^{+2}, Ba^{+2}, Mn^{+2}, Co^{+2}, Ni^{+2}, and Zn^{+2}.

The lowering in T_m by copper can be understood if Cu^{+2} helps to break the hydrogen bonds by displacing them through co-ordination to electron donor groups on the nucleotide bases. Such co-ordination would prevent hydrogen bond reformation on cooling, and thus also accounts for the complete irreversibility of the optical density increase. Cd^{+2} and Pb^{+2} also destabilize DNA, but not nearly to the same extent as Cu^{+2}.

The effect of Fe^{+2} can be explained by initial binding to phosphate, resulting in stabilization, and a subsequent change to binding of nucleotide bases, after the hydrogen bonds have been broken; reformation of hydrogen-bonds is thus prevented. No other metals have been found to behave in like manner.

It is concluded that the melting curves of DNA exhibit very different types of behaviour in the presence of 10^{-4} *M* concentrations of divalent metal ions, and that this behaviour can be related to the stabilization or destabilization of the DNA by these metal ions.

I thank Dr. Alexander Rich for his advice in this work, and Miss Barbara Randall for technical assistance.

N-Terminal Amino-Acids formed during the Activation of Prothrombin

THERE is little information concerning the specific reactions involved in the biological conversion of prothrombin to thrombin. Recently it has been shown that the *N*-terminal amino-acid of thrombin differs from that of prothrombin[1]. The work reported here was undertaken to enumerate and identify the *N*-terminal amino-acids formed by the conversion of prothrombin to thrombin.

Prothrombin was prepared by a combination of the three classical techniques of adsorption on to barium salts[2], ammonium sulphate fractionation[3], and iso-electric precipitation[4]. This was followed by chromatography on 'Amberlite *IRC*-50' as described by Miller[5].

Human brain thromboplastin was prepared and the prothrombin activated by the method described by Miller[6]. Prior to activation a concentrated solution (1–2 per cent) of the prothrombin, prepared as described above, was dialysed overnight against a buffer 0·02 *M* in *tris*(hydroxymethyl)aminomethane and 0·15 *M* in sodium chloride adjusted to *p*H 7·4 with hydrochloric acid. The activation step was done at room temperature (22–23° C.) with constant shaking. Under these conditions quantitative conversion of the prothrombin was achieved in about 3 hr., after which the thromboplastic material was removed by centrifugation.

Determination of *N*-terminal amino-acids was made by forming the dinitrophenyl derivative as described by Fraenkel-Conrat *et al.*[7]. Tentative identification of the amino-acid derivatives was determined by paper chromatography using the 'toluene' system and afterwards 1·5 *M* phosphate at *p*H 6·1 for development.

Known dinitrophenyl amino-acids were run in conjunction with the experimental samples.

N-terminal amino-acid analysis of the prothrombin showed that 85–95 per cent of the *N*-terminal amino-acid present was alanine, 5–10 per cent was threonine, and 0–5 per cent was serine. No detectable *N*-terminal amino-acid was added to the prothrombin by the thromboplastin. After conversion of the prothrombin two new *N*-terminal amino-acids were found in quantities equimolar relative to the alanine. These were tentatively identified as threonine, and leucine (or) isoleucine. The finding of alanine as the *N*-terminal amino-acid of prothrombin is in agreement with the results of others[1,5]. Glutamic acid has been reported as the *N*-terminal amino-acid of thrombin[1]. In the foregoing experiments none was found.

Other investigators[8–10] have found evidence for the formation of an intermediate in the conversion of prothrombin to thrombin. The above results are consistent with this concept. If there is a reaction sequence:

$$\text{prothrombin} \xrightarrow{k_1} \text{intermediate} \xrightarrow{k_2} \text{thrombin}$$

where k_1 and k_2 are the rate constants, and if these are first-order reactions, the equation for the rate of formation of thrombin would be[11]:

$$T = P_0 \left[1 - \frac{k_2 e^{k_1 t} + k_1 e^{k_2 t}}{k_2 - k_1} \right]$$

Where T is the amount of thrombin present at time t, and P_0 is the initial prothrombin concentration. If $k_2 < k_1$ a plot of this equation (T versus t) gives a sigmoidal shape curve.

The curves obtained by plotting the experimentally determined thrombin-levels versus incubation time are also sigmoidal in shape[12], a fact which has heretofore been interpreted as indicative of the 'autocatalytic' nature of prothrombin conversion. In view of the direct evidence presented here for the occurrence of two reactions during the activation of prothrombin, the preferable interpretation appears to be that of sequential reactions rather than autocatalysis.

Further investigation has shown that per mole of *N*-terminal alanine more than 1 mole of *N*-terminal threonine may be formed; when this occurs, as much as a mole of *N*-terminal serine may arise.

Participation of Adenine Nucleotides in the Proposed Direct Pathway of Biosynthesis of *N*-Phosphorylcreatine

EVIDENCE obtained in this laboratory[1,2] suggested that the phosphorylation of creatine by a phosphoryl donor, catalysed by a soluble enzyme system from rat muscle, might not require adenosine diphosphate (ADP). Morrison and Doherty[3] reach the opposite conclusion. Results obtained independently in this laboratory, by procedures already described[1,2], lead us to agree with their conclusion.

Either ADP or ATP is formed during the enzymatic incubation of adenosine diphosphate–ribose (ADP–R) with phospho(enol) pyruvate (PEP) (Table 1). It has previously been shown that they are not present initially in measurable quantities[2] and that they are not formed in the absence of PEP.

Table 1. EFFECT OF APYRASE ON THE PRODUCT OF THE INCUBATION OF PEP IN THE PRESENCE OF ADP–R OR ADP

Addition in first incubation	Concentration of addition ($M \times 10^3$)	*N*-Phosphorylcreatine synthesis, in last step µmoles/ml. in 20 min. Without apyrase treatment	With apyrase treatment
None	—	0·06	0·03
ADP–R	2·0	0·35	0·03
ADP	2·0	0·28	0·06

The reaction mixture contained in a total volume of 1 ml. 0·05 M *tris*-hydrochloric acid buffer *p*H 7·4; 0·04 M creatine; 0·01 M magnesium sulphate; 0·004 M PEP; 3 mgm. of rat muscle enzyme (ref. 1) and 2 μM ADP–R or ADP. After 20 min. at 37°, the contents of each tube was divided into two equal portions. To one portion was added 0·5 ml. of 0·3 N perchloric acid and to the other portion 0·8 mgm. of potato apyrase (ref. 4) and 1·25 µmoles of calcium chloride. It was incubated further for 20 min. at 37° C. and the reaction was stopped as above.

After neutralization with 2·8 N potassium hydroxide, the potassium perchlorate was removed by centrifugation. 0·2 ml. samples of all six neutral supernatants were added to a mixture containing *tris*-hydrochloric acid buffer *p*H 7·4 25 µmoles; creatine 20 µmoles; magnesium sulphate 5 µmoles; PEP 2 µmoles and 0·12 mgm. of pyruvate kinase plus 1·6 mgm. creatine phosphotransferase in a total volume of 0·5 ml.

After incubation for 20 min. at 37° reaction was stopped and *N*-phosphorylcreatine was determined (ref. 1).

Spectrophotometric analysis of a perchloric acid extract of the rat muscle enzyme[1] shows that it contains 0·2–0·6 µmoles of ADP or ATP per gm. of protein. This is in agreement with the finding of Morrison and Doherty (personal communication) that crystalline creatine phosphotransferase contains 0·1 µmole of ATP per gm.

We have not been able to find any radioactivity in an enzyme preparation obtained from rats injected with $NaH_2{}^{32}PO_4$.

Since ADP–R is enzymatically hydrolysed to AMP, the small amount of ATP present may start the autocatalytic formation of ADP in the presence of a phosphoryl donor. Thus a nucleotide which is bound in less than stoichiometric amounts to an enzyme may simulate a 'direct' phosphoryl transfer.

Synthesis of Collagen

Gerber and Altman have suggested[1] that the mechanism involved in the synthesis of fibrous proteins is different from the mechanism involved in the synthesis of globular proteins. In particular, they suggested that collagen is synthesized by the addition of polypeptides containing 70–140 amino-acids to pre-existing collagen fibres. Although the communication raised a number of interesting questions, it should be noted that the conclusions which were reached are not entirely consistent with several recent reports. They stated that the mechanism underlying the biosynthesis of fibrous proteins must be unique, since experiments on the isotopic labelling of collagen and silk fibroin indicated that specific amino-acids are labelled to varying degrees in different parts of these molecules. It is now apparent, however, that a similar situation exists in the synthesis of a number of proteins and polypeptides, including ovalbumin, ribonuclease and insulin[2]. Recently, Dintzis[3] demonstrated non-uniform labelling of specific amino-acids in the synthesis of the globular protein hæmoglobin.

Also in support of their hypothesis, Gerber and Altman observed that most fibrous proteins are considerably larger than 140 Å., the diameter of the ribosomes on which protein synthesis is assumed to occur. Since several non-fibrous proteins are also larger than 140 Å., the problem raised by the relatively small size of ribosomes has been recognized for some time. Recent studies suggest that ribosomes may be considerably larger than was originally supposed[4]. In any event, it seems premature to conclude that the problem which exists in explaining the synthesis of fibrous proteins by ribosomes is entirely different from the problem of explaining the synthesis of large globular proteins. Our own observations in chick embryos[5] indicate that collagen is synthesized by the same ribosomal system which has been postulated for the synthesis of other proteins. Lowther *et al.*[12] have recently reported similar results in work on carrageenin granulomas.

Several other suggestions which were made in the paper also appear to be unlikely. Because the number of C- and N-terminal amino-acids increase after the degradation of collagen to gelatin[6,7], it was suggested that intramolecular cleavage of peptide bonds occurs when collagen is fractionated into soluble forms and that the resulting solutions of 'soluble' collagen consist of peptides from near the termini of the collagen molecule. It was further suggested that these soluble peptides represent 'building blocks' of collagen. Although some peptide bonds are ruptured by relatively small energies[7], the mild conditions generally used to solubilize collagen cannot be expected to rupture peptide bonds. "Neutral salt soluble collagen"[8], for example, is prepared by extracting tissues with dilute, neutral salt solutions at 4° C. It is very unlikely that peptide bonds are broken by this procedure. In addition, it may be pointed out that the molecular weight of neutral salt soluble collagen has been estimated as being 340,000–500,000 (ref. 9), a size which is considerably larger than the peptides postulated by the authors.

It was also suggested that the turn-over time of the peptide 'building blocks' of collagen can be determined from the turn-over time of free hydroxyproline in urine and the turn-over time of collagen itself can be determined from the turn-over time of the peptide-bound hydroxyproline in urine. In previously published experiments, Gerber *et al.*[10] injected proline labelled with carbon-14 into rats and found a turn-over time of about 0·5 days for free urinary hydroxyproline-^{14}C and 15 days for bound urinary hydroxyproline-^{14}C. Using different analytical techniques, we were recently unable to confirm their results and instead we found comparable rates of decay for both the free and bound hydroxyproline-^{14}C in urine[11]. My own results indicated that both the free and bound hydroxyproline in rat urine originate from pools of body collagen which are both synthesized and degraded rapidly.

Although the synthesis of fibrous proteins probably involves unique mechanisms not encountered in the synthesis of globular proteins, there is at present little evidence to indicate what these unique mechanisms may be. For the moment the similarities between collagen synthesis and the synthesis of other proteins are as apparent as the differences.

Use of a Thin Layer of Calcium Sulphate for the Chromatographic Separation of Corticoids

In experiments where we sought a suitable adsorbent for the separation of corticoids by partition chromatography, we found that in calcium sulphate columns a good separation is obtained of less-polar corticoids when chloroform is used for elution. Based on this fact, a detailed analytical procedure was worked out for the fractionation of some corticoids in urinary extracts. The desirable properties of calcium sulphate were applied successfully in a method using thin layers, which substantially speeded up and simplified chromatographic analysis of steroid mixtures and separated the polar 17-OH-corticoids.

Calcium sulphate was prepared by precipitation of an aqueous solution of calcium chloride with a stoichiometric amount of sulphuric acid under constant stirring at a temperature of 70°–80° C. The precipitate of calcium sulphate was rinsed on a Büchner funnel with distilled water until the water gave a neutral reaction. The obtained precipitate was ground and spread in a 2–3 cm. thick layer and allowed to dry for 48 hr. at a temperature of 115°–120° C. Thus prepared, calcium sulphate was suspended in water (20 gm. calcium sulphate per 100 ml. water) with vigorous shaking. The suspension was rapidly poured on a thoroughly degreased glass plate 4 × 40 cm. and allowed to dry in a horizontal position for 2 hr. at 80° C. A compact layer of calcium sulphate was thus obtained which adhered firmly to the glass plate. After cooling, about 5 cm. from the lower end a mixture of standard steroids in alcoholic solution was applied. It was essential to try to keep the diameter of the spot as small as possible. The chromatogram was developed by immersing the lower edge of the plate into a chamber with a 2-cm. layer of the mobile phase at the bottom. After the chromatogram was inserted in a chamber, the latter was closed. As mobile phase we used an acetone/benzene mixture, 1 : 4. The development of the chromatogram was discontinued when the beginning of the mobile solution was 25 cm. from the start, which took about 60 min. After drying the chromatogram with a stream of warm air, we detected it using a spray of an alkaline blue tetrazolium solution[1].

When testing the separating capacity of the described method, standard preparations of pure corticoids were used:

Pregn-4-ene-17α : 21-diol-3 : 20-dione (*S*)
Pregn-4-ene-17α : 21-diol-3 : 11 : 20-trione (*E*)
Pregn-4-ene-11β : 17α : 21-triol-3 : 20-dione (*F*)
5β-Pregnane-3α : 17α : 21-triol-11 : 20-dione (*THE*)
5β-Pregnane-3α : 11β : 17α : 21-tetrol-20-one (*THF*)

By means of this technique a sharp separation was achieved, in particular of substances *S*, *E* and *F*, while the separation of *THF* and substance *THE* was only very slight. The mobility in relation to substance *F* of individual steroids is shown in Table 1. For a sharp separation of *THF* and substance *THE* the use of 3 per cent ethanol in chloroform proved very satisfactory (Table 2). In this system the substances were separated very sharply. This chromatogram was developed for 90 min. in an open chamber.

Table 1

Corticoid	R_F
THF	0·38
THE	0·41
F	1·00
E	1·43
S	3·43

Table 2

Corticoid	R_F
THF	0·54
THE	0·73
F	1·00

This technique proved suitable for the separation of corticoids in urinary extracts. The latter were prepared as follows: the urine was hydrolysed by means of β-glucuronidase and extracted with chloroform. After washing with 0·1 *N* sodium hydroxide the chloroform was dried with anhydrous sodium sulphate and evaporated to dryness. An aliquot portion corresponding to 0·3 mgm. of total 17-hydroxycorticoids estimated by Silber–Porter's method[2] was subjected to chromatography.

For these purposes the suspension of calcium sulphate (20 gm. calcium sulphate per 100 ml. water) on the two thoroughly degreased glass plates 4 × 40 cm. was heated in the horizontal position for 10 min. at 80° C. After 10 min. drying the calcium sulphate acquired a pasty consistency. In this state it could be divided into two equally wide chromatographic strips, which was done by a chisel 0·3 cm. wide. The strips are then further dried for 2 hr. at 80° C. After cooling, to one strip, about 5 cm. from the lower edge, urinary extract of corticoids was transferred dissolved in the smallest possible amount of a methanol/chloroform mixture, 1 : 1, and to the second strip a mixture of standard steroids in alcoholic solution was applied. One of the glass plates was developed in the system acetone/benzene, 1 : 4, the other in 3 per cent ethanol in chloroform. In urine samples of five normal men a *THF* spot, a strong *THE* spot, substance *F* and a trace of substance *E* were found. The preliminary experiments suggest that it will be possible to use the method successfully for quantitative analyses.

Pyruvic Acid, a Unique Component of an Exocellular Bacterial Polysaccharide

PYRUVIC acid, a compound widely distributed in Nature as a metabolic intermediate, is a building unit for many compounds of biological origin. For example, in the biosynthesis of sialic acid—a carbohydrate associated with mucoproteins in animals—pyruvic acid is combined enzymatically with *N*-acetyl mannosamine by an aldol-type condensation[1,2]. Muramic acid—a carbohydrate constituent of bacterial cell walls—is thought to arise from a condensation of pyruvic acid, as phosphoenol pyruvate, with *N*-acetyl glucosamine[3]. Also, pyruvic acid has been isolated and identified as a component of a commercial red seaweed polysaccharide. Structural studies indicate the presence of one acid residue for each 51 hexose units[4,5].

Recently, we found a polysaccharide which contains 3·0–3·5 per cent pyruvic acid as a structural component. This high-viscosity, water-soluble gum is produced exocellularly by the bacterium *Xanthomonas campestris NRRL B*-1459 (ref. 6). In addition to pyruvic acid, the polysaccharide *B*-1459 contains D-glucose, D-mannose, D-glucuronic acid and acetic acid in the ratio 2·8 : 3·0 : 2·0 : 1·7 and has a repeat unit weight of approximately 1,580 (ref. 7).

The presence of pyruvic acid was discovered when hydroxamic acid derivatives were prepared from an ether extract of a polysaccharide acid hydrolysate. Paper chromatography of the hydroxamate preparation revealed hydroxamates of both acetic acid and pyruvic acid. The keto acid was identified definitely by preparing the 2,4-dinitrophenylhydrazone (DNP) derivative. This derivative had a melting point of 216° C., and its melting point was not depressed when it was mixed with an authentic sample of pyruvic acid DNP.

A reliable assay for pyruvic acid combined in the polysaccharide was established by modifying a method originally described for the determination of keto acids in fermentation liquors[8]. A 0·2–0·4 per cent solution of polysaccharide was hydrolysed in 1 *N* hydrochloric acid for 3 hr. A 2-ml. aliquot was removed and was mixed with 1 ml. of a 2,4-dinitrophenylhydrazine reagent (0·5 per cent in 2 *N* hydrochloric acid) for 5 min. The reaction mixture was extracted with 5 ml. of ethyl acetate, and the aqueous layer was discarded. After the ethyl acetate was extracted with three 5-ml. portions of 10 per cent sodium carbonate, the extract was diluted to 25 ml. with additional 10 per cent sodium carbonate. Concentration of pyruvate was determined by measuring optical density of the sodium carbonate solution at 375 mμ.

Highly purified samples of the polysaccharide *B*-1459 contained about 3 per cent of pyruvic acid and none was lost during periodate oxidation, sodium borohydride reduction, or treatment with alkali under conditions which readily effected deacetylation. In contrast, dextran *B*-512, gum karaya, and gum tragacanth contained no pyruvic acid.

In seaweed agar, pyruvic acid exists as a ketal linkage forming a 4,6-0-(1-carboxy-ethylidine) unit attached to galactose. The behaviour of the pyruvate bond in the polysaccharide *B*-1459 to acid and base hydrolysis suggests that it, too, is in a ketal form. Preliminary studies indicate that the pyruvate is attached to the glucose moiety. Since glucose is linked within the polysaccharide chain by glycosidic bonds at the 1 and 4 positions (unpublished data), pyruvate cannot be attached to glucose at the 4 and 6 positions. Therefore, the pyruvate–ketal linkage in the polysaccharide *B*-1459 is presumed to involve two glucose units to produce a polysaccharide with a novel cross-linked structure.

We thank Dr. Allene Jeanes and Mr. S. P. Rogovin, of this Division, for the samples of native microbial polysaccharides used in this work.

Detection and Estimation of Squalene in Leaves

SQUALENE, $C_{30}H_{50}$, was discovered in the liver oils of squaloid sharks by Tsujimoto[1] and later found in olive oil by Thorbjarnarson and Drummond[2]. Values as high as 708 mgm. per 100 gm. have been reported by Fitelson[3] with much lower values, 5–28 mgm., in several other vegetable oils. More recently, Fuhrmann[4] reported a squalene content of 200 mgm. per 100 gm. in olive oil.

Squalene is usually identified by its crystalline hexahydrochloride. Three isomers, ranging in m.p. from 108° to 144° C., were separated by Heilbron *et al.*[5]. The method used for estimating total squalene is based on halogen uptake by the unsaponifiable fraction. This is inaccurate when phytoene, phytofluene or other unsaturated compounds are present. Identification is also unsatisfactory where very low concentrations of squalene are encountered.

By gas chromatography we have obtained a single sharply defined peak for squalene using a silicone-rubber column at temperatures between 240° and 290° C. Phytoene gave a broad peak 15–20 min. after the squalene had been separated. No peak was obtained for phytofluene. Results complement those of O'Neill and Gershbein[6]. The same peak, on which that for authentic squalene can be superimposed, has been detected in extracts of carrot roots, olive oil, the mould *Phycomyces blakesleeanus*, and the leaves of six species: *Acanthus*, alfalfa, carrot, elderberry, lettuce and olive.

For identification, we dehydrogenated the material with *N*-bromo-succinimide[7,8]. When fully dehydrogenated, squalene will have a lycopene-like spectrum[8]. In this test, one must exclude phytoene or phytofluene, which can be dehydrogenated to lycopene and which also yield small quantities of di- and tetra-dehydrolycopene, with 13 and 15 double bonds respectively. Exclusion can be assured by adsorption chromatography and a check on ultra-violet absorption at 286 mμ, the phytoene maximum.

The plant materials used were collected fresh or purchased locally. The following chemicals were used: squalene (Eastman technical grade, 90 per cent pure); aluminium oxide (Woelm); petroleum ether, passed over silica gel, free from ultra-violet-absorbing impurities to about 230 mμ; methanol (absolute).

The unsaponifiable fraction was prepared in the conventional manner. In two large-scale runs, alfalfa and olive leaves, the unsaponifiable fraction in about 20 ml. petroleum ether represented the extract from about 5 kgm. of leaf material.

The unsaponifiable fraction was chromatographed on alumina (activity, grade II) 25 × 4 cm., and washed with petroleum ether until 50–100 ml. eluate had been collected. Absorption at 286 mμ was negligible, showing the absence of phytoene.

In a previous test, 10 mgm. squalene were mixed with 4 mgm. phytoene and chromatographed on such a column, and each 25 ml. of eluate was examined for squalene and phytoene. Squalene was detected in the 2nd and 3rd fractions by dehydrogenation with *N*-bromosuccinimide. Phytoene did not appear until after the 5th fraction.

Authentic squalene, phytoene, and phytoene-freed unsaponifiable plant extracts were treated with *N*-bromosuccinimide. The maximum yield of material absorbing at 502, 470, 445 mμ in petroleum ether (lycopene-like spectrum) was obtained with a 1 : 2 ratio of squalene to *N*-bromosuccinimide, by weight.

A mole ratio of 1 : 1 has been recommended[7,8]; but whereas Zechmeister's laboratory was desirous of minimizing destruction of the conjugated system, in our case possible losses had to be counterbalanced by the necessity of obtaining a measurable quantity of fully dehydrogenated squalene.

The sample (authentic squalene, phytoene, plant extracts, etc.) containing 5–25 mgm. polyene was dissolved in 5 ml. chloroform and 2 ml. glacial acetic acid. *N*-bromosuccinimide in the ratio of 1 : 2 by weight was added and the mixture was gently refluxed. It slowly turned yellow and then brick red and finally brown. After 2 hr., the solution was taken up in petroleum ether, washed, dried and chromatographed on a small column of $MgO–SiO_2$, 5 × 0·8 cm., developed with petroleum ether containing acetone, then benzene and finally alcohol. The chromatogram was developed with petroleum ether containing increasing percentages of acetone, and fluorescent and yellow zones were eluted. On the addition of benzene, in the case of squalene, a pink zone separated from the upper brown. When eluted with alcohol, it showed a typical lycopene spectrum, and thus the presence of squalene was confirmed.

In the case of phytoene, two zones were detected above the lycopene. Zechmeister and Koe[9] had detected one, presumably with 13 double bonds in conjugation, maxima in benzene 540, 508, 475 mμ. The second had maxima at 555, 520, 492 mμ, and is presumably a tetra-dehydrolycopene, corresponding to the dehydrolycopene, $C_{40}H_{52}$, of Karrer and

Rutschmann[10]. The spectra showed *cis*-peaks, at 400 and 420 mμ, respectively.

Peaks for squalene were given on a silicone-rubber column ('Aerograph'), operated as follows: length of column, 5 ft.; temperature (*a*) 260°, (*b*) 244°; flow-rate (*a*) 80, (*b*) 96·8 c.c. per min.; retention time (*a*) 6·8, (*b*) 10·4 min.

Based on the ratios of areas under the curves, the following estimates (mgm. per 100 gm.) for squalene were made: olive oil, 156; olive leaves (air dried), 4·0; alfalfa dried meal, 2; *Acanthus* (fresh weight), carrot leaves and roots, elderberry, lettuce, 0·05–0·1.

PHYSIOLOGY

Standard Bicarbonate Values of Whole Blood

THE convenience of the interpolation techniques[1,2] for the assessment of acid-base imbalance in patients has been widely recognized, and in clinical surgery the ability to differentiate rapidly between the metabolic and respiratory components of such a disturbance has special value. In particular, the standard bicarbonate value, defined as the bicarbonate content of oxygenated blood at 38° C. equilibrated at a $P\text{CO}_2$ of 40 mm. mercury provides a quantitative assessment of metabolic disorder. It was therefore disconcerting that when 63 arterial blood samples from a group of 22 patients anæsthetized with halothane were analysed, the standard bicarbonate values obtained (18·14 ± 1·94 m.equiv.) were significantly lower than those quoted by Astrup *et al.*[3] (22·9 ± 1·5 m.equiv.). Because there was no other evidence of metabolic acidosis in these patients and because the bicarbonate value of plasma (23·28 ± 2·82 m.equiv.) in a similar group under the same conditions fell within the range of Astrup's figures it was decided to establish our own standards.

Accordingly, blood samples obtained from conscious volunteers were separated into three aliquots and standard bicarbonate values determined for whole blood, for true plasma (that is, plasma equilibrated at a $P\text{CO}_2$ of 40 mm. mercury before separation from blood) and for separated plasma (that is, plasma equilibrated after separation from blood). The results obtained were as follows:

	Whole blood	True plasma	Separated plasma
Standard bicarbonate (m.equiv./l.)	18·89	19·44	23·14
Standard deviation	1·79	1·37	2·29

The accuracy of the interpolation method for determining carbon dioxide tension was assessed using 12 random samples of whole blood previously equilibrated in a tonometer with known tensions of carbon dioxide. The mean difference between the calculated and the known carbon dioxide tensions was + 0·183 ± 0·14 mm. mercury.

The accuracy of the method for the measurement of total carbon dioxide was assessed by deriving values from 16 arterial blood samples both by the interpolation method and by a colorimetric method in routine use in the biochemistry laboratories of this Hospital. The results obtained were 21·59 and 21·00 m.equiv./l. respectively. A similar comparison was made between the interpolation method and the Van Slyke technique[4] using 13 venous blood samples. The mean values obtained were 24·27 and 24·39 m.equiv./litre. No statistically significant difference was found in either comparison.

When the actual bicarbonate determinations derived from the colorimetric and Van Slyke techniques were substituted in the Henderson–Hasselbalch equation and using *p*H and $P\text{CO}_2$ values derived from the interpolation method the *p*K′ values obtained were 6·11 ± 0·03 and 6·10 ± 0·02 respectively.

A further analysis was carried out on a group of twelve conscious patients after surgery from whom 48 arterial blood samples were obtained. These gave a mean standard bicarbonate value of 18·95 ± 1·24 m.equiv./l., a figure which in the light of the evidence just presented probably reflects the normal standard bicarbonate in whole blood in man.

Role of Genetic Factors in Susceptibility to Experimental Hypertension due to Chronic Excess Salt Ingestion

THERE is considerable evidence indicating a familial trend in human essential hypertension[1]. A familial disease could be due exclusively to common environmental factors, exclusively to common genetic factors, or to an interaction of the two.

We have been investigating the effects of chronic excess salt ingestion in both man and animals and have obtained evidence which supports the thesis that dietary salt plays an ætiological part in human essential hypertension[2]. However, it was observed that some individuals remained normotensive despite the fact that they were chronically consuming large amounts of salt. In salt-feeding experiments with rats, in a given group some never developed hypertension whereas a few developed fulminating hypertension after a short time on the diet. Such wide variations in response to excess salt consumption could be ascribed either to statistical limits of a homogeneous population or to variations in sensitivity to salt based on genetic differences. If the last were true, it should be possible by selective inbreeding to

Table 1

Median	164	161	182	178·5	143	139·5

Effect of L-triiodothyronine-sea salt regimen on systolic blood pressures of Sprague–Dawley rats: response of original breeding stock compared with third generation of animals inbred for sensitivity (S_3) and resistance (R_3) to hypertension from regimen.

By Student's *t* test, mean systolic blood pressure for S_3 > original breeders ($P < 0·001$) and R_3 < original breeders ($P < 0·001$).

separate strains that differ significantly in their liability to hypertension from excess salt consumption. This communication reports experiments on rats which confirmed this postulate. It seems probable that these observations are pertinent to man as well.

In rats, hypertension from chronic excess salt feeding usually develops slowly[3]. However, we have observed that the administration of L-triiodothyronine to intact salt-fed animals leads to marked hypertension in some animals within one month while animals treated similarly, except fed a low salt control diet, do not develop hypertension. This technique was used to isolate two strains of animals, one of which was resistant while the other was sensitive to the triiodothyronine–high salt regimen. After development of these two strains, salt-feeding without triiodothyronine led to the rapid development of hypertension in the strain known to be sensitive to the triiodothyronine–salt regimen whereas hypertension did not develop in the other resistant strain. The technique was as follows:

Twenty-three male and 24 female unselected 3-week-old Sprague–Dawley weanling rats constituted the initial breeding stock. Each received 50 µgm. triiodothyronine intraperitoneally on each of four successive days and then at about 2-day intervals ten 5 µgm. doses in the next 21 days. All were fed a chow containing 11·6 per cent sea salt containing about 7·3 per cent sodium chloride[3]; systolic blood pressures were measured in a standard fashion[3] 48 hr. after the last injection of triiodothyronine. Males and females with the highest blood pressures were selected for inbreeding as were those with the lowest pressures, and animals with intermediate pressures were discarded. The first generation of animals derived from these matings of parents with high or low blood pressures were called S_1 (sensitive) or R_1 (resistant) respectively; afterwards, no interbreeding between the *S* and *R* strains occurred.

The S_1 and R_1 animals were weaned at 3–4 weeks and immediately put on the triiodothyronine–sea salt regimen already described. Animals that responded in the S_1 strain with the highest, in the R_1 strain with the lowest, pressures were selected for further inbreeding and the remaining animals killed; usually brother–sister matings were possible. After two generations of such selective inbreeding there was evidence of a significant increase in the fraction of S_2 animals that responded with high blood pressure and a decrease in the fraction with normal pressures. Just the opposite was true for the R_2 strain. Therefore when the third generation was weaned, half the S_3 and R_3 animals of each sex were put on the triiodothyronine–sea salt regimen, while the other half were treated as described later.

Table 1 is a summary of the blood pressure response of the S_3 and R_3 animals to the standard triiodothyronine–sea salt regimen. It is compared with the response of the original breeding stock from which the two strains were derived. The difference in response between the S_3 and the R_3 animals was striking and highly significant, statistically. On the basis of this evidence it was concluded that a difference in susceptibility to the triiodothyronine–sea salt regimen had been developed after three generations of selective inbreeding although neither the S_3 nor the R_3 strains were as yet pure.

One hundred and thirty-one siblings of animals from the S_3 and R_3 strains shown in Table 1 received either the control low sodium diet or the same high sodium, sea salt chow used before but no triiodothyronine. Table 2 is a summary of the blood-pressure responses of these animals. The differences in blood-pressure response between the salt-fed S_3 and salt-fed R_3 animals were more striking than was indicated in Table 2: after 6 months of salt feeding none of the 39 R_3 animals had hypertension whereas after only 3 months on the same programme 49 of the 60 S_3 animals were hypertensive and many of them severely so. The 3-month lag was occasioned by differences in times at which litters were delivered as well as because S_3 animals tended to have smaller litters so that a longer time was required to get sufficient numbers of S_3 rats. Therefore, an increase in sensitivity to salt would tend to be minimized in the S_3 strain with differences in response of the two strains thereby being under- rather than over-estimated. When members of the same S_3 strain were maintained on the control low salt diet, hypertension did not develop. Thus, however strong the genetic tendency to hypertension may be in this strain, the addition of a high salt diet seems necessary to unmask it. Among the R_3 animals, the presence or absence of excess dietary salt did not seem to affect the blood-pressure response.

It seems reasonable to expect that similar genetic factors operate in man. If salt plays the important ætiological part that we said it does in human hyper-

Table 2

Strain	S_3				R_3			
Sex	♂		♀		♂		♀

Systolic blood pressure (mm. mercury)								
Mean (± *S.D.*)	180·2 (±19·4)	125·8 (±6·8)	156·8 (±28·4)	112·2 (±7·3)	119·7 (±14·5)	120·1 (±8·5)	105·2 (±12·5)	106·4 (±10·7)
Median	180	126	146	114	121·5	119	108	104

Effect of high intake of salt without L-triiodothyronine on systolic blood pressures of Sprague–Dawley rats that were selectively inbred for three generations to develop strains sensitive (S_3) and resistant (R_3) to development of hypertension from salt. Blood pressures of S_3 strain after only 3 months whereas those of R_3 strain were after 6 months on same diet.

By Student's *t* test, the mean systolic blood pressures differed significantly ($P < 0·001$) as follows: S_3 salt-fed ♂ > S_3 control-fed ♂; S_3 salt-fed ♀ > S_3 control-fed ♀; S_3 salt-fed ♂ > R_3 salt-fed ♂; S_3 salt-fed ♀ > R_3 salt-fed ♀. By the same test, for comparably fed strains the mean systolic pressures for males exceeded that for females ($P < 0·01$).

tension, and given the usual genetically heterogeneous population characteristic of man, it would be illogical to expect all individuals on similar salt intakes to have similar blood pressures. On the contrary, one would expect to find individuals on high average salt intakes who did not develop hypertension as well as individuals on lower average salt intakes who did. It is unlikely that strains of humans can be found with the sensitivity to salt evinced by our rats, although studies of isolated populations might be helpful. In the absence of such genetic homogeneity, it is sufficient to re-emphasize[2b,c] that the available data relating intake of salt to hypertension in man indicate group rather than individual probability of developing hypertension.

Iproniazid and Experimental Hypertension in Rabbits

MONOAMINO oxidase affects serotonin metabolism, degrading this substance to 5-hydroxy-indolyl acetic acid. Monoamino oxidase also affects epinephrine and norepinephrine metabolism[1]. Minz and Walaszeck[2] have shown that the substances of the hydrazid group such as iproniazid, inhibit monoamino oxidase, *in vivo* and *in vitro*; and produce a variation of the pressor effect of epinephrine applied on the brain cortex.

This pressor effect of cortically applied epinephrine is lowered by the previous action of iproniazid injected repeatedly into experimental animals; this was explained as being due to the raising of the serotonin-level in hypothalamus, resulting in inhibition of monoamino oxidase by iproniazid. This pressor effect was, on the contrary, exaggerated in the animals to which reserpine was given; in these animals serotonin was lowered as a result of reserpine injection.

We used 20 rabbits, in which arterial pressure was recorded with an intra-arterial catheter in the popliteal artery using a mercury manometer and a graphic recorder.

Increase of systemic blood pressure was obtained by intravenous injection of epinephrine (1 mgm./kgm. weight)[3]. In the control group, using 10 animals (average weight 1,700–3,000 gm.), the raising of tension was between 20 and 35 mm. mercury (Table 1).

In the other group 10 animals were used. An injection of iproniazid (450 mgm./kgm.) was given intravenously[4,5], and 60 min. after the injection the rise in systemic blood pressure varied from 20 to 45 mm. mercury; in 4 animals it was more than 35 mm. No variation was seen in initial blood pressure in the two groups—the control and those treated with iproniazid.

Table 1

Animals No.	Controls (mgm./mercury)	Animals No.	Iproniazid (mgm /mercury)
1	25	11	25
2	25	12	30
3	30	13	40
4	20	14	45
5	35	15	12
6	20	16	25
7	25	17	40
8	30	18	30
9	30	19	25
10	20	20	45

A single injection of iproniazid was given. The inhibition of monoamino oxidase was intense and acute; we suppose that this did not modify the hypothalamic serotonin-level, and that is why we did not obtain a lowered pressor response; on the contrary, it seems that those of the group pretreated with iproniazid have a higher pressor response than the controls.

Changes in Mucoprotein in Serum and Aqueous Humour during the Sexual Cycle of the Rat

ŒSTROGENIC hormones appear to increase the acid mucopolysaccharide content in the connective tissue and the degree of polymerization. They also stimulate an increase in the mucopolysaccharides of the genital mucosa[1].

The mucoprotein content was examined in the serum and aqueous humour of 88 female rats at varied time-intervals during their sexual cycle and in 30 male rats of the same age. The quantity of mucoproteins was determined by the tryptophan method[2]. The total sugar content was determined in the aqueous humour by the same method. The qualitative degree of polymerization of the mucopolysaccharides was examined by the toluidine blue microtest[3] and the phenomenon of rhythmic crystallization in the aqueous humour[4].

A higher serum mucoprotein content was found in the female rats in œstrus than in those in diœstrus and moderate values were encountered in metœstrus and pro-œstrus. In the males, the mucoprotein content was the same as in females in diœstrus.

In the aqueous humour of female rats in œstrus, a lesser content of mucoproteins with a greater degree of polymerization and a 'fern-type' rhythmic crystallization were found. In female rats in diœstrus there is a greater mucoprotein content with a lesser degree of polymerization and a 'mixed coral-fern type' of rhythmic crystallization. In pro-œstrus and metœstrus, intermediate values were found. In the males, the mucoprotein values were similar to those found in pro-œstrus and metœstrus and the degree of polymerization and crystallization were similar to that found in diœstrus.

Table 1. MUCOPROTEINS IN SERUM AND AQUEOUS HUMOUR

	Serum		Aqueous humour			
	No. of rats	Mucoproteins Galactose–mannose (mgm./per cent)	No. of samples pooled	Mucoproteins Galactose–mannose (mgm./per cent)	No. of pools	Total sugar Galactose–mannose (mgm./per cent)
Diœstrus	40	190 ± 3	6	99·6 ± 8	4	178·4 ± 22
Pro-œstrus	15	200·5 ± 5	4	69·0 ± 8	2	140 ± 2
Œstrus	24	214 ± 6	9	51·8 ± 3	4	147·7 ± 7
Met-œstrus	18	200·3 ± 6	4	67·3 ± 9	3	160 ± 3
Males	30	188 ± 10	5	67·7 ± 5	3	174·1 ± 0·5

Quantitative results are presented in Table 1. From these results, we conclude that a cyclic variation in the content and quality of the mucoproteins of the serum and aqueous humour exists in the sexual cycle of the female rat. In the male rat, the values are similar to those found in the female rat in diœstrus. It may be supposed that the œstrogens are responsible for the variations seen.

Effect of Altitude on the Body/Venous Hæmatocrit Ratio

THE concentration of red cells is not the same in all parts of the circulatory system[1], the cell plasma ratio being lower in the capillaries and small vessels than in the larger arteries and veins. The over-all cell percentage (body hæmatocrit) is determined from the direct measurement of both red cell volume and plasma volume, and from this the body/venous hæmatocrit ratio (*BH*/*VH* ratio) is calculated. In normal adults resident at sea-level the *BH*/*VH* ratio averages 0·91 (ref. 2).

Little is known of the constancy of the *BH*/*VH* ratio in varying physiological and pathological conditions. The ratio increases during pregnancy[3], and in patients with splenomegaly[4], and may decrease in congestive heart failure with fluid retention[5].

In subjects resident at an altitude of 5,740 ft. above sea-level there is contraction of the plasma volume[6], and an increase in red cell volume[7], compared with values at sea-level. It is not known, however, whether the *BH*/*VH* ratio remains at 0·91. To investigate this an investigation was undertaken, where red cell volume was measured with red cells labelled with chromium-51 and plasma volume with radioiodinated human serum albumin. Venous hæmatocrit was measured in a microhæmatocrit centrifuge, spinning at 12,000*g*. Observations were made on 36 young White adult males, 18 resident at sea-level (Durban) and 18 resident at an altitude of 5,740 ft. (Johannesburg). The results are shown in Table 1. The difference in the mean *BH*/*VH* ratio in the two groups is highly significant ($t = 5{\cdot}17$; $P = < 0{\cdot}01$).

Table 1. BLOOD VOLUME IN SUBJECTS RESIDENT AT SEA-LEVEL AND AT 5,740 FT.

No. of subjects	Altitude	Red cell volume (^{51}Cr) (ml./kgm.)	Plasma volume (RISA) (ml./kgm.)	Venous haematocrit (per cent)	Body haematocrit (per cent)	Body venous haematocrit ratio
18	Sea-level	30·53 ± 0·694	43·96 ± 0·799	45·83 ± 0·512	40·99 ± 0·358	0·902 ± 0·00965
18	5,740 ft.	35·72 ± 0·817	41·40 ± 0·584	48·11 ± 0·551	46·25 ± 0·549	0·962 ± 0·00830

The raised body hæmatocrit in subjects resident at a high altitude probably represents a compensatory mechanism enabling more red cells per unit volume to pass through the lungs in unit time. This compensation in capillaries is evidently not completely reflected in the larger vessels, and the *BH*/*VH* ratio is thus nearer unity in subjects resident at this altitude.

There is evidence from experiments on animals that the response to altitude is not uniform throughout the body vascular system. Thus in rats exposed to simulated altitudes of 20,000–22,000 ft. for periods of 1–4 weeks there is a greater increase in the capacity of the non-capillary vessels (arteries, veins, arterioles and venules) than in the capillary bed[8].

This observation has practical application in the routine clinical estimation of volume of blood. In practice, either the red cell volume or plasma volume are measured directly, and the other compartment then calculated from the body hæmatocrit, which is the product of the venous hæmatocrit and the *BH*/*VH* ratio. In subjects resident at altitudes above sea-level it is inaccurate to assume a *BH*/*VH* ratio of 0·91, and it is necessary to determine this value for subjects resident at any particular altitude.

Plasma Clearance of *p*-Aminohippuric Acid by the Kidneys of Fœtal, Neonatal and Adult Sheep

AN investigation into the development of secretory activity in the renal tubules has been undertaken using *p*-aminohippuric acid.

Observations were made on fœtuses ranging from 89 days to 148 days (term), on lambs up to 2 weeks and on Welsh Mountain ewes. Pregnant ewes received a procaine spinal anæsthetic supplemented when necessary during the course of the experiment

Table 1. Glomerular Filtration-Rate and *p*-Aminohippuric Acid Clearance by the Sheep Metanephros at Different Ages

* 24 hr. after delivery at full term by Caesarean section from comatose ewe.

by intravenous sodium thiopentone ('Pentothal'). Anæsthesia was induced and maintained in lambs by intravenous administration of sodium thiopentone. The ewes were placed in a cradle which held them lying at an angle of 45° above the horizontal. The dorsalis pedis artery and vein of one leg were then cannulated for subsequent arterial blood sampling and intravenous injections. The fœtus was delivered by Caesarean section and supported on a warmed platform placed beside the ewe's abdomen. The fœtal head was enclosed in a polythene bag of warm saline as soon as it was delivered in order to prevent the onset of respiration. The umbilical cord was kept slack and moist with warm saline. Cannulation of the fœtal bladder was performed following an abdominal incision under procaine local anæsthesia. An umbilical artery and vein were catheterized through tributaries for giving intravenous injections and the removal of blood samples.

Experiments on unanæsthetized ewes required a preliminary operation under thiopentone anæsthesia for cannulation of one dorsalis pedis artery and vein and for the passage of a Foley catheter (size 12 French gauge) into the bladder. Allowing 24 hr. for recovery it was then possible to obtain data over several weeks from each animal. For the duration of an experiment the animals were restrained by placing the limbs through holes in a canvas hammock slung sufficiently low to allow the animals to stand.

A priming dose of 20 per cent sodium *p*-aminohippurate and 10 per cent inulin (for determination of glomerular filtration-rate) was given intravenously followed by a maintaining dose made up in isotonic sodium sulphate, 0·6 or 0·9 per cent sodium chloride, administered by drip. The quantities to be injected were determined on a body-weight basis. In fœtuses no inulin was injected, instead the glomerular filtration-rate was calculated from the clearance of endogenous fructose[1]. The concentrations of *p*-aminohippurate were determined by the method of Smith *et al.*[2]. Inulin was hydrolysed and determined as fructose by the method of Chinard, *et al.*[3].

Steady plasma concentrations of *p*-aminohippuric acid were tried over a wide range. It was found that an increase in the plasma-level of *p*-aminohippuric acid to 10·0 mgm./100 ml. in any one fœtus gave similar values for plasma clearance. However, in lambs and adults most clearances were determined using plasma concentrations in the range of 1–4·5 mgm./100 ml.

Table 1 shows that the glomerular filtration-rate increases with age when expressed as ml./min. and does in fact attain adult values in the lambs when expressed as ml./min./kgm. The clearance of *p*-aminohippuric acid also increases with age expressed either as ml./min. or ml./min./kgm. but does not attain adult values. Calculation of the filtration fraction further reveals the lag in appearance of tubular secretory activity for *p*-aminohippuric acid.

In the adult kidney of several species *p*-aminohippuric acid is so efficiently secreted by the tubular tissue that its plasma clearance represents the effective renal plasma flow. The values found for adult sheep are similar to those obtained by McDonald and MacFarlane[4] and are assumed to represent the renal plasma flow. The low clearance values of this substance (as ml./min./kgm.) obtained in fœtuses and lambs compared with the adults suggest either an immature secretory mechanism or an inadequate distribution of plasma flow to the secretory cells.

It is hoped that work in progress on the direct measurement of renal blood flow and on the determination of the renal extraction ratio for *p*-aminohippuric acid will demonstrate the relative importance of these two factors.

Effect of Moderate Low Temperature on the Accumulation of Liver Fat of Rats fed an Amino-Acid Unbalanced Diet

It has been reported by several workers that various kinds of unbalanced amounts of amino-acid in the diet lead to the accumulation of liver fat of rats. For example, the rats fed a diet containing 8–9 per cent of casein supplemented with sulphur-containing amino-acids and choline develop moderate fatty liver, but if the same diet low in casein is supplemented with both sulphur-containing amino-acids and threonine, the accumulation of fat is reduced[1,2].

In a previous report Yoshida, Ashida and Harper demonstrated a distinct decrease in liver fat accumulation due to threonine deficiency by moderate caloric restriction; however, this effect was not observed when the fatty liver was caused by choline deficiency[3]. From those results and the isotopic experiments[4] we suggested that rats fed this amino-acid unbalanced diet consume an excess of calories in relation to their intake of balanced protein and that the extra calories are used for the synthesis of fat. In subsequent work, it was demonstrated that only 20 per cent reduction of caloric intake prevented accumulation of fat in the liver due to threonine deficiency[5].

It is expected that when the caloric requirement of rats fed an unbalanced amino-acid diet is increased, an excess of calories in relation to their intake of balanced protein would be catabolized without accumulation of fat in the liver. Exposing the animals to cold is one of the means of increasing the caloric requirement of the animals.

The present communication describes observations made on the effect of the environmental temperature on the production of fatty liver. Moderate low temperature effectively prevented the development of fatty livers in rats fed the threonine-deficient diet, but the accumulation of liver fat due to choline deficiency was less affected at the same temperature.

Male weanling albino rats of the Wistar strain were used. The experiments consisted of two parts; in one a threonine-deficient diet was fed, in the other a choline-deficient diet. The threonine-deficient diet contained: casein, 8 per cent; DL-methionine, 0·3 per cent; sucrose, 82·5 per cent; sesame oil, 5 per cent; salt *B* (ref. 6), 4 per cent; and a complete vitamin mixture including 0·15 per cent choline chloride. The choline-deficient diet contained the same amounts of casein, salt *B*, sesame oil and sucrose, but choline chloride was omitted from the vitamin mixture and 0·5 per cent cholesterol was added. In both parts of the experiments, one group of rats was kept at 25° and the other group at 9°. The rats were fed *ad lib.* and the food consumption was measured daily. At the end of two weeks the rats were killed, their livers were removed and fat extracted with ether from the dried and finely powdered liver.

Table 1. EFFECT OF ENVIRONMENTAL TEMPERATURE ON LIVER FAT CONTENT OF RATS FED ON THREONINE- OR CHOLINE-DEFICIENT DIETS

	Threonine deficiency		Choline deficiency	
	25°	9°	25°	9°
Gain in 2 weeks (gm.)	23·4 ± 2·5*	22·7 ± 4·1	16·5 ± 2·1	13·1 ± 2·1
Food intake†	100	154	100	144
Liver fat (per cent)‡	24·7 ± 1·9	11·9 ± 0·7	28·1 ± 2·9	21·1 ± 2·7

* *S.E.*

† Food intake is expressed as percentage of the group at 25°.

‡ Liver fat is expressed as percentage of dried liver.

In the threonine-deficient experiment, the rats at 9° took about 150 per cent of the diet as compared with the group at 25°; however, the gains in body-weight for 2 weeks were essentially the same for both groups. This fact indicates the caloric requirement at 9° is significantly higher than at 25°. The liver fat of rats at 25° was 24·7 per cent on a dry weight basis; but the value decreased to 11·9 per cent when the rats were kept at 9°. Thus a moderate cold temperature prevented the fatty infiltration without appreciably reducing growth. These results quite resemble those obtained in the previous experiment[3], which showed a moderate caloric restriction in the threonine deficiency prevented the fatty liver.

The effect of moderate low temperature was not so effective in preventing the fatty liver caused by choline deficiency. The liver fat of rats was 28·1 per cent at 25°; at 9° it was 21·1 per cent, still higher than the normal range. Several workers reported the reduction of liver fat of choline-deficient animals when they were kept at 1° (refs. 7–10). Sellers stated that the choline-deficient diet must be restricted greatly to achieve the lowering of liver lipids at normal room temperature and the prevention of the liver fat accumulation at 1° was not due to the balance of energy requirement and caloric intake[7]. In threonine deficiency, deposition of fat in the liver was prevented by either moderate caloric restriction or moderate low temperature. These facts support our previous concept[3] that fatty liver caused by threonine deficiency is the result of a relatively high intake of calories in relation to the intake of balanced protein.

PHARMACOLOGY

Biologically Active Citrulline Peptides

To the best of our knowledge no peptides have so far been synthesized with citrulline as a building component. This alone could be sufficient reason to study citrulline peptides, but our investigations were prompted by other considerations as well.

The interesting change in the pattern of biological activity which occurs when members of the adrenocorticotrophic hormone–melanocyte stimulating hormone (ACTH–MSH) group of the pituitary hormones are briefly heated in an alkaline solution[1] was tentatively explained[2] by the assumption that the arginine moiety of these molecules was converted into an ornithine residue. We have suspected that the possibility that hot dilute alkali could degrade the guanidino group of arginine to a ureido rather than to an amino group should also be considered, the more so since streptidine, for example, is rapidly converted in hot alkaline solution to streptureа but only very slowly to streptamine[3]. Thus, perhaps citrulline peptides might be responsible for the increased and prolonged activity of alkali-treated peptides related to MSH.

In the work recorded here citrulline-containing analogues of biologically active peptides were synthesized and examined. No melanophore-stimulating properties were exhibited by the pentapeptide L-histidyl-L-phenylalanyl-L-citrullyl-L-tryptophyl-glycine; instead, significant inhibition of the activity of α-MSH by this compound was observed. On the other hand, 1-L-citrulline bradykinin, that is, L-citrullyl-L-prolyl-L-prolyl-glycyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-L-arginine, shows bradykinin-like activity on the isolated rat uterus at a concentration of 0·1 γ/ml. In our experiments synthetic bradykinin prepared in our laboratory was active at 0·0001–0·001 γ/ml.; the corresponding nonapeptide with nitroarginine residues instead of the arginine moieties was active at 0·1 γ/ml. Neither the *N*-benzyloxycarbonyl derivative of this last-mentioned nonapeptide nor the octapeptide L-arginyl-L-prolyl-L-prolyl-glycyl-L-phenylalanyl-L-seryl-L-phenylalanyl-L-arginine[4] was active in the same test, even at a concentration of 10 γ/ml. Each of the three nonapeptides was less than 0·01 as potent as bradykinin as a vasodepressor agent in the anæsthetized rat[5].

The hormone analogues, 8-L-citrulline vasopressin and 8-L-citrulline oxytocin, were active in several biological tests. Thus, 8-L-citrulline vasopressin was found to be about eight times less active than lysine vasopressin in the rat vasopressor test[5] and also in the dog anti-diuretic assay[6], but at least as active as lysine vasopressin on the isolated rat uterus. The 8-L-citrulline oxytocin showed about the same activity as oxytocin on the rat uterus, but half the activity in the avian depressor test.

The experience gained with citrulline-containing analogues of biologically active arginine peptides seems to indicate that the highly ionized character of the guanidino group contributes to, but, at least in certain instances, is not essential for biological activity. Some significance must undoubtedly be ascribed to the geometry of the arginine moiety.

In the synthesis of the aforementioned peptides the stepwise synthesis[8] by the nitrophenyl ester method[9] was applied with a few exceptions. The required *p*-nitrophenyl ester of *N* α-benzyloxycarbonyl-L-citrulline (m.p. 163–165°; $[\alpha]^{20}_{D} - 19°$ (*c*. 1, dimethylformamide)) was prepared via *N*α-benzyloxycarbonyl-L-citrulline (m.p. 115–117°). Since we did not succeed in preparing the *p*-nitrophenyl ester of *N*α-benzyloxycarbonyl-L-histidine, the azide of this protected amino-acid served in the last coupling step in the synthesis of the pentapeptide mentioned above. In the preparation of 1-L-citrulline bradykinin and also in that of bradykinin itself the *p*-nitrophenyl ester of *N*-benzyloxycarbonyl-*O*-benzyl-L-serine (m.p. 55–57°; $[\alpha]_{20}^{D} - 12°$ (*c*. 2, dimethylformamide) and the *p*-nitrophenyl ester of benzyloxycarbonyl-L-prolylglycine (m.p. 143·5–145°; $[\alpha]^{22}_{D} - 63°$ (*c* 1, dimethylformamide)) were used. The coupling of this dipeptide represents the only departure from the stepwise approach used in these studies.

The details of the synthesis of the citrulline peptides will be presented elsewhere.

We thank Prof. Aaron B. Lerner and Dr. M. Ruth Wright for the assays on the melanocyte-stimulating activity of the above-mentioned pentapeptide.

Tryptamine and Serotonin Receptors

A RECENT communication by Vane *et al.* entitled "Tryptamine Receptors in the Central Nervous System"[1] concluded, on the basis of indirect evidence, that the receptors for tryptamine and for serotonin (5-hydroxytryptamine) were the same. Because the authors neglected to mention some earlier evidence of a more direct kind which showed clearly that certain receptors for these two substances were different, we wish to direct attention to this contrary evidence before the conclusion about their identity becomes widespread.

Two kinds of evidence suggest that the receptors are different.

(*a*) When a suitable antimetabolite of serotonin (such as 1-benzyl-2-methyl-5-methoxytryptamine or 1-benzyl-2-methyl-5-hydroxytryptamine) is given to a dog the rise in arterial blood pressure due to injected serotonin is completely prevented, but the rise due to injected tryptamine is not. This shows that the antimetabolite has blocked the serotonin receptors which control blood pressure, but not the tryptamine receptors. This experiment was published by us in 1957 (ref. 2).

(*b*) By storage of suitable tissues at 4° the ability to respond to tryptamine is retained, but the ability to respond to serotonin is lost. This experiment was carried out with sections of sheep carotid arteries and suggested[3] that the receptors for tryptamine were more stable than those for serotonin.

Although the experiments of Vane *et al.* were concerned with receptors in the central nervous system and our own dealt with peripheral ones, the conclusion of their communication implied (probably quite unintentionally) that the supposed identity of the two receptors might be generally true in many tissues. We therefore wish to direct attention to the direct evidence which indicates that at least in some parts of the body receptors for serotonin and for tryptamine are clearly not the same. Before their identity even in the central nervous system is accepted as established it would be desirable to have more direct evidence.

[3] Woolley, D. W., and Shaw, E., *J. Biol. Chem.*, **203**, 69 (1953).

WE were aware of the work to which Profs. Woolley and Shaw refer but it did not seem relevant to the central nervous system. We did not intend to give the impression that all responses to 5-hydroxytryptamine (5-HT) and tryptamine throughout the body are mediated by an action on receptor sites common to both drugs: indeed, there is substantial evidence that they are not. The blood-pressure response, on which Woolley and Shaw worked, provides an interesting example. The ratio of activities of 5-HT and tryptamine in several different biological preparations[1] suggests straight away that the blood-pressure response differs from other responses. The actions of 5-HT on blood pressure are a complex of: (*a*) stimulation of carotid chemoreceptors[2]; (*b*) stimulation of the heart; (*c*) liberation of catecholamine into the circulation from the adrenal medulla[3]; (*d*) direct action on vascular smooth muscle, unaffected by pretreatment with reserpine. The effects of tryptamine seem to be mediated by the local release of catecholamine in the vessel walls, for the pressor response is: (*a*) prevented by cocaine; (*b*) abolished by pretreatment of the animal with reserpine; (*c*) then restored by an infusion of noradrenaline[4]. Thus, for equipressor effects, there are receptors which are activated by 5-HT and not by tryptamine and vice versa. The antagonism by 1-benzyl-2-methyl-5-methoxytryptamine of the pressor response to 5-HT, but not to tryptamine, may be explained, as suggested by Woolley and Shaw, by supposing that the two amines act on different receptors.

In a much simpler system, the isolated rat stomach strip, 1-benzyl-2-methyl-5-methoxytryptamine, does not antagonize the direct actions of 5-HT or tryptamine[5]: but brom-LSD and LSD, both of which are good general antagonists of indoles, appear to antagonize 5-HT to a greater extent than tryptamine[6]. This difference disappears if the preparation is pretreated with an amine oxidase inhibitor[4]. In the same tissue, inhibition of amine oxidase selectively potentiates the response to tryptamine without altering that to 5-HT[7]. Here, then, tryptamine is acting on two receptors (smooth muscle and amine oxidase), whereas 5-HT, perhaps because of a diffusion barrier, is acting on only one of them (smooth muscle); the effects of amine oxidase inhibitors and brom-LSD can be explained on this basis.

To say that, in some sites, 5-HT and tryptamine may act on different receptors (including active spots on amine oxidase, chemoreceptors and different types of chromaffin cells) does not exclude the possibility that these substances act mainly at receptors common to both drugs peripherally and centrally. To explain the main actions we described, we thought it unnecessary to postulate different types of receptors for tryptamine and 5-HT in the central nervous system.

ANATOMY

Centrifugal Fibres to the Retina in the Pigeon

DESPITE the description of centrifugal fibres in the retina of the bird by Cajal, Dogiel and others[1,2], and the finding of Wallenberg[3] of Marchi degeneration passing from the brain-stem to the retina, there is still considerable doubt as to the existence of a centrifugal fibre system in the visual system.

In a previous investigation of the avian visual pathway indirect evidence was obtained for such a centrifugal projection originating in the nucleus isthmo-opticus[4]. The relevant findings are that this nucleus undergoes complete cell loss following removal of the eye, and that the nature and time-course of the fibre degeneration in the isthmo-optic tract are strikingly different from that in all other components of the visual pathway. To prove that this nucleus is the site of origin of centrifugal fibres it must be demonstrated that localized lesions involving it result in fibre degeneration which can be traced through the associated pathway to terminate in the retina. Such degenerating fibres have now been traced, by the paraffin Nauta method, through the isthmo-optic tract into the dorsal part of the optic tract. From here the fibres can be clearly followed into the central region of the optic chiasma and thence into the contralateral optic nerve. In sections of the eye heavy degeneration is found in the optic nerve head, from which it spreads out in the optic nerve layer to all parts of the retina as recorded in the Marchi experiments of Wallenberg[3]. Occasional degenerating fibres can be traced through the ganglion cell layer and across the internal plexiform layer to terminate around cells on the inner aspect of the bipolar cell layer. The form of the axon terminals closely resembles those described by Cajal around the amacrine cells. The ipsilateral optic nerve and retina were completely free of degeneration in all experiments.

PATHOLOGY

Experimental Production of Spermatic Granuloma in Rats

SPERMATOZOAL invasion of the epididymis is a recognized phenomenon in man, but when reviewing the literature on the subject it was found that no detailed systematic experimental study of the cellular reactions to spermatozoa in the interstitial tissues of the epididymis in animals has been made, nor has there been any such correlation with human lesions of this type.

Russell and Friedman[1] severed the vas deferens in rats, transplanted it to either the scrotal or abdominal walls, or to the retroperitoneum. 'Granulomatous' lesions developed at the resected ends, and no such lesions were found when the testes were removed. No histological descriptions were given other than the mention of pools of sperm surrounded by a wall of histiocytes (macrophages) nor did they state the time-interval between resection and killing of the animals. However, the legends of two of their photographs (very low power fields) carry the times 2½ and 3 weeks. The purpose of this preliminary communication is to describe the experimental production of spermatic granuloma by a variety of techniques with the histological changes found at different intervals post-operatively and to attempt to relate the findings to human material available to me.

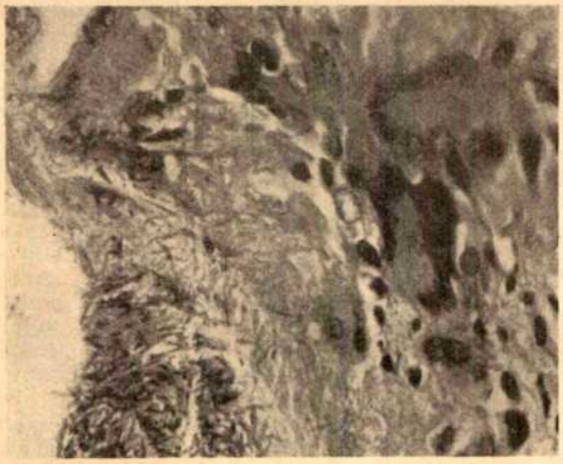

Fig. 1. Giant cells and epithelioid cells on right and aggregated spermatozoa on left in interstitial tissue of rat epididymis. Rat killed at 208 days

Adult male Wistar rats of average weight 250–300 gm. were anæsthetized with open ether. Five groups of experiments were performed. Group I, The seminal vesicles were divided and one half was removed to allow the seminal fluid to flow into the peritoneal cavity. Group II, The junction of the vas deferens with the epididymis was ligated. Group III, The rete testis was tied. Group IV, About 2 cm. of the beginning of the vas deferens was resected. The proximal end was diathermized and the tail portion of the epididymis was allowed to leak into the scrotal sac. Group V, Ligation of the body of the epididymis and the junction of tail of epididymis and vas was performed. The animals were killed at 2, 4, 7, 10, 14, 29, 39, 98 and 208 days.

In Group I no lesions developed; repair and organization of the resected seminal vesicles occurred almost immediately. To date, Group IV was the best type of experiment, of those used in this series, for examination of the cellular reactions to extravasated spermatozoa. After operation extensive extravasation of spermatozoa occurred, and at 2 days polymorphonuclear cells surrounded and intermingled with the spermatozoa.

At 4 days histiocytes of epithelioid character began to arrange themselves in a palisade at the periphery of the pool of sperms. The outline of the lesion gradually assumed a convoluted appearance after 14 days and the histiocytes began to group themselves into giant cells at 39 days approximately. 208 days post-operatively the spermatozoa appeared to be morphologically still intact in the main part of the lesion but were aggregated, suggesting agglutination. The cellular reaction at this stage was very striking and included numerous giant cells of Langhans' type (Fig. 1). The lesions now closely resembled tuberculosis and particularly in some foci where spermatozoa were not obviously present though the products of their disintegration may well have been.

The literature on human material from both autopsy and surgical sources shows considerable difference of opinion, and the varied manner of clinical and pathological presentation tends to suggest in some of the reports that ætiological agents other than the spermatozoa may be involved, for example, *Myco. tuberculosis* and *N. gonorrhoeae*.

This work shows that the spermatozoa *per se* are responsible for a definite type of cellular reaction similar to that excited by the tubercle bacillus, and may be caused by acid fast fractions known to be present in spermatozoa. These experimental lesions show a close similarity to primary spermatic granuloma in man at its various stages.

The final fate of the spermatozoa in these lesions and the mechanisms of healing are still being studied and a more detailed account will be published at a later date.

I thank the Medical Research Council of Ireland for a grant-in-aid for this work.

Pulmonary Tumours in Mice induced by Oral Isoniazid and its Metabolites

Juhašz *et al.*[1] induced solitary or multiple pulmonary adenomas in 7 of 45 albino mice which received intraperitoneal injections of isoniazid in water for three months and survived for periods up to 7½ months. Mori *et al.*[2] incorporated the same compound in varying doses in the diet of *dd* mice for periods of 2, 3 or 4 months, obtaining 100 per cent of pulmonary 'tumours' in mice surviving the largest dose for 7½ months. Subcutaneous injection was also effective.

In the experiment reported here strain *Balb/c* virgin female mice, 8 weeks old, received equimolecular doses of isoniazid, hydrazine sulphate and the sodium salt of isonicotinic acid by mouth daily in watery solution over a period of 46 weeks, when the mice were killed (Table 1). All those which received isoniazid or hydrazine sulphate developed pulmonary tumours but only 19 per cent of those receiving the sodium salt of isonicotinic acid. Of 216 untreated virgins or breeders of the same strain 50 died before 46 weeks and 166 at periods varying from 47 to 121 weeks, but none had pulmonary tumours. Andervont and Dunn[3] observed 24 per cent of these tumours in breeding females of this strain 17–25 months of age.

Table 1. INCIDENCE OF PULMONARY TUMOURS FOLLOWING TREATMENT

Compound	Daily dose (mgm.)	No. of treatments	Total dose (mgm.)	No. of mice surviving for 46 weeks following start of treatment	Mice with tumours	
					No.	Per cent
Isoniazid	2·0	251	502	38	38	100
Hydrazine sulphate	1·13	251	283	22	22	100
Sodium salt of isonicotinic acid	1·30	251	326	21	4	19

The induced tumours were multiple in all the mice treated with the first two compounds, on an average 4 per mouse following isoniazid and 18 per mouse following hydrazine sulphate. Approximately 40 per cent of all the tumours were in the left lung, which is the smaller, and in the right lung, which has four lobes, the lobar distribution ranged from 13 to 22 per cent. The morphology of the tumours is shown in Table 2. A very large proportion had the structure of papillary or solid adenomas, but 15 tumours were judged on histological grounds to be undergoing malignant change. In addition 10 tumours were regarded as carcinomas on the grounds of atypical

Table 2. Incidence of Different Types of Pulmonary Tumours

Compound	No. of mice	Total No. of tumours	Morphology of the tumours: Adenoma		Adenoma becoming malignant		Carcinoma	
			No.	Per cent	No.	Per cent	No.	Per cent
Isoniazid	38	144	134	93	6	4·1	4	2·7
Hydrazine sulphate	22	393	378	96	9	2·2	6	1·7
Sodium salt of isonicotinic acid	21	5	5	100				

structure, or local invasion of lung alveoli or bronchioli. In one mouse treated with hydrazine sulphate metastasis to the liver and ovary had occurred.

Thus isoniazid has now been shown to induce pulmonary adenomas in mice from three sources, and occasional pulmonary carcinomas in *Balb/c* mice. Hydrazine sulphate has similar properties in *Balb/c* mice and one tumour metastasized to distant organs. The sodium salt of isonicotinic acid has very low tumour-inducing properties.

Krüger-Thiemer[4] showed that isoniazid is converted in the rat and ox to isonicotinic acid and hydrazine, which is rapidly degraded to ammonia. Our results suggest that it is possible that the tumours observed after the administration of isoniazid to the mouse are due mainly to the liberation of hydrazine. If this is so, any drug which liberates hydrazine on metabolism must be regarded as potentially carcinogenic and its use in medicine limited as far as is practicable.

Virus-like Particles in the Cells of a Primary Carcinoma of the Liver

PRIMARY hepatocellular carcinoma of the liver (malignant hepatoma) is a tumour which is frequently encountered in the Bantu of Southern Africa. After an extensive review of the ætiology and pathology of liver cancer and cirrhosis in Africa, Steiner[1] came to the conclusion that "a likely cause for African liver cancer was viral infectious hepatitis with, possibly, prior malnutrition acting as an adjuvant". In view of the possible ætiological importance of virus infection we decided to conduct electron microscopical investigations of liver biopsies from Bantu patients with malignant hepatomas. The technique used in the preparation of biopsy material for cytological studies with the electron microscope has been described[2].

Surgical liver biopsies from three patients were studied. The diagnosis of malignant hepatoma was confirmed by light microscopical investigations of the same material. In one of these patients structural modifications of the cytoplasm of the tumour cells, suggestive of virus-like particles, were encountered. Two types of particles were observed: (*a*) The paranuclear cytoplasm showed the presence of dense zones containing a fine granular material (Fig. 1). The zones were more or less sharply defined, but no obvious limiting membrane could be discerned. These structures correspond to the 'viroplasm' one of the type of cytoplasmic inclusions described by Bernhard *et al.*[3,4] in the Shope fibroma. (*b*) In the paranuclear cytoplasm of other cells from the same tumour, a later stage in the development of the virus-like particles was observed (Fig. 2). In these cells membranes appeared within the matrix of the 'viroplasm' to form spherical corpuscles (Fig. 2, arrow 1). Some of the corpuscles contained granular material (Fig. 2, arrow 2), which appeared similar to the granular matrix of the surrounding 'viroplasm' (Fig. 2, arrow 3). Other corpuscles had no granular core (Fig. 2, arrow 4). These virus-like particles are again similar to cytoplasmic inclusions described by Bernhard *et al.*[3,4] in the cells of the Shope fibroma. According to Bernhard[5] the particles without any granular material should be regarded as "abortive

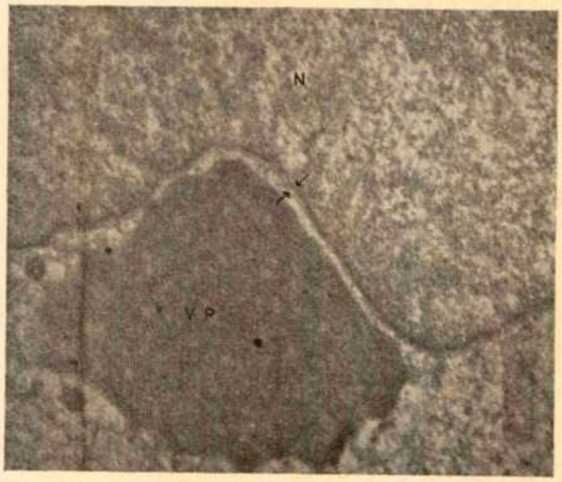

Fig. 1. 'Viroplasm' (*VP*) in the paranuclear cytoplasm of a malignant hepatoma cell. *N*, Nucleus. The arrows point to the double nuclear membrane. Note indentation of nuclear membrane by 'viroplasm'. (× 30,000)

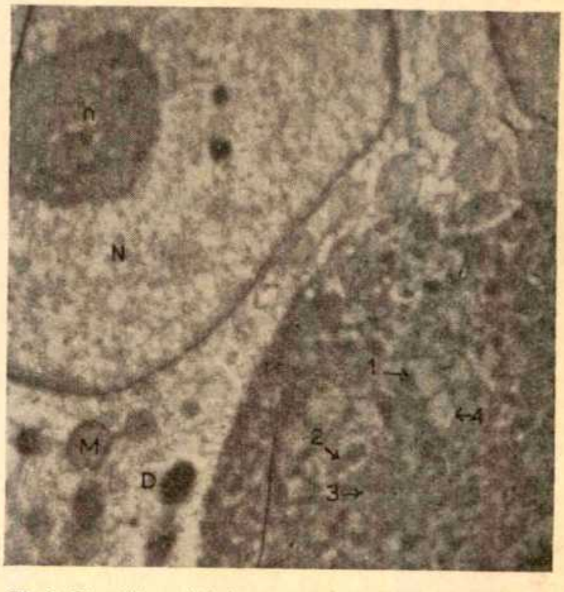

Fig. 2. Virus-like particles in paranuclear cytoplasm of malignant hepatoma cell. *N*, Nucleus; *n*, nucleolus; *M*, mitochondria; *D*, dense body. Arrow 1, Spherical corpuscle; arrow 2, granular material within corpuscle; arrow 3, 'viroplasm'; arrow 4, empty corpuscle. (× 10,000)

forms of the virus the membranes of which were closed before the granular mass could be included". Although there was a marked variation in the size of the spherical corpuscles, the majority had a diameter of approximately 240 mμ.

Virus-like particles have previously been visualized in the liver cells of patients with infectious hepatitis[6,7]. To our knowledge no such particles have been described in malignant hepatoma cells in human beings. It is obvious that the presence of these particles in hepatoma cells cannot be considered as final proof of the role of previous virus infection in the ætiology of this tumour. Our observations do, however, lend some support to the conclusion reached by Steiner[1] in 1960. A detailed report of the cytology and histochemistry of malignant hepatoma will be published elsewhere.

IMMUNOLOGY

Oral Immunization of Guinea Pigs with Avirulent *Pasteurella pseudotuberculosis*

Immunity to pseudotuberculosis and plague is generally considered to be of a cellular nature[1-3]. Because of the common *R* antigen in *Pasteurella pestis* and *P. pseudotuberculosis*[4] and the stable immunity that this immunochemically common factor is able to induce against both infections[5], further experiments with avirulent strain 32/IV of *P. pseudotuberculosis* were thought to have some bearing on the elucidation of theoretical and practical problems of immunity in plague.

Virulent *P. pseudotuberculosis* bacteria, which in many respects behave like the enteric group, are often the cause of mesenterial lymphadenitis[6,7] in human beings. The aim of this investigation was to find out: (*a*) if avirulent strain 32/IV-bacteria could be transported to the intestinal tract, and if they were able to establish themselves in the mesenteric lymph nodes; (*b*) if the persistence in the mesenteric lymph nodes were sufficiently long to trigger off the formation of a demonstrable immunity.

The persistence of strain 32/IV after oral inoculation was investigated in 10 guinea pigs, of which two were killed after 1, 3, 7, 11 and 18 days, respectively. As can be seen from Table 1 the avirulent strain was isolated during this period five times from the mesenteric lymph nodes, three times from the small intestine and cæcum, respectively, and twice from the rectum. Although I used enrichment methods the bacteria were never found in the spleen, liver, lungs or heart blood.

Table 1. Persistence of *P. pseudotuberculosis* Avirulent Strain 32/IV after Oral Inoculation*

Isolation after	1 day		3 days		7 days		11 days		18 days

* 50 × 10^9 bacteria of strain 32/IV in 5-ml. saline were given *per os* through a urinary catheter of 1 mm. diameter.

Table 2 shows the results of oral compared with intraperitoneal immunization.

Obviously it is possible to protect guinea pigs against massive infection with *P. pseudotuberculosis* by the oral route. The avirulent bacteria are able to persist in the mesenteric lymph nodes for at least three weeks. No tests after that time were carried out. Since there was no evidence that strain 32/IV penetrated farther than the intestinal wall and the mesenteric lymph nodes, hæmatogeneous or further lymphatic dissemination apparently was not a factor in eliciting the immune response. The significance of humoral antibodies has not yet been investigated.

Table 2. Vaccination with *P. pseudotuberculosis* Avirulent Strain 32/IV* and Challenge with *P. pseudotuberculosis* Virulent Strain 14/1†

Mode of vaccination	No. of vaccinated animals	No. of survivors 30 days after challenge
Orally	8	7/8‡
Intraperitoneally	8	8/8
Controls		2/8§

* Strain 32/IV approximately, 50 × 10^9 bacteria orally. Strain 32/IV approximately, 10 × 10^7 bacteria intraperitoneally.

† Strain 14/I approximately, 10 × 10^7 bacteria intraperitoneally 3 weeks after vaccination.

‡ One guinea pig died intercurrently after a fortnight in a staphylococcal infection.

§ Six controls died within a week in *P. pseudotuberculosis* septicæmia, one of the survivors had a large abscess in the ventral abdominal wall from which the challenge strain was recovered as well as from the spleen and lungs.

Up to now, only a few strains belonging to *O*-group VI have been isolated[8]. It was considered necessary to investigate if this serological group in itself is endowed with certain antigenic properties which enable it to protect against strains belonging to other *O*-groups and another species. Strain 190/IV and strain Ikegaki[9] were tested. Both proved avirulent to guinea pigs[10], but gave after three weeks no protection against a standard test infection. It thus seems reasonable to conclude that *O* IV-antigen alone cannot be responsible for the immunity induced.

The effectiveness of oral immunization has traditionally been considered inferior to parenteral. In my experiments the avirulent strain 32/IV could be re-isolated from only 5 out of 10 guinea pigs. To leave the guinea pigs without feed 24 hr. before oral administration of the bacteria seems to result in better immunization.

In another series of experiments on guinea pigs intranasal instillation of a few drops of a 48 hr. broth culture of avirulent strain 32/IV conferred a solid immunity against massive infection with virulent *P. pseudotuberculosis* by the same route. The pathological changes and bacteriological findings in these animals will be described in a forthcoming communication[11].

The work reported here was started during the tenure of a fellowship supported by the International

Co-operation Administration under the Visiting Research Scientists Programme administered by the U.S. National Academy of Sciences.

Immunological Properties of Electrophoretic Fractions of Human Growth Hormone

In a previous investigation we showed that human growth hormone, prepared by Raben's method, presented on agar gel electrophoresis two distinct strongly staining components and a less-distinctive faster moving component[1]. Component 1 moved between β- and α-globulin, component 2 corresponded to α-2-globulin and component 3 to α-1-globulin. Similar findings have been reported with starch gel electrophoresis[2,3]. Our previous work confirmed the suspicion of Boucher[4] and Hirschfeld *et al.*[5] that the human growth hormone preparations, obtained by both Raben's and Li's methods, are contaminated with human albumin.

In the present work the immunological properties of the individual components of human growth hormone were investigated. The hormone was prepared from human pituitaries according to Raben's[6] method, and the same batch, *A*–3, was used throughout. The immunological methods used have been described in detail[1].

Following agar gel electrophoresis[7] for $3\frac{1}{2}$ hr. and identification of the fractions by staining a longitudinal slice which had been cut off and transferred to another glass plate, the individual components (Fig. 1) were prepared for testing by cutting horizontal strips of gel. The pieces of gel containing the respective component were eluted with saline, centrifuged and the supernatant used. When tested by the Ouchterlony agar gel double diffusion test[8] using antiserum against whole human growth hormone, components 1, 2, 3 formed one precipitation line (Fig. 2). These lines were confluent between themselves and with the precipitation line formed by whole human growth hormone, indicating immunological identity. When tested by agar gel immunoelectrophoresis[7] using antiserum against whole human growth hormone, the level of the maximum convexity of the precipitation arc formed by the individual components differed corresponding to the electrophoretic mobility of the respective component. Fig. 3 illustrates the behaviour of components 1 and 2. None of the components gave a precipitation line with antiserum against human albumin by either agar gel double diffusion or immunoelectrophoresis. The eluate of the area of application (area 0 of Fig. 1) reacted with the antiserum to whole human growth hormone, both in agar gel double diffusion and agar

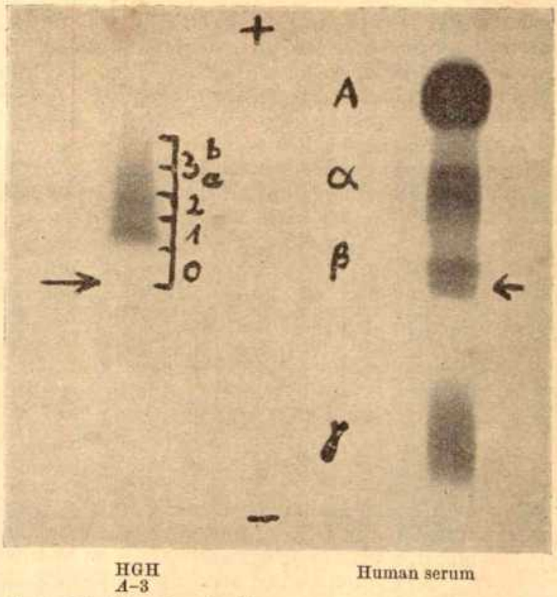

Fig. 1. Gel electrophoresis of human growth hormone (HGH, 0·35 mgm.) as compared with human serum. Arrows indicate origin. Stained with amido-black

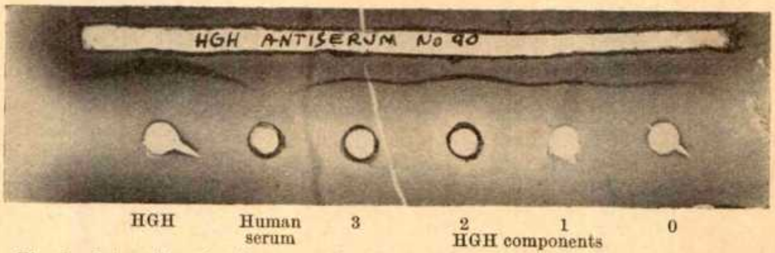

Fig. 2. Interaction of antiserum against whole human growth hormone (HGH) with individual components of human growth hormone and human serum as determined by the Ouchterlony agar gel double diffusion technique. Stained with amido-black

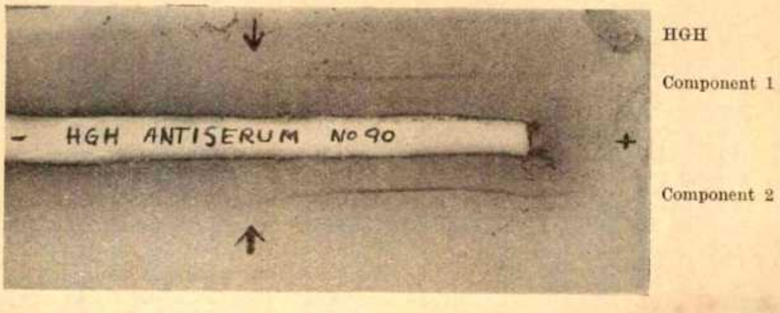

Fig. 3. Interaction of antiserum against whole human growth hormone (HGH) with individual components of human growth hormone as determined by agar gel immunoelectrophoresis. Arrow indicates origin. Stained by amido-black

gel immunoelectrophoresis, demonstrating that some hormone did not migrate from the application area, but its quantity was too small to be visible by the method of staining used. When testing the individual components with antiserum against human growth hormone and antiserum to human albumin by the hæmagglutination technique[9], it was found that all the components reacted with the antiserum to human growth hormone, but only component 3*b*, and sometimes 3*a*, reacted with the anti-albumin serum (Table 1).

Table 1. HÆMAGGLUTINATION REACTIONS OF ELECTROPHORETIC COMPONENTS (*C*) OF HUMAN GROWTH HORMONE (HGH) WITH ANTISERUM TO WHOLE HUMAN GROWTH HORMONE OR TO HUMAN ALBUMIN

Antibody Antigen	Anti-HGH	Anti-human albumin
Area of application 0	+	–
C 1	+	–
C 2	+	–
C 3*a*	+	+ or –
C 3*b*	+	+

As a further step in this investigation, antiserum to the individual components of human growth hormone was prepared by immunizing rabbits (component 3 was used non-divided). The gel strip containing the respective component was homogenized in water and the rabbits injected as follows: 0·1 ml. of a mixture of approximately 0·5 mgm. hormone component in 0·3 ml. water and an equal amount of complete Freund's adjuvant (Difco) was injected intradermally into each of two footpads: the remaining 0·4 ml. was injected subcutaneously. Two weeks later the procedure was repeated injecting the two other footpads. After a further two weeks about 1 mgm. of the respective human growth hormone component mixed with 0·6 ml. water and 0·6 ml. complete Freund's adjuvant was injected subcutaneously. Ten days after this subcutaneous booster the rabbits were bled; the antisera titres ranged between 1/10,000 and 1/12,000. When testing the interaction of the individual components with the different antisera by agar gel double diffusion, it was found that each component reacted with its own antiserum as well as with the antisera against the other components used. Similar findings were registered by the hæmagglutination technique (Table 2). The only difference encountered was the positive reaction between human albumin (1/1,000) with the antiserum to component 3. In the agar gel double diffusion test human albumin did not react with any of the antisera.

Table 2. HÆMAGGLUTINATION REACTIONS OF WHOLE HUMAN GROWTH HORMONE (HGH), ITS ELECTROPHORETIC COMPONENTS (*C*) AND HUMAN ALBUMIN WITH ANTISERUM TO THE INDIVIDUAL COMPONENTS OF HUMAN GROWTH HORMONE (ANTI-*C*)

Antibody Antigen	Anti-*C* 1	Anti-*C* 2	Anti-*C* 3
Whole HGH	+	+	+
C 1	+	+	+
C 2	+	+	+
C 3	+	+	+
Human albumin 1/1,000	–	–	+

The results of these experiments indicate that the components of human growth hormone, separated by agar gel electrophoresis, are immunologically identical and antigenically potent, and that the component contaminated with albumin can be singled out and separated. The formation of the precipitation arc at different levels by the individual immunologically identical components on immunoelectrophoresis explains the occasional two-peak precipitation line obtained when using whole human growth hormone[5]. The biological activity of the components of human growth hormone remains to be established.

RADIOBIOLOGY

Protection of Primates against Lethal Doses of X-Radiation

THE protective effect of 2-amino ethylisothiouronium bromide (AET) against lethal doses of total body X-radiation administered to rats and mice is well documented[1,2]. In the dog, however, the protective effect of AET is obscured by the toxic response to the drug when levels sufficient to be protective are administered[3]. AET and cysteine administered simultaneously, however, were effective against a lethal exposure of X-radiation in dogs.

The protective effect of AET in primates has received only modest consideration. In the single investigation known to us[4], doses of X-rays were used which were lower than those utilized in the present report. Further studies concerning the effects of radio-protective agents in primates exposed to large single doses of X-radiation are of interest for several reasons. Positive protective effects of the two sulphydril-containing compounds would establish a continuity of the mechanism of action in the vertebrate kingdom. Furthermore, the phylogenetic relationship of monkey and man would suggest that knowledge of the active dose, toxicity of the drug, as well as the biological effects in the monkey could be more reasonably extrapolated to man. It is to these ends that the present report is directed.

Rhesus monkeys (*M. mulatta*) weighing between 4 and 5 kgm. were used. Radiation was administered with a General Electric Maxitron 250 X-ray tube operated at 250 kVp. and 30 m.amp., using filters of 0·5 mm. copper and 1 mm. aluminium. The half-value layer for the radiation was 1·5 mm. of copper. The animals were placed 150 cm. from the focal spot of the tube and the dose-rate in air at this distance was 11 r./min. The animals were completely immobilized in a wire cage and were rotated in the X-ray beam at the rate of 1 r.p.m. Measurements with a Victoreen meter at numerous places on the skin and in the abdominal cavity of a dead monkey under these conditions showed that the dose-rate at all places measured was within 10 per cent of the dose-rate in air at the centre of the field. Prior to each radiation session the dose-rate in air at the centre of the field was measured with a Victoreen meter which had been previously calibrated against a Bureau of Standards meter. AET and cysteine were rendered soluble, brought to pH 7 with 3 N sodium hydroxide, and administered intravenously immediately before exposure to X-radiation at a dosage-level of 100 and 500 mgm./kgm. body-weight respectively. Epinephrine was injected subcutaneously to avoid collapse of blood pressure.

A marked increase in the 30-day survival of rhesus monkeys receiving AET and cysteine prior to a total body X-radiation of 800 r. was observed. Five of the six drug-treated animals not only survived the 30-day period following exposure to 800 r., but are alive and in apparent good health at the time of writing, 90 days following irradiation. In contrast, 5 of the 7 unprotected animals died within 14–18 days following radiation.

A progressive decline in both leucocyte count and hæmatocrit was observed following X-radiation in non-treated animals. In the protected animals, however, the degree of depression was less dramatic (Figs. 1 and 2). Moreover, by day 21 following exposure a gradual recovery of both white cell counts and hæmatocrit was evident. A similar recovery pattern was noted in the two non-treated animals which ultimately survived the 30-day post-exposure period.

No obvious effect of the drug was observed in the injected animals. In contrast, the non-injected animals presented the classical symptoms of radiation sickness, namely, apathy, diarrhœa, vomiting and anorexia.

Six animals both treated and untreated had been ovariectomized six months prior to X-radiation. Since these animals were in good health and could not be utilized for breeding purposes they were included in this investigation. In view of the radio-protective effect of œstrogen in mice[5], it was conceivable that the operated animals might be more sensitive to X-radiation than intact monkeys. It was apparent, however, that the response of these animals, as indicated by both survival and hæmatological changes, was not affected by this operative procedure.

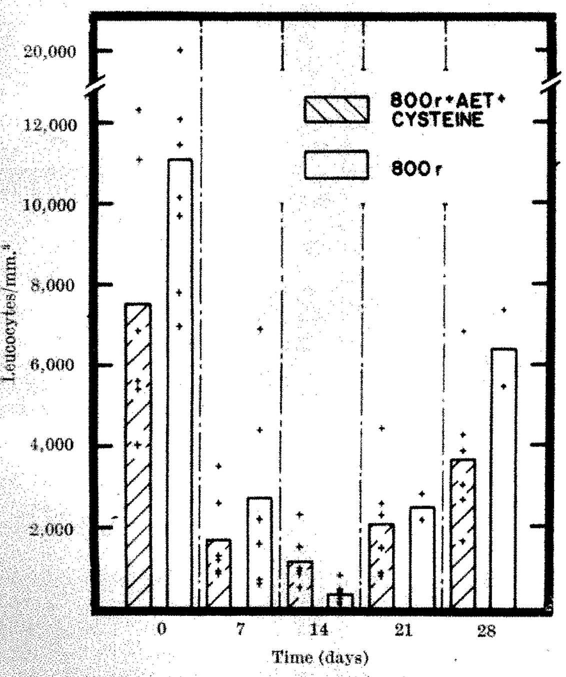

Fig. 1. Effect of AET and cysteine on leucocyte counts in irradiated monkeys. The figure demonstrates the changes in leucocyte counts/mm.³ of individual monkeys immediately prior to (0 days) and at weekly intervals after irradiation

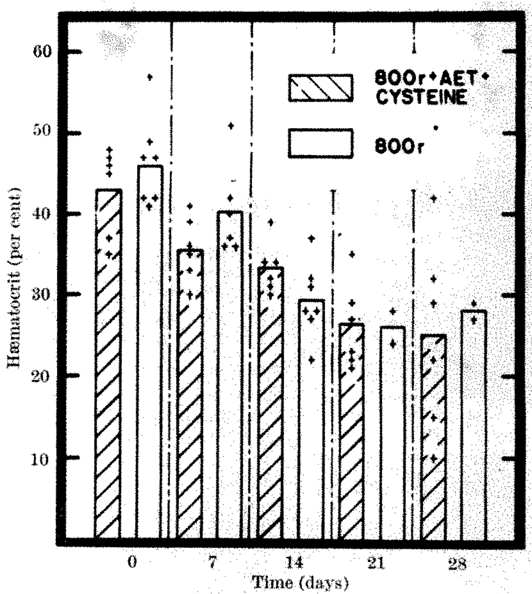

Fig. 2. Effect of AET and cysteine on the hæmatocrit of irradiated monkeys. The figure demonstrates the changes in the hæmatocrit of individual monkeys immediately prior to (0 days) and at weekly intervals after irradiation

These results clearly demonstrate the practicality of protecting primates against 800 r. administered during a period of 1 hr. It seems logical to conclude from these results that it is possible to protect monkeys against a dose of 800 r. administered at the rate of 11 r./min., provided that AET and cysteine are injected simultaneously before X-radiation.

Curative Effect of Homologous Bone Marrow Transfusions in Rats receiving Lethal Doses of 'Myleran'

Weston *et al.* have reported on the curative effect of isologous bone marrow transfusions in aplastic anæmia in rats by 'Myleran', a radiomimetic chemical[1]. Talbot and Elson improved the survival of rats with isologous bone marrow after the administration of a lethal dose of dimethyl homologue of 'Myleran'[2]. The curative effect of isologous bone marrow also has been reported in mice by other investigators after administering lethal doses of thioguanine and nitrogen mustards[3–5]. Dunjic and Maisin confirmed the results obtained by Weston *et al.*, and investigated the relationship between the number of transfused bone marrow cells, and the survival of rats receiving a lethal dose of ‘Myleran’[6]. In the latter experiment the rats used were from a randomly bred strain. Further investigation established that individual antigenic differences between the host and the donor in randomly bred rats could be overcome either by administering higher lethal doses of ‘Myleran’ or by transfusing bone marrow on the day when immunological defence reactions of the host are at the lowest level[7].

In previously reported experiments the homologous bone marrow transfusions failed to restore the bone marrow aplasia induced by radiomimetic agents[2,4,5,7]. However, the trials were performed under experimental conditions (that is, the dose of agent, amount of injected bone marrow, time and route of injection) which allowed successful transplantation of isologous bone marrow in animals of inbred, as well as randomly bred, strains. I have already suggested that homologous bone marrow transfusions could produce more interesting results after administrations of higher doses of ‘Myleran’ and/or bone marrow cells[7]. In the present report the first successful results obtained with homologous bone marrow transfusions in rats receiving lethal doses of ‘Myleran’ are given.

The white male *L*-strain rats used were bred in the Institute by random mating. At the start of the experiment they were 3–4 months old, weighing 140–150 gm. Homologous bone marrow donors were female *R*-rats from an inbred strain purchased from R.I.T. Laboratories (Louvain, Belgium) when six weeks old. Methods of the preparation and mode of administration of ‘Myleran’ and suspensions of bone marrow cells are presented elsewhere[6,7]. The doses of ‘Myleran’ administered orally ranged from 20·7 to 41·4 mgm./kgm.; these were lethal between the eighth and fifteenth day for rats which were not treated. The $LD_{50/30}$ and *MLD* (maximum lethal dose) for the *L*-strain rats are, respectively, 14 and about 17 mgm./kgm. The bone marrow suspensions, containing 128 × 10^6 nucleated bone marrow cells were injected on the first or third day following the ‘Myleran’ administration.

Table 1. MORTALITY DATA OF *L*-STRAIN RATS TREATED WITH 128 × 10^6 HOMOLOGOUS BONE MARROW CELLS FROM *R*-STRAIN DONORS AFTER ADMINISTRATION OF SINGLE SUPRALETHAL DOSES OF ‘MYLERAN’

	No. of rats	mgm./kgm. of ‘Myleran’	Percentage mortality at 30 days	Distribution of deaths (in days)	Median survival time (in days)
Bone marrow injected on the first day	10	20·7	70·0	11–16	13
	11	27·6	63·6	9–19	13
	11	34·6	63·6	11–15	13
	10	41·4	80·0	8–14	10
Bone marrow injected on the third day	9	20·7	44·4	14–20	15
	12	27·6	58·3	10–16	11
	10	34·5	40·0	9–16	12
	10	41·4	60·0	8–18	11

The results are given in Table 1. The homologous bone marrow transfusions given on the first day following administration of ‘Myleran’ decreased the 30-day mortality-rate to values of between 80 and 63·6 per cent. When bone marrow transfusions were given on the third day, the decrease of mortality was more important and the mortality-rates varied from 60 to 44·4 per cent. The mortality-rates seem to be independent of ‘Myleran’ dosage for both the injection days and the dose-range of ‘Myleran’ used.

It is interesting to compare these results with those obtained previously with different donor–host combinations[7,8]. From my intra-strain experiments it is known that the mortality of highly inbred *R*-strain rats is completely suppressed if 32 × 10^6 nucleated bone marrow cells are transfused invariably on the first or third day after administration of ‘Myleran’ dose of 20·7–34·5 mgm./kgm.[8]. In order to decrease the mortality of randomly bred *L*-strain rats first, four times as many cells must be transfused, and secondly, this decrease of mortality is dependent on the dose of ‘Myleran’ and/or the time of bone marrow transfusion[7]. By transfusing 128 × 10^6 bone marrow cells on the first day, the mortality decreases with increasing doses of ‘Myleran’ and is almost completely suppressed for doses between 27·6 and 41·4 mgm./kgm. When the same amount of bone marrow cells is given on the third day, the mortality decreases independently of ‘Myleran’ dose to about 30 per cent. Furthermore, by increasing the interval between the administration of ‘Myleran’ and the injection of bone marrow to 5 days, the dose–response relationship again becomes dependent on the dose of ‘Myleran’ and its pattern resembles the one obtained by giving the bone marrow on the first day. On the other hand, in one of the inter-strain experiments, homologous bone marrow of randomly bred *H*-strain rats failed to decrease the mortality of *L*-strain rats after administering 20·7 and 27·6 mgm./kgm. of ‘Myleran’ 3 days before[7].

Thus the general pattern of dose–response relationship obtained in the present investigation partially resembles that encountered in randomly bred animals. As a comparison, Fig. 1 gives the relationship between the dose of ‘Myleran’ and the mortality at 30 days for randomly bred *L*-strain rats receiving bone marrow from donors of the same strain and from inbred *R*-strain donors on the first and third day after administration of increasing doses of ‘Myleran’. While the results obtained on the third day are quantitatively almost the same, the homologous bone marrow injected on the first day did not reduce the mortality to the same level. The present results confirm the fact that on the third day after administering ‘Myleran’, the immunological defence re-

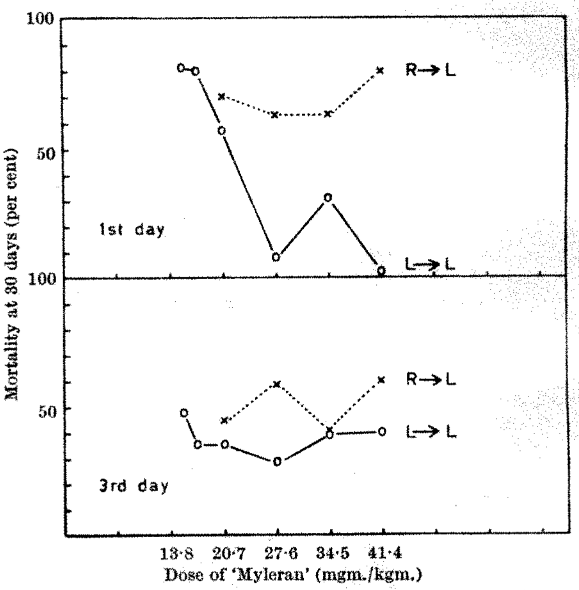

Fig. 1. Relationship between the dose of ‘Myleran’ and the mortality at 30 days of randomly bred *L*-strain rats receiving 128 × 10^6 nucleated bone marrow cells on the first or third day after ‘Myleran’ administration. *L*—*L*, Bone marrow from donors of the same strain (ref. 7); *R*—*L*, bone marrow from donors of the inbred *R*-strain

actions of the host are at the maximum of depression[7]. Also it can be assumed that quantitative differences on the first day indicate more or less a close antigenic relationship between the donor and host animals.

It can be concluded, in opposition to what was previously believed[2,4,5,7], that, under some experimental conditions, the homologous bone marrow treatment may be obtained following the administration of radiomimetic chemicals, and that the requirements for successful homologous bone marrow transplantation are similar to those met in bone marrow experiments with irradiated mammals[9].

This work was supported by grants from the Home Office (Ministère de l'Intérieur) of Belgium. The 'Myleran' (1 : 4-dimethanesulphonyloxybutane) used in this work was kindly supplied by Burroughs Wellcome and Co. Laboratories, London.

Preparation of Iodine-131 Labelled Human Growth Hormone of High Specific Activity

RECENT procedures for the immunological assay of protein hormones in human plasma[1-3] require the routine preparation of hormones labelled with iodine-131 of high specific activity.

The present methods available[1,3,4] require the handling of 10–80 mc. of the isotope in volatile or organic solvents, and applied to human growth hormone[3] give low specific activity (5 μc./μgm.). Purification of the labelled hormones is required to remove damaged components.

The following method has been developed which allows the preparation in 1 hr. of 2–3 μgm. of labelled human growth hormone with specific activities of 250–590 μc./μgm. (up to 1·2 atoms of iodine per molecule). Human growth hormone (5 μgm.) is reacted with 2–4 mc. of carrier-free iodine-131 using chloramine *T* as the oxidizing agent; the efficiency of utilization of the iodine is 60–75 per cent. No purification of the product is required and it has been shown to be immunologically identical with unlabelled human growth hormone.

Reaction is carried out in the rubber-capped vial (10 ml.) in which the isotope is packaged ('*IBS*/3', Radiochemical Centre, Amersham). Care is taken that the vial is kept upright in transit. The iodine-131 (2–4 mc.) is used within 24 hr. of arrival. Storage of the material for 5 days results in the loss of iodinating activity.

The activity is counted using a scintillation counter with a well-type, sodium iodide crystal with the geometry modified such that 2 mc. in 0·05 ml. gives approximately 400 counts/sec. The rubber cap is removed and counted separately.

To the sample are added human growth hormone (5 μgm.) and fresh chloramine *T* (88 μgm.). These additions (0·025 ml.) are in 0·05 *M* sodium phosphate buffer (*p*H 7·5) and are made using an 'Agla' micrometer syringe by injection through the rubber cap. After gentle mixing, the vial is stood for approximately 1 min. and sodium metabisulphite is then added (0·1 ml. of a 2·4 mgm./ml. w/v solution in *p*H 7·5 phosphate buffer). This addition prevents any subsequent iodination of the dextran-gel bed by converting iodine to iodide. This residual iodide is diluted with carrier potassium iodide (0·2 ml. of a 10 mgm./ml. solution in the phosphate buffer). The reaction mixture is transferred to a dextran column followed by a single wash with further potassium iodide (0·4 ml. of a 10 mgm./ml. w/v solution in the phosphate buffer). The reaction vial and pipette are then counted.

Separation of labelled human growth hormone from the reaction mixture is carried out by gel filtration using a 1 gm., *G*50 dextran column. Equilibration of the gel and elution from it are carried out with *p*H 8·6 sodium barbitone buffer (0·07 *M*). Before the dextran column is used, crystalline bovine serum albumin (20 mgm. in 1 ml. *p*H 8·6 buffer) is passed through it, followed by 20 ml. wash with the same buffer. This 'presaturation' of the dextran with albumin allows the subsequent recovery of 3–4 μgm. of labelled hormone from the dextran in 80 per cent yield.

The elution pattern, determined by counting 1 ml. eluates, is reproducible and allows for a routine collection of a discard fraction (1·5 ml.), a protein peak (4·0 ml.) and a salt peak (3 × 5 ml. fractions) into calibrated counting vials. The protein peak is collected into a vial containing bovine serum albumin (0·5 ml. of a 5 mgm./ml. solution in *p*H 7·5 sodium phosphate buffer, 0·5 *M*, in normal saline). After counting each fraction the amount of labelled hormone eluted is calculated and this is then diluted to a final concentration of 50 mμgm./ml. with *p*H 7·5 sodium phosphate buffer (0·05 *M*) in normal saline containing 0·5 mgm./ml. of bovine serum albumin.

In control experiments without added hormone, radioactivity is recovered quantitatively from the vial and the column in the salt peak. The yield of the reaction in the presence of protein is therefore based upon the percentage of the total radioactivity collected in the salt peak. The iodinated protein is distributed between a fraction adsorbing to the glass surface of the reaction vial (26 per cent), the protein peak eluate (60 per cent) and a third fraction remaining adsorbed to the column (14 per cent). The recovery of the iodinated protein added to the column is 82 per cent.

Antisera to unlabelled human growth hormone when incubated with two preparations of labelled human growth hormone (237 and 590 μc./μgm.) were found to react with 95·5 per cent of the modified antigen. The extent of this reaction was judged by the transfer of the labelled hormone to the antibody region on electrophoresis of the incubation mixture. The preparation with a specific activity of 590 μc./μgm. contained 1·2 atoms of total iodine per molecule, assuming an isotope abundance of 90 per cent. This was assayed in terms of unlabelled human growth hormone by an immunoelectrophoretic method. Immunological activity was unaffected at this level of substitution as was human growth hormone substituted with iodine-127 up to 9·5 atoms per molecule. Substitution with up to 19·3 atoms iodine-127 per molecule resulted in a reduction of immunological reactivity to 1–2 per cent.

The undiminished immunological reactivity and the absence of degradation products in the labelled hormone appears to be due to the following factors: a low degree of iodination but with high specific activity; the use of carrier free isotope in a high efficiency reaction; and the rapid separation of the iodinated hormone from unreacted isotope.

BIOLOGY

Inhibition of Cell Division by Carbon Dioxide

A DEMONSTRATION of utilization of carbon dioxide by propionic acid bacteria[1] drastically changed the long-entertained idea that carbon dioxide played only an indirect part in heterotrophic growth, by utilization of organic substances produced in autotrophic assimilation. After later evidence indicated that growth of many bacterial cultures stopped below a minimum concentration of carbon dioxide, the opinion gained support that heterotrophs, and indeed all living cells, can utilize, and possibly even require, carbon dioxide for growth and reproduction[2]. Reproduction on a cellular level means cell multiplication. The requirement for carbon dioxide in cell multiplication could not be proved or disproved until a technique was developed enabling separation of growth from cell division[3,4].

The effect of carbon dioxide on cell division was studied on synchronized cultures of the high-temperature alga, *Chlorella* 7-11-05 (ref. 5). Algal cells were synchronized by intermittent light–dark régime[6,7] and then grown for 8 hr. in a complete inorganic medium at 39° and 2,000 ft.-candles. During growth period in light, carbon dioxide was supplied by bubbling through algal suspensions a 5 per cent carbon dioxide in air mixture.

After 8 hr. of growth the majority of cells generally did not reveal any internal subdivision into daughter cells. However, potentially these cells were capable of cell division. If, after 8 hr. in light, cells were transferred in the same medium into darkness, they divided in the course of time to the extent that after 16 hr. in darkness 99 or more per cent of cells appeared as small daughter cells.

To observe the effect of carbon dioxide on cell division the 8-hr. cells were centrifuged, transferred into distilled water, and placed in darkness at 35°. The percentage of carbon dioxide in air, bubbled through algal cultures during dark period, varied from 0 to 100. The progress in cell division in a given algal suspension was recorded by placing it into one of the arbitrary categories characterized by the approximate percentage of cells which divided, or were in the process of cell division, at the time of observation, after 16 hr. in darkness. The categories were as follows: 0, 1, 10, 50, 90, and 99 per cent of divided cells referred to the corresponding initial number of mother cells. A degree of cell division between these categories was qualitatively indicated by placing a plus or a minus after corresponding percentages.

Table 1. A DEGREE OF COMPLETION OF CELL DIVISION IN SUSPENSIONS OF SYNCHRONIZED 8-HR. CELLS OF *Chlorella* 7–11–05 after 16 HR. IN DARKNESS AT 35° AND DIFFERENT CONCENTRATIONS OF CARBON DIOXIDE

Total No. of experiments	53	20	9	3	2	1
On No. of days	35	16	7	3	2	1

The results of 88 observations (experiments) are presented in Table 1. Of 53 experiments conducted in carbon dioxide-free air on 35 days, cell division was completed to 90 or more per cent in 48 (90 per cent) experiments. In 5 experiments the division after 16 hr. proceeded in less than 90 but not less than in 10 per cent of cells.

At 1 per cent carbon dioxide in 16 experiments there was no cell division, and in 4 experiments the degree of division was negligible. That some cells could divide at 1 per cent carbon dioxide was probably due to imperfect synchronization of cells. Some cells in 8-hr. cell suspension proceeded further in their development than others and were capable of division even in the atmosphere of 1 per cent of carbon dioxide in air, generally unsuitable for cell division. No cell division was recorded at 5–100 per cent of carbon dioxide.

Differences in the degree of completion of cell division in different experiments at 0 per cent carbon dioxide are understandable in view of the fact that even in air free from carbon dioxide cells were influenced by carbon dioxide produced by cells in the course of their dark metabolism. The amount of carbon dioxide evolved by cells into a volume of cell suspension per unit of time evidently depended on the density of cell population (size of inoculum), which differed in different experiments. The removal of carbon dioxide produced by cells depended on the degree of aeration (volume of gas bubbled through a volume of cell suspension in a unit of time) and on the degree of dispersion of the gas (size of gas bubbles) which, for technical reasons, varied in different experiments. Thus, a combination of a heavy inoculum with low aeration might create conditions under which the concentration of carbon dioxide produced by cells remained, during some experiments, high enough to retard cell division.

In darkness, and in the absence of other ions from the suspending medium, carbon dioxide acts on *Chlorella* cells as a powerful suppressor of cell division. Attention is directed to the fact that during 8 hr. of growth, cells in these experiments accumulated all necessary constituents and were capable of division after being moved into darkness. However, this capability was or was not realized, depending on the presence of carbon dioxide in the air bubbled through cell suspension during dark period.

Under natural conditions, carbon dioxide may act as a factor regulating cell division. In unicellular organisms metabolically produced carbon dioxide diffuses to the surface of a cell and escapes into the surrounding medium. If this carbon dioxide does not accumulate in the medium beyond a critical concentration, other conditions permitting, cell division proceeds in a succession of cells uninterruptedly for indefinite time. In multicellular organisms, an increase in bulk of embryonic tissues and resulting complications in transport systems may reach a point where accumulation of carbon dioxide will act as an inhibitor of cell division. The effect of carbon dioxide on cell division depends on several factors, particularly on the presence and concentration of other ions. Elucidation of these factors is of considerable interest in studies of normal and possibly neoplastic growth.

Wart Structure of Gymnosperm Tracheids

THE wart structure of mature tracheids was first described by Kobayashi and Utsumi[1] and by Liese[2]. It was observed to consist of small excrescences (warts) (0·03–0·04μ diam.) on the inner surface of the cell wall. Subsequent surveys of the occurrence of these structures showed them to be of limited taxonomic significance[3,4].

In *Actinostrobus pyramidalis* the wart structure is large and readily seen in an optical microscope. Wardrop, Liese and Davies[5] concluded that the isolated structure consisted of a non-cellulosic membrane which formed a lining of the cell lumen and was extended in a series of diverticula protruding into the lumen. In some of these diverticula were strongly ultra-violet absorbing, nearly spherical bodies.

In a further investigation the wart structure in *Actinostrobus* has been shown by electron microscopic examination of sections after shadow casting to consist of a localized thickening of the cell wall in the form of a papilla (Fig. 1). In permanganate-fixed material the thickening could be seen to be covered by a strongly staining membrane (Fig. 2).

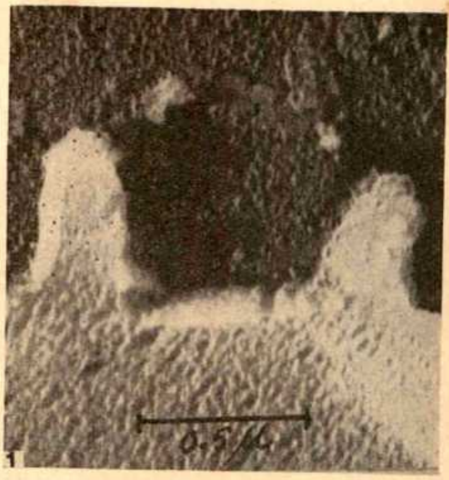

Fig. 1. Section through the wart structure of *Actinostrobus pyramidalis* showing the continuity of the wart structure with the cell wall

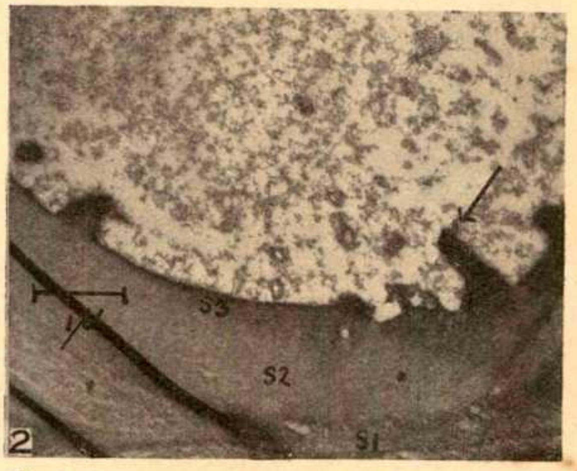

Fig. 2. Transverse section through a tracheid of *Actinostrobus pyramidalis* after fixation in potassium permanganate. Formation of the wart structure is almost complete and the heavily staining membrane covering it is apparent. The arrow indicates a spherical body at the tip of the wart structure

The first indication of the development of the wart structure was a localized withdrawal of the plasmalemma from the cell wall and the beginning of the formation of a localized thickening on the wall (Fig. 3), which continued until the wart structure reached its mature size (Fig. 2). Since the plasmalemma remained in contact with the wart thickening throughout the period of its formation, the associated spherical bodies previously described must arise within the cytoplasm. In cells which were conspicuously vacuolated the various cytoplasmic organelles were observed to be confined between the tonoplast and plasmalemma. At the death of the cell it might be anticipated that the tonoplast and membranous components of the cytoplasm would retract and dry on the surface of the lumen enclosing the remains of any cytoplasmic organelles between it and the plasmalemma. The spherical bodies associated with the wart structure of *Actinostrobus*[5] and some other species[6] are assumed to arise from these dena-

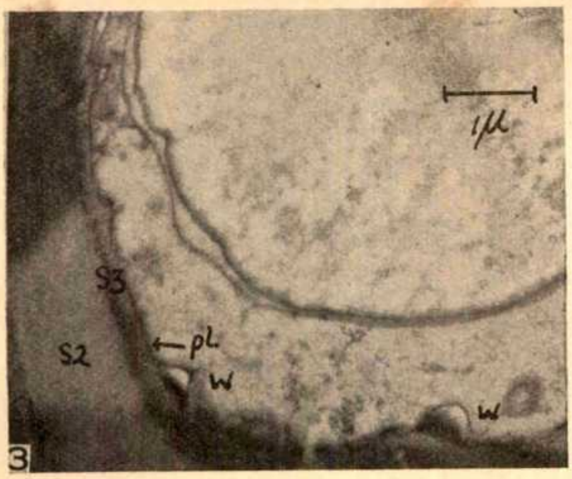

Fig. 3. As Fig. 2, showing the beginning of the formation of the wart structure (*W*) and the plasmalemma (*pl*) and the outer (S_1), middle (S_2) and inner (S_3) layers of the secondary cell wall

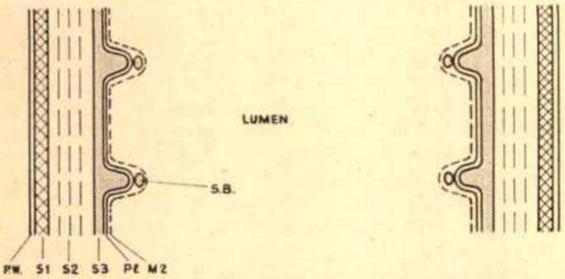

Fig. 4. Diagrammatic representation of the wart structure in *Actinostrobus pyramidalis* showing primary wall (*P.W.*). with three layers of the secondary wall (S_1, S_2 and S_3), plasmalemma (*Pl*) and spherical body (*SB*) and the second membrane system (*M*2) formed by the degenerating protoplast

tured organelles. As seen in mature xylem the wart structure may thus be represented as in Fig. 4.

From this account it is clear that the wart structure, as observed in mature cells, consists in part of a localized cell wall thickening and in part of residual components of the cytoplasm. It follows that the material previously isolated[5] consisted only of the cytoplasmic component, since the technique of isolation involved dissolution of the cell walls. Observed variations in the composition of the isolated material from different species is thus understandable[6].

From the manner of its formation it is reasonable to conclude that the cell wall component of the wart structure would be as significant a taxonomic feature as other forms of cell wall sculpturing, such as helical thickenings. However, differences in appearance between species resulting from the cytoplasmic component of the structure would not be expected to be significant in this respect.

Finally, it may be noted that Frey-Wyssling[7], in discussing the formation of secondary cell walls, has referred to the presence of a tertiary lamella between the cytoplasm and the cell wall which is present during the whole process of cell wall thickening, and of which the wart structure forms a part. From the present investigation, however, it would appear that the only limiting structure between the cell wall and the cytoplasm is the plasmalemma and the wart structure is a feature of the cell wall rather than one of the adjacent cytoplasmic membrane.

Alteration of Sporulation in *Aspergillus niger* by Heat and Deuterium Oxide

ZAMENHOF[1] reported that unstable phenotypic variants sometimes result when bacterial cells or spores are heated. We wish to report the results of a similar investigation of the effects of heating spores of the mould *Aspergillus niger*. Our work has been extended to include the effect of heating the spores in a 99·5 per cent deuterium oxide medium, as well as heating in a water medium and in the dry state.

In this work we utilized *Aspergillus niger* A.T.C.C. No. 10581, and the minimal growth medium of Nicholas[2]; cultures were grown in a 30° C. incubator. Five-ml. aliquots of a washed spore suspension (about 10^8 spores/ml.), in 0·01 per cent sodium lauryl sulphate or 99·5 per cent deuterium oxide, was heated in a water or oil bath maintained at the indicated temperature. Dry spore preparations were prepared by lyophilization. After heating, a suitable aliquot was cooled quickly by dilution with ice-cold 0·01 per cent sodium lauryl sulphate; serial dilutions and pour plates were made by conventional methods.

Table 1 shows that spores suspended in deuterium oxide are considerably more resistant to heat inactivation than spores suspended in water. However, the most notable variation observed in heated spores involved the subsequent capacity for sporulation—inability of aerial hyphæ to differentiate into conidiophores, changes in the appearance and pigmentation of conidiophores with only minimum sporulation allowed, or delayed sporulation. The elicitation of non-sporulating strains by heating was confined almost exclusively to spores suspended in deuterium

Table 1. EFFECT OF HEAT ON *Aspergillus niger* SPORES

Heating conditions	Suspension medium	Survival (per cent)*	Sporulation variants among survivors (per cent)
3 hr., 70° C.	H_2O	0·001–0·0001	< 5
1 hr., 100° C.	H_2O	< 0·00001	—
3 hr., 100° C.	None (dry)	0·1–1	None detected
1–2 hr., 100° C.	D_2O	0·01–0·1	48

* Ability to form colonies on minimal media supplemented with 2 per cent 'Bacto' agar, 0·1 per cent Difco proteose peptone and 0·1 per cent Nutritional Biochemicals yeast extract.

Table 2. SPORULATION VARIANTS OF *Aspergillus niger* PRODUCED BY HEATING SPORES IN DEUTERIUM OXIDE FOR 1–2 HR. AT 100° C. TYPICAL RESULTS

	No. of strains isolated	Percentage
Green, irregular conidiophores	15	32
Blue, irregular conidiophores	1	2
Non-sporulating	6	13
Black, wild-type conidiophores	24	52

oxide. These sporulation anomalies have been observed to persist for several transfers, though reversion to wild-type usually occurs after several weeks.

The incorporation of 70–100 per cent deuterium oxide into culture media has been found to inhibit sporulation in *A. niger*[3,4], but recovery ensues after a short lag period in aqueous media. In such cases of organisms grown in deuterium oxide, it has proved difficult to differentiate between possible primary biological effects of deuterium and secondary isotope effects[5]. In the system discussed here, secondary isotope effects are relatively insignificant, in view of the short period of exposure and the known low metabolic rate of spores in general.

The replacement of exchangeable hydrogens by deuterium in proteins, and the resulting increased resistance to heat denaturation which has been reported in some cases[6] might explain the decreased rate of inactivation of spores heated in deuterium oxide, but such does not adequately explain the increased incidence of sporulation anomalies.

Alteration of the primary structure of deoxyribonucleic acid (DNA) under these conditions is likewise unlikely since no stable nutritional mutants have been detected under the stated conditions. Yet it is evident that an impression has been made on the information-bearing units which persists for a considerable period of time after exposure to deuterium oxide as previously reported by Hughes *et al.*[7].

A more probable explanation of the synergistic effect of deuterium oxide and heat in producing sporulation anomalies is an alteration of the hydrogen-bonded secondary structure of DNA. Temperatures of 70°–100° C. (depending on the solvent) have been shown to lead to an alteration of DNA *in vitro* from a predominantly helical configuration to a random coil structure[8].

DNA extracted from variant strains has been noted to exhibit a significantly different heat denaturation profile as is seen in Table 3. Rather than an abrupt increase in absorbance from 80° to 95° C. as is observed in the case of DNA extracted from control cultures, DNA extracted from aberrant strains exhibited a random absorbance increase over the entire temperature range. This type of behaviour has been previously noted in the case of DNA isolated from a hybrid strain of bacteria containing a random-coil type of DNA[10].

Table 3. CHARACTERISTICS OF DNA EXTRACTED FROM *A. niger* BY THE METHOD OF MARMUR (REF. 9)

Strain	T_m*	Percentage of hyperchromicity at 260 mμ
10581 control	90° C.	37
Non-sporulating 8–1–1	88° C.	12
Non-sporulating 9–28	57° C.	20
Slow sporulating 4–28	88° C.	20

* T_m defined as the temperature corresponding to the mid-point of the thermally induced absorbance increase. DNA solutions were made in 0·15 *M* sodium chloride, 0 015 *M* sodium citrate solution *p*H 7·0.

Thus the consistent isolation of 'denatured' DNA's from variant strains of *A. niger* which exhibit sporulation anomalies leads one to suspect that maintenance of the secondary structure in certain regions or in certain fractions of the DNA may be of major importance in so far as the capacity for development and differentiation is concerned, while it is somewhat less critical with respect to the capacity for growth.

The synergism between deuterium oxide and heat which has been noted suggests that alteration of the random coil vs. ordered helix equilibrium of DNA structure may represent one of the primary modes of action of deuterium oxide on biological systems.

Embryonic Death in Aged Mice

THE breeding history of mice follows a fairly well established pattern[1,2]. Initially there is a period in which the size of litter is fairly constant. This is followed by a phase during which successive litters become progressively smaller until breeding ceases. This decline in size of litter could be due either to a gradual decrease in the number of oocytes produced or to the failure of an increasing proportion of the ovulated eggs to result in living offspring. Perry[3]. from a comparison of corpora lutea counts and embryo counts in slaughterhouse pig material, postulates that the decline in fertility with age in this species is due to failure of the ageing uterus to maintain all the fertilized eggs. Jones and Krohn[4], working with mice, showed a progressive decrease in the oocyte content of the ovaries of aged females. However, they concluded that the decline in size of litter is probably not due primarily to decreasing output of oocytes. Similarly, Biggers, Finn and McLaren[2] conclude that the gradual decline in size of litter in mice and the eventual cessation of breeding are probably due to factors concerned in the maintenance of the embryos in the uterus, and not to exhaustion of oocytes.

The experiments reported here were conducted to determine whether there is greater embryonic loss in aged mice than in young mice. Pairs of *TO* strain mice were allowed to breed continuously and records kept of all litters born, the young being removed soon after birth. When the mice had reached the declining phase of their reproductive life, laparotomies were performed and the uterus inspected. This was done at approximately the fifteenth day of pregnancy, when it is easy to distinguish normal embryos from regressing implantations.

Ten aged mice were examined, and the results are set out in Table 1. The breeding history of each mouse is given, followed by the number of normal embryos and old implantation sites found at laparotomy. From previous work it is known that the incidence of post-implantation embryonic loss in young mice of this strain is very low. However, to check this five young virgin females were mated and examined on the fifteenth day of pregnancy.

Table 1. Aged Mice

Sizes of all litters born	Appearance of uterus: Normal embryos	Appearance of uterus: Regressing implantations	Age: months	Age: days
M, 6, 7, 6, 10, 7, 11, 6, 9, 2, 5	6	5	10	2
6, 8, 10, 10, 9, *M*, 10, 8, 10, 7, 7, 6	3	4	9	21
10, 6, 10, 5, 6, 8, 2	3	12	9	17
12, 10, 10, 8, 6, 3, 5, 2	2	4	9	11
9, 4, 9, 10, 12, 7, 8, 8, 3, 4, 4	4	4	9	15
8, 7, 2, 10, 10, 7, 3, 11, 8, 9, 7	11	1	9	15
8, 10, 11, 10, 7, 3, 5, 3	4	5	9	15
11, 10, 13, 12, 4, 7, 7, 6, 8	7	4	10	18
9, 7, 7, 12, *M*, *M*, 9, 7, 7, 2, 6	5	3	10	11
8, 12, 8, 9, 10, 9, 7, 4, 9, 8, 3, 3	8	5	10	20
Young mice				
Virgin	7	0	Approx. 2 months	
,,	7	1	,,	
,,	9	0	,,	
,,	3	1	,,	
,,	8	0	,,	

M, litter mutilated by mother before it could be counted.

It will be seen that the embryonic loss in the aged mice is considerably higher than in the young mice, although the total number of implantations is not much less than the number of offspring per litter born during their early breeding life.

These results provide further direct evidence of the cause of the declining fertility in aged mice. However, they still leave open the question as to whether the failure of the implanted embryos to develop is due to structural changes in the uterus, changes in the endocrine environment or lethal factors in the eggs.

A Phosphorus–Magnesium Interaction in Tomato Nutrition

Applications of phosphorus to an acid greenhouse soil initially low in this nutrient has resulted in increased tomato yield and reduced the incidence of manganese toxicity[1]. This observation has previously been noted[2]. Other effects accruing from phosphorus applications, however, are decreased leaf contents of nitrogen and potassium[3].

In further experimental work on the acid soil referred to[1] superphosphate and lime were applied at 0 and 2½, 6 and 0 and 10 and 20 oz. per sq. yd. respectively. Apart from the beneficial effect of both fertilizers on yield, plant growth and excess manganese symptoms it was further observed that some plants developed leaf chlorosis typical of magnesium deficiency. Soil and plant analysis confirmed this observation (Table 1).

The most notable feature of the results is that at the 'no calcium' level the available magnesium of the soil and the magnesium status of the plant decreased with increasing phosphorus application. The available soil magnesium content and plant uptake increased with rate of lime applied. While levels of available soil potassium were reduced by the phosphorus fertilizer particularly in the 'no calcium' treatment no clear-cut effect was discernible in the potassium status of the plants.

Table 1. Effect of Superphosphate and Lime on Available Soil Cations and Plant Uptake

Treatment	Soil Ca (lb. per acre)*	Soil P (lb. per acre)*	Soil K (lb. per acre)*	Soil Mg (lb. per acre)*	Leaves Ca (percentage oven-dried samples)	Leaves P (percentage oven-dried samples)	Leaves K (percentage oven-dried samples)	Leaves Mg (percentage oven-dried samples)
No P No Ca	2,367	5·5	1,000	185	3·6	0·08	5·5	0·70
Med. P No Ca	2,400	10·67	978	170	2·9	0·08	6·9	0·47
High P No Ca	3,833	19·67	754	120	3·7	0·16	5·3	0·36
No P Med. Ca	2,333	4·5	972	215	2·7	0·06	5·8	0·77
Med. P Med. Ca	2,633	11·83	976	235	2·9	0·08	5·8	0·86
High P Med. Ca	4,233	24·67	856	215	2·9	0·14	6·1	0·52
No P High Ca	2,733	5·33	925	255	3·1	0·06	5·3	0·86
Med. P High Ca	2·500	13·67	905	245	3·6	0·07	5·5	0·89
High P High Ca	4,800	18·17	942	255	3·5	0·14	5·2	0·72

* Extracted with sodium acetate buffer (Morgan's reagent).

While magnesium deficiency of tomatoes has been largely attributed to excess soil potassium[4,5] on this particular soil there has been an interaction between available soil magnesium, plant magnesium and applied phosphorus.

An Unusual Parasymbiont of Marine Lichens

The ascocarps of lichens vary in form from one species to another. Their development in several species has been examined by Doppelbaur[1], but nothing is known of the mechanism controlling their morphology. Study of a recently identified lichen parasymbiont suggests that the thallus may have a determining role.

Deakin[2] described as *Sagedia marina* a plant which was collected on "rocks submerged by the sea at high-water, Meadfoot, etc., near Torquay, Devonshire". It has since been found elsewhere between high- and low-water marks on the coasts of the British Isles and of Western Europe[3,4]. Hitherto classed as a lichen, it has usually borne the name *Arthopyrenia marina* (Deakin) A. L. Sm., though von Keissler transferred it to the genus *Thelidium* Mass.[5] and (from the synonymous *Verrucaria leptotera* Nyl.) to *Pseudarthopyrenia* Keissl.[6]. But examination of the type specimen in the British Museum Herbarium shows that it is in fact a parasymbiont on *Verrucaria mucosa* Wahlenb.—that is, a parasite which does not harm the lichen but appears to share the thallus with the lichen's own ascocarps. Authentic material of *Arthopyrenia leptotera* (Nyl.) Arn. named by Nylander and also in the British Museum Herbarium belongs to the same species and the name is a later synonym. Since it is a parasymbiont the species should be transferred to the genus *Pharcidia* Körber. This will be dealt with elsewhere; but unfortunately the combination *Pharcidia marina* is precluded by its application (illegitimate) by Bommer[7] to the species now known as *Arthopyrenia consequens* (Nyl.) Arn. (syn. *A. sublitoralis* (Leight.) Arn.).

Material of the parasymbiont that I collected in July 1961 in Ireland, West Cork (vice-county *H*3), Tragumna Bay, on acidic shale shows an interesting state of affairs. It had for its hosts fertile plants of both *Verrucaria mucosa* Wahlenb. and *V. microspora* Nyl. in adjacent patches on rocks between high- and low-water marks. The involucrellum of the parasymbiont is found to take the form of the involucrellum of its host species (Figs. 1–4). With *Verrucaria mucosa* the ascocarp of the parasymbiont is only subcompound, as is the ascocarp of the lichen host, while with *V. microspora* it is fully compound (these terms have been previously defined[8]). There can be no doubt that the two groups of material represent the same species of parasymbiont, for apart from the involucrellum the ascocarps are identical in form and dimensions. The similarity of the spores is worth emphasizing because they are peculiarly distinctive with the central septum dividing off two equal, rather elongate cells, each of which shows two locules divided by an obscure septum.

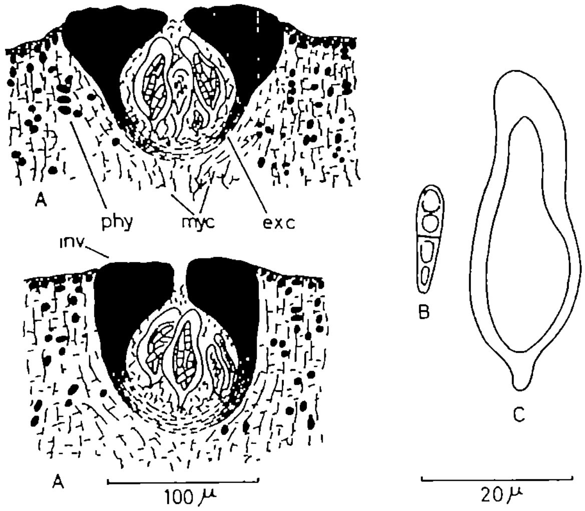

Fig. 1. '*Arthopyrenia marina*' on *Verrucaria mucosa*. Left, *A*, vertical sections of two ascocarps (*inv*, involucrellum; *exc*, excipulum; *phy*, phycobiont of host thallus; *myc*, mycobiont of host thallus); *B* and *C*, spore and ascus of '*Arthopyrenia marina*'

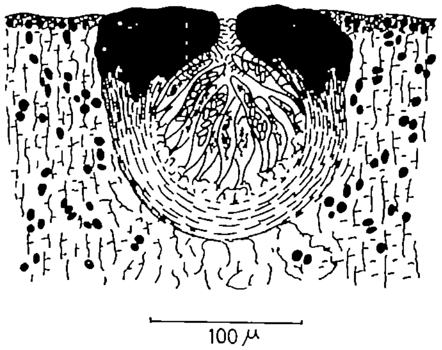

Fig. 2. *Verrucaria mucosa*, vertical section of ascocarp

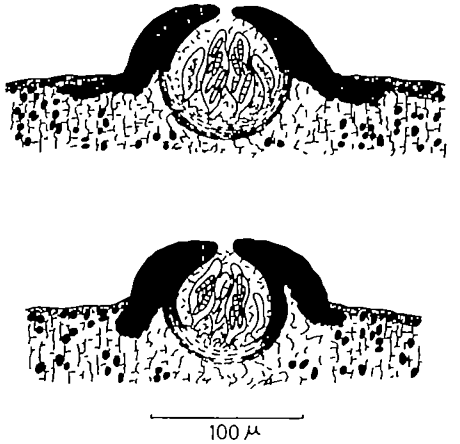

Fig. 3. '*Arthopyrenia marina*' on *Verrucaria microspora*, vertical sections of two ascocarps

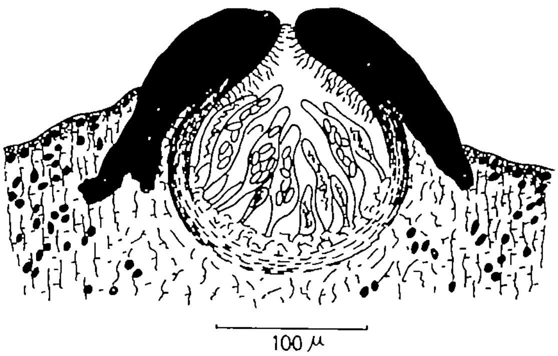

Fig. 4. *Verrucaria microspora*, vertical section of ascocarp

Doppelbaur[1] has shown that the involucrellum appears in the apex of the developing ascogone first as a ring of black plectenchyma. This then extends and thickens to assume the form of an inverted dish or bowl. The thallus could influence the course of this development, and it seems possible that the mechanism which controls the form of the involucrellum in *Verrucaria mucosa* and *V. microspora* is likewise shaping the ascocarps of the parasymbiont.

I thank the British Museum (Natural History) for facilities to examine specimens in its keeping.

Effect of Polyvinyl Alcohol on *Chlamydomonas* Species

In previous communications it was shown that polyvinyl alcohol has a beneficial effect on the growth of peas and *Chlorella pyridinosa* and increase in chlorophyll in both those plants. When an appropriate concentration of polyvinyl alcohol was added, chlorophyll content was much greater than in the control aquarium to which polyvinyl alcohol had not been added[1,2].

We wished to discover how other species of Chlorophyta would behave if placed in a suitable concentration of polyvinyl alcohol. For this purpose we chose *Chlamydomonas* sp., which is to be found in abundance in the pool in the Academy grounds. Water taken from the pool was poured into jars.

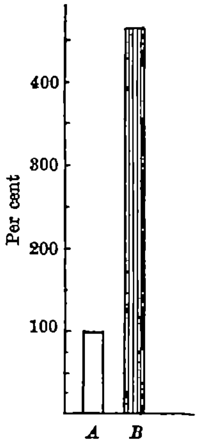

Fig. 1. Effect of polyvinyl alcohol on *Chlamydomonas* sp. *A*, Chlorophyll content in the controls; *B*, in the aquariums to which polyvinyl alcohol had been added

The appropriate concentration of polyvinyl alcohol being added to some, the others were left as controls. The greatest quantities of chlorophyll were present in the jars containing a concentration of 0·1 per cent polyvinyl alcohol. This concentration was used for the experiments on *Chlamydomonas* sp.

The experiment was begun on March 10, 1961. 10 days later (March 20) the chlorophyll content in the aquariums, that is, those without polyvinyl alcohol was determined. The results are given in Table 1 and Fig. 1. As these results show, 10 days after the addition of polyvinyl alcohol the number of *Chlamydomonas* sp. had increased considerably and the amount of chlorophyll was several times greater than that of the controls. The average chlorophyll content in the controls was only 0·072 mgm./l. whereas in the *Chlamydomonas* sp. culture to which 0·1 per cent polyvinyl alcohol had been added, it reached an average of 0·334 mgm./l. If the chlorophyll content of the controls is said to be 100 per cent (Fig. 1 *A*), then the chlorophyll content of the aquariums to which polyvinyl alcohol had been added increased by an average of 464 per cent (Fig. 1 *B*).

Table 1. Chlorophyll Content (mgm./l.) in the Cultures of *Chlamydomonas* sp.

Controls	With polyvinyl alcohol (0·1 per cent)
0·075	0·336
0·070	0·315
	0·350
0·072	0·334

From these experiments it is therefore obvious that polyvinyl alcohol has a beneficial effect on *Chlamydomonas* sp. as it had on *Chlorella pyridinosa* and *Pisum sativum* in our earlier experiments. It is worthy of note that Wetter[3] also observed the effect of polyvinyl alcohol on the growth of *Aspergillus niger*.

ENTOMOLOGY

Effect of Cholesterol in the Larval Diet on Ovarian Development in the Adult House-Fly

The adult house-fly has been reported to require a dietary source of both protein and carbohydrate for ovarian maturation and to show little or no ovarian growth on an adult diet consisting solely of carbohydrates[1-5]. This requirement of the adult for protein could not be fulfilled by supplementing the larval diet with additional protein[4].

In the course of our investigations on nutrition and reproduction in the house-fly (*Musca domestica* L.) we observed that flies reared on larval medium supplemented with cholesterol developed mature ovaries when held on an adult diet of only sucrose and water. For these tests approximately 450 eggs from an *NAIDM* strain of flies were added to 75 gm. of cholesterol-supplemented 'CSMA' (Ralston Purina Co., St. Louis, Mo.) medium to which had been added 160 ml. of water. Flies reared on 'CSMA' medium not supplemented with cholesterol served as controls. After the pupæ were removed from the medium and cleaned the adults were allowed to emerge and then were kept on a diet of sucrose and water. At 6 days after emergence, and at subsequent intervals, the ovaries were removed from groups of 25 flies and the degree of ovarian development determined. The results in Table 1 indicate that under these experimental conditions, supplementing the larval diet with cholesterol results in ovarian maturation in about half the adult flies, even in the absence of a source of protein in the adult diet. Doubling the concentration of cholesterol appeared to give no increase in ovarian development. These results were confirmed with four other laboratory strains of house-flies.

Table 1. Ovarian Development in House-Flies reared on Cholesterol-Supplemented 'CSMA' Larval Medium and held on Adult Diet of Sucrose and Water for 6 Days

Cholesterol added to diet (Per cent dry weight)	Per cent flies with mature ovaries*
1	53±5
2	61±3
Control (non-supplemented)	2±1

*Means for 3 replicates ± *S.E.*, 2 groups of 25 flies per replicate.

This ovarian maturation occurred in the absence of any mortality, which indicated that it was not brought about by the female flies feeding on dead flies, as has previously been reported[4]. In addition, eggs from these flies were viable and produced larvæ which developed to adults.

To determine whether or not the activity observed was brought about by micro-organisms present in the larval medium, the tests were repeated with a synthetic larval diet and aseptic rearing techniques[6]. For comparison, the phytosterol β-sitosterol, which is one of the major sterols present in the 'CSMA' medium, was also tested. The cholesterol used in these tests was purified through the dibromide (m.p. 149·5° C.), and the β-sitosterol (m.p. 139–140·5° C.) was found to be greater than 97 per cent pure by gas-liquid chromatographic analysis. 25–68 per cent of the flies reared aseptically on the synthetic larval diet containing the various concentrations of cholesterol and held on an adult diet of sucrose and water were found to contain mature ovaries, whereas those flies reared on the diet containing β-sitosterol showed only slight ovarian development (Table 2). This lack

Table 2. OVARIAN DEVELOPMENT IN HOUSE-FLIES REARED ASEPTICALLY ON A SYNTHETIC MEDIUM CONTAINING VARIOUS CONCENTRATIONS OF STEROLS AND THEN HELD ON AN ADULT DIET OF SUCROSE AND WATER

Sterol in diet (Per cent dry weight)	Per cent flies with mature ovaries* Days 6	9	12

of equivalence in the biological activity of cholesterol and β-sitosterol is in agreement with the results of our prior biochemical studies with the house-fly, using tritiated β-sitosterol, in which no conversion of β-sitosterol to cholesterol could be detected[7].

These results point to an interesting physiological role for cholesterol in the house-fly, an insect which has previously been shown to require a dietary source of sterol for growth and development[8,9] and for sustained viable egg production[10]. It is not known whether cholesterol as such is responsible for this effect, or whether it serves as precursor for an essential steroid metabolite which regulates gonadal development.

Population Density and Atypical Behaviour in Male Odonata

A 7-YEAR study of the behaviour and population ecology of imaginal dragonflies in Dorset, England, has revealed two features common to all fifteen species studied.

(1) The upper limit of population density (the highest steady density) of males by water is determined by the behaviour of the insects themselves. The number of insects per unit area of water edge differs from species to species, but each has a characteristic highest steady density.

(2) Male dragonflies often exhibit atypical and apparently dysgenic behaviour.

The values of highest steady density for several species were checked by field experiments. In one type of experiment a population at highest steady density was collected out. When there were many surplus individuals near the pond it was quickly recolonized: the new population was found to agree closely with the original. In another type of experiment individual insects were caught elsewhere and released at a pond the population of which had been counted previously. The new population density was found frequently to equal, but never to exceed, the highest steady density recorded for the species under natural conditions. The highest steady densities, both natural and experimental, which were obtained in the study-area during 1954–60 are given in Table 1. It will be seen that the highest steady densities have an approximate inverse relationship to the size of insect. By using the figures in Table 1 it is possible to predict the approximate upper limits of male dragonfly populations of any pond the circumference of which is known. Many such predictions were made on ponds outside the study-area and were found to agree closely with the observed values.

The control of population density and hence dispersal was observed to result both from aggressive and homosexual attack. The latter was the commonest type of abnormal behaviour observed. Attempts to mate with males and females of other species were also recorded but much less frequently. Much inter-specific fighting occurred between certain species which superficially closely resembled each other (for example, *Pyrrhosoma nymphula* and *Ceriagrion tenellum*). Abnormal behaviour also occurred in habitat selection; males were often observed defending territories by waters (pools in salt marsh, etc.) which were shown to be unsuitable breeding places. Poor discrimination in selecting habitat appeared to occur when dragonflies were particularly abundant. By contrast female dragonflies were very rarely observed to oviposit in unsuitable habitats.

The work of Mayer[1] and my own more recent work[2] suggest that male dragonflies can distinguish between males and females, and between their own species and others, and have accurate habitat selection mechanisms. Therefore, it would appear that the frequently observed reactions to sub-optimal stimuli described here are atypical and are due to a lowering

Table 1. HIGHEST STEADY DENSITY OF MALE DRAGONFLIES BY WATER

Family	Species	Length (mm.) (ref. 1) (min.)	(max.)	Highest natural steady density recorded 1954–60. No of males per 100 m. of pond edge	Highest experimental steady density recorded 1954–60. No. of males per 100 m of pond edge
Aeshnidae	*Aeshna cyanea*	71	76	1	
Aeshnidae	*Aeshna juncea*	71	76	1	
Aeshnidae	*Anax imperator*	76	81	2	
Cordulidae	*Cordulia aenea*	48	51	2	
Libellulidae	*Libellula depressa*	48	48	8	
Libellulidae	*Orthetrum coerulescens*	40	43	15	
Libellulidae	*Sympetrum striolatum*	36	40	16	
Libellulidae	*Sympetrum danae*	30	33	17	
Libellulidae	*Libellula quadrimaculata*	46	48	28	(17)
Coenagriidae	*Ischnura elegans*	30	33	40	40
Coenagriidae	*Pyrrhosoma nymphula*	33	38	44	44
Coenagriidae	*Enallagma cyathigerum*	30	38	60	(60)
Lestidae	*Lestes sponsa*	33	40	65	(57)
Coenagriidae	*Coenagrion puella*	33	36	115	(61)
Coenagriidac	*Ceriagrion tenellum*	28	33	147	129

Note Figures in parentheses were obtained in a series of less than 20 experiments in each case of the threshold of response. The threshold of response appears to be low unusually often in all the species of Odonata investigated.

It must be concluded that either much dragonfly behaviour is dysgenic or that the atypical behaviour observed has some biological advantage. When females or suitable breeding areas are scarce, discrimination in choice of mate and habitat appears to decrease. Therefore the occurrence of normal or abnormal behaviour appears to be dependent on density. What seems to be a wasteful abundance of dysgenic behaviour in dragonflies may be part of behaviour mechanisms dependent on density based on threshold effects.

MICROBIOLOGY

A Copper Requirement for the Sporulation of *Bacillus megaterium*

AN important relationship exists between metal ions and bacterial sporulation[1,2]. In previous mineral studies with spore-formers c.p. or reagent grade chemicals were used, and although important metal associations with sporulation have been revealed the presence and effect of unsuspected trace amounts of metallic ions were not considered.

This communication describes experiments in which purification procedures and additions of extremely pure chemicals give a highly pure medium which has been used to follow trace element requirements during bacterial sporulation.

The unpurified medium utilized consisted of the following c.p. or reagent grade chemicals: 1 gm. sucrose, 1 gm. NaCl, 0·2 gm. $MgSO_4 \cdot 7H_2O$, 2·4 gm. KH_2PO_4, 11 gm. $(NH_4)_2HPO_4$, 10 mgm. $FeSO_4 \cdot 7H_2O$, 10 mgm. $ZnSO_4 \cdot 7H_2O$, 7 mgm. $MnSO_4$ and 5 mgm. $CaCl_2$ in 1 litre of distilled de-ionized water, final *p*H 7·1–7·3. The phosphates were sterilized separately prior to the addition to the medium. Purification of this medium to eliminate trace contamination was accomplished by the replacement of most medium components with Matthey spectrographically pure standardized chemicals (spec.-pure) or by purification of some medium ingredients. NaCl, $MgSO_4 \cdot 7H_2O$, $MnSO_4$, $CaCl_2$, KH_2PO_4, $ZnSO_4 \cdot 7H_2O$ and $FeSO_4 \cdot 7H_2O$ were available in this form; however, sucrose and $(NH_4)_2HPO_4$ were not. Sucrose was purified by passage through a cation exchange column. Elimination of trace contamination by this procedure was indicated by a decrease in iron content as measured by the orthophenanthroline method[3]. Further examination for specific ions was not necessary since subsequent experiments showed that a trace metal contaminant resided in the $FeSO_4$, $ZnSO_4$, $MnSO_4$ or $CaCl_2$ portion of the medium. $(NH_4)_2HPO_4$ was purified by the 8-hydroxyquinoline method[4].

All other materials used were cleaned according to accepted procedures for the removal of trace contamination[4,5]. Polypropylene ware was substituted wherever possible[6]. All water used was first distilled and then de-ionized by passage through a cation exchange column. A spore inoculum of *Bacillus megaterium* collected from a 60-hr. culture of the unpurified synthetic medium by centrifugation in a Servall *SS*–1 angle centrifuge at 1,200*g* for 15 min. at 6° C. was used. The spores were stored at − 20° C. until use, when they were defrosted at 6° C., washed twice and standardized with distilled deionized water. A 1-ml. inoculum of 500 Klett units, as measured in a Klett–Summerson photoelectric colorimeter, consisting of about 20×10^7 spores per ml. (dry wt., 0·5 mgm.) was used per 100 ml. of medium in 350 ml. Erlenmeyer glass flasks or 500 ml. Erlenmeyer polypropylene containers. Flasks or containers were incubated at 30° C. on a reciprocating shaking machine operating at 78 four-in. strokes per min. Five-ml. aliquots were removed at various time intervals for turbidimetric determinations on a Klett–Summerson photoelectric colorimeter and direct counts in a Petroff–Hauser Chamber. Cell types were distinguished by dark contrast phase contrast microscopy. Non-refractile rod-shaped cells were scored as vegetative cells; rod-shaped cells containing a distinct refractile body were considered sporangia; and oval or spherical highly refractile bodies were counted as free spores.

Growth and sporulation patterns of *B. megaterium* in the unpurified medium in glassware and polypropylene were similar. The growth peak, indicated by turbidimetric measurements and total counts, was reached at approximately 28 hr. Sporangia started to appear at 24 hr. while spores first appeared at 28 hr. Complete sporulation, greater than 90 per cent, occurred by 38 hr. These results mean that polypropylene substitution for glassware had no effects on growth or sporulation. However, purified medium in polypropylene supported good vegetative growth only, with a growth peak at 24 hr. Sporangia or spore formation was never observed.

This suggested that the unpurified medium was deleted of some important component(s), vital for sporulation, during the purification and substitution procedure. This missing component(s) was shown to be part of the four salts: $FeSO_4$, $ZnSO_4$, $MnSO_4$ or $CaCl_2$. When these four spec.-pure salts were replaced with c.p. or reagent grade salts, the medium became conducive to sporulation. A spectrographic qualitative analysis of a mixture of these four salts showed traces of aluminium, copper, strontium, magnesium, silicon, cobalt, and molybdenum. In the quest for this component(s) necessary for sporulation, the following compounds were added to the purified synthetic medium: spec.-pure $CoSO_4 \cdot 7H_2O$, $CuSO_4 \cdot 5H_2O$, $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$ and c.p. or reagent grade $NiCl_2 \cdot 6H_2O$, $NaSiO_3 \cdot 5H_2O$, $AlCl_3$, $LiCl_2$, CrO_3, H_3BO_3 and $BaCl_2 \cdot 2H_2O$. Only the addition of the copper salt (0·05 μgm./ml.) induced sporulation. The concentration of the $CuSO_4 \cdot 5H_2O$ must be within the 0·025–0·10 μgm./ml. range to stimulate maximum sporulation. Below the lower limit sporulation is decreased until 0·01 μgm. per ml. is reached when no sporulation occurs. Greater than 0·1 μgm. per ml. results in inhibition of germination of the spore inoculum, and although eventually the cells will germinate and cells reproduce after a long lag phase incomplete sporulation occurs by 62 hr.

These results indicate that copper must be added as a supplement to the purified medium to facilitate sporulation and suggest that this element may be the trace contaminant component of the regular salts which is absent from the medium upon replacement with spec.-pure salts.

Occasionally, the addition of copper alone did not stimulate sporulation; however, in all cases, the addition of molybdenum as spec.-pure $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (50 μgm. per ml.), although not having an effect on sporulation when added alone, resulted in sporulation when added with the copper.

Although copper has never been implicated as a requirement for sporulation, previous studies[6] indicate its presence both in vegetative cells and spores.

The specific function of minerals in sporulation is not known. In all probability, they act catalytically in the activation of many enzyme systems. They may accelerate the complex enzymatic systems involved in intracellular protein degradation and resynthesis postulated[7] as the basic mechanism in sporogenesis.

It is now possible to study in more completeness, without concern about trace contamination, the role of other metals in sporulation. A more detailed publication reporting experiments indicating when the copper requirement occurs during the sporulation cycle and the effects of deletion of various metals from the Cu–Mo supplemented purified medium is in preparation.

Lysogeny in the Genus *Lactobacillus*

We have reported[1] the isolation of 14 phages active on *Lactobacilli* by the use of an enrichment technique in which 10 batches of sewage were incubated with groups of *Lactobacilli*. Each group comprised 12 different strains. These experiments have now been repeated with one modification: the sewage in the mixtures has been replaced by an equal volume of tap water. No phage was isolated. It would appear that none of the 120 strains of *Lactobacillus* used was lysogenic and that the phages originally isolated were present in the sewage.

Using the same media and techniques, lysogeny in many strains of the species previously used was investigated as follows. Fifteen strains of *Lactobacilli* were grown in all combinations of two according to Scholtens's method[2] by sub-culturing two drops of an overnight culture into 40 ml. of broth. Cultures were incubated for 14 days, centrifuged to clarity and the supernatants spotted on lawns of 102 strains of *Lactobacilli*. No phage activity was demonstrated. Another batch of 15 strains was similarly investigated using the same 102 indicator strains, again with negative results. Afterwards, 200 strains were grown singly in broth for 10 days. Cultures were then spun to clarity and the supernatant spotted on lawns of these 200 strains. Although a number of diffusible antibiotics[3] was obtained, no phage activity was demonstrated. Finally, the bacilli in 10 ml. of overnight broth cultures of 50 strains were deposited by centrifugation and resuspended in equal volumes of sterile distilled water in Petri dishes. The suspensions were irradiated with a 30-W. Hanovia Sterilamp from 25 cm. The lamp delivers more than 80 per cent of its output at a wave-length of 2357 Å.

At intervals of 5, 15 and 30 sec., 3 ml. were pipetted into 10-ml. pre-warmed broth and incubated in the dark overnight. The cultures were then centrifuged to clarity and the supernatants spotted on lawns of 109 strains of *Lactobacilli*. Two of the 50 strains proved lysogenic. They are both strains of *L. fermenti* (Nos. 535 and 544). The phage liberated by strain 535 forms small clear plaques in *L. fermenti* strains 222*a* and 196. The other phage forms larger turbid plaques on *L. fermenti* strains *F*1, 184 and 525. Strains 535 and 544 were actually used in all three other experiments listed above. These experiments were afterwards repeated with the two strains. Results were again negative. So far the only method of demonstrating the lysogenic property of the strains is by ultra-violet irradiation.

The 16 phages we now possess have been tested for lytic activity on large numbers of strains of other genera of the family Lactobacteriaceae. No activity has been demonstrated. Tests on numerous strains of Enterobacteriaceae were also negative.

In summary, 92 *L. acidophilus* strains, 42 *L. salivarius*, 30 *L. casei*, 72 *L. casei* var. *rhamnosus*, 19 *L. plantarum*, 76 *L. fermenti*, 12 *L. brevis* and one each of *L. bulgaricus* and *L. helveticus* were examined for lysogenicity by one or more methods. Two *L. fermenti* strains were found to be lysogenic by ultra-violet induction. This, we think, is the first report of lysogenic *Lactobacilli*. The host-range of *Lactobacillus* phages appears to be genus-specific.

GENETICS

Twin Data in Support of the Lyon Hypothesis

The Lyon hypothesis[1,2] suggests that in the *XX* mouse and human female one *X* chromosome is genetically inactive after a certain stage in embryogenesis; that this 'inactive' *X* chromosome forms the Barr body, which can be identified at about the sixteenth day in the human embryo; that it is a random proposition which of the two *X* chromosomes in a given cell becomes the genetically inactive one; that once it is decided which *X* chromosome is to be the genetically inactive one in a given cell all descendants of this cell abide by the decision and have the same *X* chromosome inactive; and that the germ cell line does not participate in this process of *X* chromosome differentiation. The hypothesis suggests a mechanism: (1) of dosage compensation for the 'excess' genetic material in females; (2) of the observed phenotypic variability in females heterozygous for X-borne recessive mutations. The hypothesis requires the existence, in heterozygous females, of two populations of cells with regard to a particular trait for which the female is heterozygous. Beutler[3] seems to have indirect evidence for such, in females heterozygous for glucose-6-phosphate dehydrogenase deficiency. All the genetic and cytological evidence supporting this attractive hypothesis[1-4] will not be reviewed here. Some further evidence in its support will, however, be presented.

The Lyon hypothesis would predict that for many metrical characters intrapair differences are greater for monozygotic female twins than for monozygotic male twins, on the assumption that at least one of the genetic factors determining the character is on the X-chromosome. Because the random decision as to which X-chromosome is to be the genetically inactive one is made at a time when relatively few anlage cells are present, the possibility for chance deviations between two female MZ co-twins exists. If it is a matter of chance as to which X chromosome is genetically inactive and if the outcomes in the several cells are at least in part independent. then the number of cells in which a particular X chromosome becomes inactive may vary from none to all. In male twins, however, there is only one X chromosome, and thus there can be, from this source, no genetic variation between male MZ twins.

With these considerations in mind, the results from the Hereditary Abilities Study of the Institute of Human Biology of the University of Michigan were checked. In connexion with other reports[5-8] most of the necessary calculations had already been made on the IBM 650 of the University of Michigan Computer Laboratory.

The within pair variance of the twins is given by:

$$S_w^2 = \frac{1}{N}\,\Sigma(x_A - x_B)^2$$

where x_A and x_B are the values for twins A and B, and N is the number of pairs.

Table 1. No. of Variables with Specified Values for $F = S_{w♀}^2/S_{w♂}^2$

Nature of measures	< 0·10	0 10– 0 19	0 20– 0·49	0·50– 0 99	1·00– 1·99	2·00– 4·99	5 00– 9·99	10·00 or more
P	1	3	3	8	11	16	12	1
C				9	9	5	1	
A					13	28	7	
H			3	1	6	11		
B		1	8	27	28	28	6	
ψ	2	4	16	86	155	67	8	
Total	3	8	30	131	222	150	34	1
	Significant increase in S_w^2 for males			No significant F ratio		Significant increase in S_w^2 for females		
	41 variables			353 variables		185 variables		

Table 1 summarizes the comparison by F test of the within pair variances of 21 female and 23 male pairs of monozygous twins. The ages of the twins varied from 12 to 18 years, with identical mean ages in the two groups (16 years 4 months). Monozygosity was established by means of 8 characteristics (7 blood groups and secretor). Although there were occasional missing values, we will here, for ease of presentation, assume equal degrees of freedom for all variables. The variables are broken down into the following six areas: P for polygraph measures, C for cardiovascular data, A for anthropometric data, H for hæmatological data, B for biochemical data and ψ for psychological data. Examples of the variables analysed are change in heart-rate after loud noise (P). resting systolic blood pressure (C), stature (A), erythrocyte count (H), urinary beta-amino-isobutyric acid (B), and verbal score on Chicago Primary Mental Abilities test (ψ).

From Table 1 it is evident that for the metrical characters studied monozygotic female twins show significantly greater intrapair differences than do monozygotic male twins much more often than the converse. The only evident explanation for the finding is that afforded by the Lyon hypothesis. If the female co-twins were at different phases of their menstrual cycles at the time of study, this might possibly account for increased female intrapair difference in regard to some characters, but could scarcely account for the findings with regard to anthropometric traits.

GERONTOLOGY

Senescence and Senility

NEEDHAM[1] has recently claimed that Minot's paradox[2]: "Senescence is at its maximum in the very young stages and the rate of senescence diminishes with age", is false. Instead of the relationship $\dot{S} = \dot{G}$ (where $\dot{S}$ = rate of senescence, $\dot{G}$ = specific growth-rate) indicated by Minot he advocates the use of the relationship $\dot{S} = k/\dot{G}$ in which, however, $\dot{G}$ refers to growth "in the broadest sense .... perhaps in fact anabolism in toto". It will be argued here that Minot's paradox is derived correctly from the simplest model of a living system; and that Needham's relationship gives only an approximation to the increase in senility in a more complex model. Secondly, it will be suggested that the changes under discussion bear no direct relationship to the rates of anabolism and catabolism at any time, and that changes in senescent systems are not related to changes in specific growth-rates.

Let S be the senility of any living system, presumably a 'function of state' for that system. Then dS/dt will be the senescence-rate, $\dot{S}$, for that system. Similarly, if G is the size, or more accurately the state of development of the system, then dG/dt, or $\dot{G}$ will be the rate of growth or development. The system can pass through a series of theoretically defined states in a continuous manner (that is, at any time the system comprises contributions from several states):

$$E_1 \xrightarrow{k_1} E_2 \xrightarrow{k_2} E_3 \xrightarrow{k_3} E_4 \;.\;.\;.\; E_j \xrightarrow{k_j} \;.\;.\;.\; E_n$$

The actual system then equals ΣE_j at all times, and in material terms $\Sigma E_j(t = t_1) = E_1(t = t_0) = E_0$. As this is constant, at all times $\Sigma\Delta E_j = 0$, that is, the sum of all changes decreasing given E states must be equal to the sum of all changes increasing other E states. If, therefore, the initial rate of change, $(\mathrm{d}E_1/\mathrm{d}t)_{t_0}$ ($= k_1E_0$ if first-order kinetics are assumed), is the maximal one, then it will also be the maximal rate of transition of the whole system (ΣE_j at all times) to its final state (E_n). These two rates, however, only correspond necessarily to the rates of growth and senescence in the simplest model, where $n = 2$. In this case, the rate of growth (disappearance of E_1) equals the rate of senescence (appearance of E_2), and for the first order case (exponential decay of E_1) the rate of senescence is greatest when $E_1 = E_0$.

If $n > 2$, intermediate states exist, and it then becomes necessary to define the state (or set of states) constituting maturity (E_m), and the state (or set of states) constituting senility. It is reasonable to assume that the former precede the latter, and that the most senile states are the terminal ones. The growth, or development rate, can then be considered the sum of all processes leading to E_m, and the senescence rate the sum of all processes leading away from E_m. Under simple conditions, given here, the absolute rate of growth will have a maximum value $\dot{G}_{\max}$ at a time t_g and the absolute rate of senescence a maximum value $\dot{S}_{\max}$ at a time t_s, where t_s is later than t_m (the time when E_m is maximal) and t_m is later than t_g. The differential rates of growth and senescence are given by: $\dot{G}_{\text{net.}} = \dot{G}-\dot{S}$ and $\dot{S}_{\text{net.}} = \dot{S}-\dot{G}$. Before E_m is maximal (t_m), $\dot{G}_{\text{net.}}$ is positive and $\dot{S}_{\text{net.}}$ is negative; after t_m, $\dot{G}_{\text{net.}}$ is negative and $\dot{S}_{\text{net.}}$ is positive. But always: $\dot{G}_{\text{net.}} = -\dot{S}_{\text{net.}}$. This relationship is quite different from that which gives $\dot{G} = \dot{S}$ for the system where $n = 2$ (in that case, $\dot{G}_{\text{net.}} = \dot{S}_{\text{net.}} = 0$).

The empirical relationships given by Needham[1] can be summarized as follows. If the growth-rate equals x, then according to Needham, Minot's postulate predicts that 'senescence' $= k-x$, while it is more reasonable to think that 'senescence' $= k/x$. Here 'k' corresponds to k_1E_0 above and 'x' to $\dot{G}$ above. For the system where $n = 2$, '$k-x$' is, however, proportional to the amount of senile state E_2 and not to the rate of its attainment (senescence). For systems where $n > 2$, 'k/x' can likewise sometimes be an approximation to the amount of a later state than E_2 that is present (cf. the relationship $(E_3)_t \propto t^2$ for the analogous chemical system where $n = 3$ and t is small[3]). In a system involving a sequence of first order changes, the rate of change in the system after E_2 may be proportional to the amount of E_3 or of a subsequent state. But there is no reason to believe that the value of $\dot{S}$ or $\dot{S}_{\text{net.}}$ is ever of this particular reciprocal form, while the actual relation expressed by Minot of the form $\dot{S} = \dot{G}$ is at least accurate for $\dot{S}$ in the simplest system.

If it is assumed that, at each stage, each contributing state maintains itself partly stable against induced change, we have at each point the condition:

$$\begin{tikzcd} {} \arrow[r] & E_j{}^1 \arrow[r, "k^1{}_j"] \arrow[d, shift left, "K_j"] & {} \\ & E_j{}^s \arrow[u, shift left] & \end{tikzcd}$$

($k^1{}_j$ = rate of change of $E_j{}^1$
K_j = equilibrium between $E_j{}^1$ and $E_j{}^s$)

where $E_j{}^1$ is the labile form and E_j^s the form stabilized by some anabolic processes, then the rates of change k_jE_j can be written $\left(\dfrac{k^1{}_j}{K_j + 1}\right)E_j$. That is, the rate of transition will be determined at each stage not only by the growth-determining and senescence-determining rate constants ($k^1{}_j$) but also by the active equilibrium K_j, determined by metabolic processes and environmental influence. As indicated by Needham, even the states composing senile systems are capable of anabolism maintaining large positive K_j values. This anabolism cannot itself be a measure of growth- or senescence-rates, which are determined by the transitions between the several E states. If the values of $k^1{}_j$ and K_j are independent of the amounts of various E states at any time (that is, the k_j values are time invariant) then the relation given here 't_s is later than t_m which is later than t_g' is probably true. The kinetics of such a system have been described for the corresponding chemical reactions[4]. If the k_j values are highly dependent on the E states, then the values of $\dot{G}$ and $\dot{S}$ will vary in a complex manner to which no simple generalizations can apply.

In particular, the fact that the rate of shrinkage in man decreases in extreme old age cannot lead to any conclusions about $\dot{G}$ at that time. The rate of shrinkage is not necessarily equivalent to the differential ageing rate, $\dot{S}_{\text{net.}}$, as defined here. It probably deals with changes in states lying between E_m (the mature state) and E_n (the final senile state) and hence must diminish when the times giving maximal contribution from these intermediate states of senility have passed. Even if it were equivalent to $\dot{S}_{\text{net.}}$, as $\dot{S}_{\text{net.}} = \dot{S}-\dot{G}$, a decrease can be due to either an increase in $\dot{G}$ or a decrease in $\dot{S}$, and cannot definitively be attributed to either. But in this case the latter would seem the more likely effect; there is no mathematical or grammatical need to equate the most senile with the most senescent.

P. Nicholls

Molteno Institute of Biology
and Parasitology.

[2] Minot, C. S., *The Problem of Age, Growth and Death* (John Murray, London, 1908).

[3] Roughton, F. J., *Disc. Farad Soc.*, 17, 116 (1954).

[4] Rakowski, *Z. Physik Chem* , 57, 321 (1907)

The application of formal mathematics to the present problem of senescence is very desirable, and Dr. Nicholls's treatment therefore is a welcome contribution. The main object of my previous communication was to show that the foundation of Minot's quantitative estimate of senescence was very shaky. The alternative proposed by me not only resolves his incongruous paradox, but also is in harmony with a good deal of empirical knowledge concerning senescence, growth and anabolism in general. Its theoretical foundations do need to be tested more fully. however, for it is probably not the only one which would be consistent with the empirical observations.

Nicholls claims to show that Minot's relation is after all more plausible than mine, and while I do not feel that he has established either this or his other main claims, I think that the approach is very valuable. For this reason and also in the hope of clarifying a number of aspects of the problem, it is worth examining his thesis in more detail.

One of its weaknesses is the large number of premises required to develop it, and not all these are well founded in the general theory of growth. A second shortcoming is that it is rarely clear how the really significant conclusions actually emerge from the mathematics. The theory of consecutive reactions has been little applied in this field so that details and documentation which would not be necessary to the physical chemist are indispensable in this context.

It is not evident that he does more in support of his main contention than show Minot's relation to be relevant to the theoretical and biologically trivial case of a development which consists of only a single step, $E_1 \rightarrow E_2$. On the other hand he admits that mine gives a reasonable approximation to more complex situations, and these are the type likely to be found in actual ontogenesis. Moreover, it is difficult to reconcile the main contention with his final conclusion that changes in senescent systems are not related to changes in specific growth-rate at all—since it was the essence of Minot's theory that these changes give a quantitative measure of the senescent process. Another surprising conclusion is that the changes under discussion (presumably senescence and growth) bear no relation to the rates of anabolism and catabolism—for growth is by definition anabolic.

The explanation lies mainly in the fact that although he ostensibly used the growth component of development, symbolized by $\dot{G}$, in practice he used sometimes the differentiation component and sometimes development as a whole. Confusion of growth with development as a whole is shown by such expressions as "growth or developmental rate" and "size, or more accurately the state of development". Development consists of the two components, growth: purely quantitative and differentiation: qualitative. Since Nicholls's sequence $E_1 \rightarrow E_2 \rightarrow$ etc. is characterized by ΣE_j = a constant (or $\Sigma \Delta E_j = 0$) it excludes any auxesis, and defines purely qualitative changes. Auxetic changes are the only ones relevant to pure growth, on the other hand.

That his $\dot{G}$ does represent differentiation-rate is shown also by the need he eventually feels to define state(s) of maturity, rather than of maximal size, although he still visualizes $\dot{G}_{\max.}$ as the maximal rate of growth rather than of differentiation. It is no doubt useful to obtain a relation between senescence and differentiation, but this is not what Minot did; he related it to growth—if only because measurements of growth were the only quantitative data available. This led to his conclusion that the rate of senescence was maximal at the outset; but Nicholls is led to postulate a maximal rate later than the stage of maturity, a decision much more in accord with the evidence in my previous communication.

He implies that in this I related the specific growth-rate to the rate of senescence rather than to its cumulative effect, the state of senility, but this is not so, although no doubt the phrase "state of senescence" is more open to misunderstanding than "state of senility". I followed Minot in relating S to $\dot{G}$ and not $\dot{S}$ to $\dot{G}$, and it is interesting that this form is also the one indicated by Nicholls's treatment. Misunderstanding appears to have originated in Nicholls's own initial formulation as $\dot{S} = \dot{G}$ rather than $S = \dot{G}$ (or more precisely $S = k - \dot{G}$). He also defined $\dot{G}$ initially as the specific growth-rate (rate per unit of mass) but later G is defined as size so that $\dot{G}$ (dG/dt) is the absolute or gross growth-rate. There are other minor points which increase the difficulty in following his treatment; one is that while E_1, E_2, etc., are amounts of material in the successive states of development, E_0 is not the first member of this sequence but the initial concentration of material in state E_1.

He expresses the differential rate of $\dot{G}$ and $\dot{S}$ as the difference $\dot{G} - \dot{S}$, rather than as the ratio $\dot{G}/\dot{S}$ which is more usual in growth studies. The rationale for this lies in the essentially multiplicative nature of growth. This was one of my main reasons for advocating the relation $S = k/x$ rather than the linear form $S + x = k$ (S = degree of senility and x = specific growth-rate). If we may follow Nicholls in supposing a very close affinity between senescence and differentiation, then there is perhaps some further evidence in favour of the first relation from such cases as the behaviour of iris cells *in vitro*. Here the degree of differentiation is measured by the concentration of melanin granules, and in a general way this is inversely related (that is, by dilution) to the growth- and proliferation-rates of the cells. Nevertheless the relation undoubtedly needs a more rigid mathematical derivation.

Irrespective of the contribution of Nicholls's approach to the solution of the present problem it is a potentially valuable approach. Even if it only provided a quantitative relation between differentiation and time, it would fulfil a long-standing hope of morphogeneticists. There seems no formal reason, however, why it should not be extended to include also the growth component. The theory of consecutive reactions naturally was first applied to the more simple case of closed systems, with an expendable amount of initial raw material, E_1, but in order to grow, and indeed even to maintain its bulk, an organism is necessarily an open system, with a continuous inflow of raw material, from yolk-depots or other food. It will be evident that under these conditions the first step, $E_1 \rightarrow E_2$, of the sequence no longer has the unique attribute of an exponential progress curve. It is also worth considering the further possibility that raw materials feed in at various points of the sequence. This could be done by substituting open tributaries for the stabilizing backwaters, $E_j S$.

The theory should be applied with due caution. Benson[1] emphasizes that at present even inanimate systems when investigated in detail appear to "display an anarchistic tendency to become unique laws unto themselves". There may be a further danger in attempting to compare a sequence of ontogenetic processes directly with a sequence of chemical reactions; as indicated above the early exponential fall in specific growth-rate does not have its basis in an initial, first order, chemical reaction. The danger is not only of confusing processes of two very different degrees of complexity but also of confusing two very different time scales, the slow ontogenetic and the rapid metabolic[2]. The body fabric which, in quantity and quality, changes slowly along the axis of ontogenesis is at each point the overall steady state maintained by all contemporary systems of (rapid) metabolic reactions. The slow shift of the steady state with time has a more obscure driving force, perhaps hormonal as opposed to enzymatic, and might also require a different mathematical theory from that of reaction sequences.

In conclusion, it seems fair to say that Nicholls's approach does not decide the present issue in favour of Minot's view but that it is a tool of great potential value for the mathematical definition not only of growth and senescence but also of differentiation.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Monday, May 7

University of London (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, Paddington, London, W.2), at 5 p.m.—Prof. Frank Fenner: "Reactivation of Animal Viruses".* (First of four Almroth Wright Lectures.)

University of London (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Dr. I. M. Glynn: "Sodium and Potassium Movements in Living Cells".* (Further lecture on May 14.)

British Society for the Philosophy of Science (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Mr. A. W. Haslett: "Limits of Explanation".

Institution of Electrical Engineers, Electronics and Communications Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. S. Welch: "The Signalling Problems associated with Large-Register-Controlled Automatic Telephone Exchanges".

University of London (in the Physics Lecture Theatre, Queen Mary College, London, E.1), at 5.30 p.m.—Prof. R. Righini (Florence). "The Abundance of Isotopes in the Solar Atmosphere".*

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. A. Winegarten: "Agriculture". (First of three Cantor Lectures on "The Development of Natural Resources".)

Society of Chemical Industry, London Section (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Prof. L. Lacqué (Paris). "The French Chemical Industry".

Women's Engineering Society, London Branch (at "Hope House", 45 Great Peter Street, Westminster, London, S.W.1), at 7 p.m.—Mr. P. F. Mariner. "Microminiaturization".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. John H. Hemming and Mr. Christopher S. Lambert. "The Iriri River Expedition".

Monday, May 7—Tuesday, May 8

Powder Metallurgy Joint Group of the Iron and Steel Institute and the Institute of Metals (at Church House, Great Smith Street, London, S.W.1)—Spring Meeting.

Tuesday, May 8

Zoological Society of London (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Sir Keith Murray. "Major Issues in the Expansion of University Education".

Royal Society of Medicine, Experimental Medicine and Therapeutics Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Annual General Meeting. Dr. P. L. Mollison. "The Reticulo-endothelial System and Red Cell Destruction" (Presidential Address).

University of London (at the Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. Sir Willis Jackson. "The Partnership between Science and Electrical Engineering" (Inaugural Lecture).

Institution of Polish Engineers in Great Britain, Group for Economic, Social and Management Studies (at 55 Princes Gate, Exhibition Road, London, S.W.7), at 7 p.m.—Dr. S. A. Young: "Technical Snobbery and its Damaging Effects".

Tuesday, May 8—Saturday, May 12

Institute of Metal Finishing (at the Hotel Metropole, Brighton)—Metal Finishing Conference.

Tuesday, May 8—Wednesday, May 23

Building Research Station (D.S.I.R.) (at the Building Centre, Store Street, London, W.C.1)—Exhibition—"Research in Building".*

Wednesday, May 9

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. K. R. Dumbell: "Temperature and Infection".*

Imperial College of Science and Technology (in association with the Surface Activity Group of the Society of Chemical Industry, in the Mining Lecture Theatre, Royal School of Mines, Prince Consort Road, London, S.W.7), at 5 p.m.—Prof. F. Sebba: "Ion Flotation" (Lecture and Demonstration).

Institution of Electrical Engineers, Supply Section (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. G. de Zoeten: "Aim and Facilities of KEMA Laboratories".

British Institution of Radio Engineers, Radar Group (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6 p.m.—Mr. A. J. Harrison and Mr. D. Chamberlain: "The Integrated Radar Systems for S.S. *Canberra*".

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. T. Lyddon Gardner: "The Cosmetics Industry".

Society of Environmental Engineers (in the Mechanical Engineering Department, Imperial College of Science and Technology, London, S.W.7), at 6 p.m.—Mr. S. S. Duncan: "The Operation of a Combined Climatic and Random Vibration Test Facility".

Society of Instrument Technology, Control Section (at Manson House, 26 Portland Place, London, W.1), at 6.15 p.m.—Annual General Meeting. 7 p.m.—Mr. A. J. Young and Mr. I. Gray: "Computer Control of Processes".

Thursday, May 10

British Steel Founders' Association (at the Criterion, Piccadilly, London, W.1), at 9.45 a.m.—Technical Conference.

University of London (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. T. A. J. Prankerd: "Glucose-6-phosphate Dehydrogenase Deficiency".*

University of London (at Queen Elizabeth College, Campden Hill Road, London, W.8), at 5.30 p.m.—Prof. W. B. Bonnor: "The Future of Applied Mathematics" (Inaugural Lecture).*

Chemical Society (in the Large Chemistry Lecture Theatre, Imperial College of Science and Technology, London, S.W.7), at 7.30 p.m.—Prof. H. B. Henbest: "Stereoselectivity in the Reactions of Cyclic Compounds" (Tilden Lecture).

Friday, May 11

Institution of Electrical Engineers, Medical Electronics Discussion Group (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Problems associated with (i) Blood Pressure Measurements and (ii) Storage Devices".

Royal Institution (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. G. M. Carstairs: "Psychotic Illness and Artistic Production".

Monday, May 14

University of London (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, Paddington, London, W.2), at 5 p.m.—Dr. J. L. Gowans: "The Role of Lymphocytes in Immunological Reactions".* (Second of four Almrith Wright Lectures.)

British Society for the History of Science (at the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Mr. A. W. Badcock. "Physical Optics at the Royal Society to 1800".

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 6 p.m.—"Adventure in Nepal", Colour films with commentary by Mr. J. B. Tyson.

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 6 p.m.—Mr. J. Macdonald: "Forestry". (Second of three Cantor Lectures on "The Development of Natural Resources".)

Institution of Electrical Engineers, London Graduate and Student Section (at Savoy Place, London, W.C.2), at 6.45 p.m.—Annual General Meeting, followed by Dr. H. G. Taylor: "The Work of the Electrical Research Association"

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer or Assistant Lecturer (preferably with an active research interest in one aspect of experimental botany including microbiology) in Botany—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (May 11).

Lecturer in the Department of Zoology—The Secretary, The University, Edinburgh (May 12).

Lecturer in the Department of Mathematical Physics—The Secretary, The University, Edinburgh (May 14).

Lecturer or Assistant Lecturer in Statistics in the Department of Mathematics—The Registrar, The University, Leeds 2 (May 14).

Lecturer (with qualifications in either pure or applied mathematics) in Mathematics—The Registrar (Room 22, O.R.B.), The University, Reading (May 14).

Research Assistant (with special interests in animal learning) in Psychology—The Registrar and Secretary, The University, 38 North Bailey, Durham (May 14).

Assistants (2) in Mathematics—The Secretary of University Court, The University, Glasgow (May 15).

Assistants (3) in Organic, Inorganic and Physical Chemistry; and a Lecturer in Physical Chemistry—The Secretary, The University, Aberdeen (May 19).

Lecturer and an Assistant Lecturer in Psychology—The Secretary, The Queen's University, Belfast, N. Ireland (May 19).

Baxter Chair of Mathematics in Queen's College, Dundee—The Secretary, The University, College Gate, St. Andrews, Fife (May 21).

Lecturers (2) in the Department of Natural Philosophy—The Secretary, The University, Edinburgh (May 21).

Junior Research Fellow (with a good first degree in zoology) in Locust Physiology in the Department of Zoology, University College of Rhodesia and Nyasaland, for work on water relations of locusts—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (May 22).

Senior Lecturer in Bacteriology; a Lecturer in Pathology (Morbid Anatomy); and a Lecturer in Hæmatology and Blood Transfusion at University College, Ibadan, Nigeria—The Secretary, Senate Committee on Colleges Overseas in Special Relation, Senate House, University of London, London, W.C.1 (May 28).

RESEARCH ASSISTANT (with a science degree) IN THE DEPARTMENT OF BOTANY, for work on glycollate formation during photosynthesis—The Registrar, University College of Wales, Aberystwyth (May 31).

DEMONSTRATOR IN THE DEPARTMENT OF BOTANY—The Registrar, The University, Liverpool (June 2).

UNIVERSITY LECTURER IN THEORETICAL PHYSICS (with emphasis on low or high energy nuclear physics preferred)—The Secretary of the Faculties, University Registry, Oxford (June 5).

LECTURER/SENIOR LECTURER IN APPLIED MATHEMATICS at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House Pall Mall, London, S.W.1 (Australia and London, June 8).

RESEARCH FELLOW (preferably specialized in the fields of agricultural geography or geomorphology) IN GEOGRAPHY at the Institute of Advanced Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 8).

EDWIN CUTHBERT HALL CHAIR OF MIDDLE EASTERN ARCHÆOLOGY in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 15).

ASSISTANT DIRECTOR (with previous experience in a computing laboratory and the qualifications and experience to teach mathematics at Diploma in Technology level) OF THE COMPUTING LABORATORY—The Registrar, Bradford Institute of Technology, Bradford 7

FIELD ASSISTANT or ASSISTANT WARDEN (man or woman, with an honours degree in botany, together with a general interest in other field subjects) at Malham Tarn Field Centre, near Settle, Yorks—The Secretary, Field Studies Council, 9 Devereux Court, Strand, London, W.C.2.

MATHEMATICIANS (with at least an honours degree in mathematics, and preferably previous experience with computers) at the Computation Centre, National Research Council of Canada, for work involving the analysis and programming of problems which arise in the various scientific and engineering divisions of the Council—The Employment Officer, National Research Council, 100 Sussex Drive, Ottawa, Ontario, quoting file E.R.-210.

MEDICAL LABORATORY TECHNICIAN (qualified A.I.M.L.T., science degree or equivalent)—The Administrative Officer, North London Blood Transfusion Centre, Deansbrook Road, Edgware, Middlesex.

PLANT VIROLOGIST (under 45, with an honours degree in botany or agricultural botany, specialized in plant pathology, and preferably a knowledge of population genetics) with the East African Agriculture and Forestry Research Organization, to study either (*a*) virus diseases affecting agricultural crops, or (*b*) the genetics of resistance of plants to disease—The Director of Recruitment, Department of Technical Co-operation, Carlton House Terrace, London, S.W.1, quoting Ref RC.264/348/02/T.

READER IN THE DEPARTMENT OF CHEMISTRY—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

RESEARCH FELLOW IN LOW TEMPERATURE PHYSICS, to study nuclear and electronic interactions in ferromagnetic and antiferromagnetic metals at very low temperatures—The Secretary and Registrar, The University, Southampton.

SENIOR BIOCHEMIST (with previous experience in research, and preferably a higher degree) in the Institute of Dental Research—The Acting Director, United Dental Hospital of Sydney, 2 Chalmers Street, Sydney, N S.W., Australia.

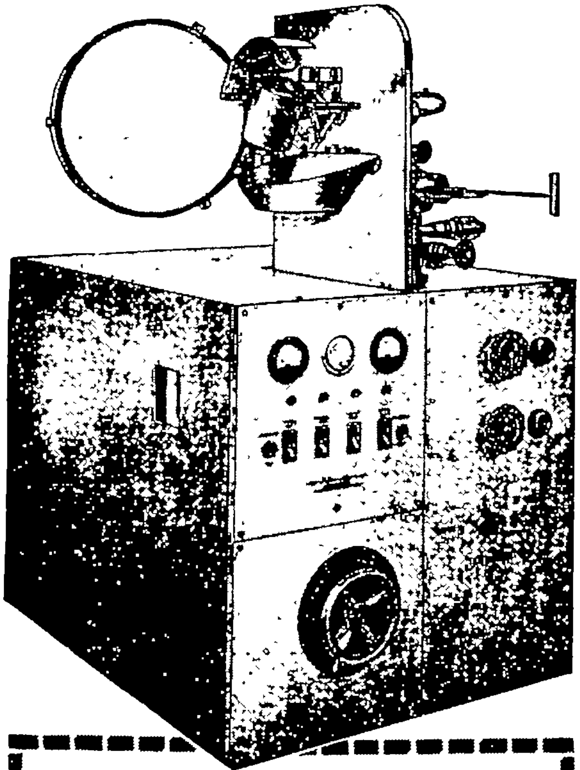
WILD BARFIELD NRC*

Laboratory Vacuum Furnace



Model 2904

2 lb. to 8 lb. capacity

(FOR OPERATION UP TO 2,000°C)

Made in Britain to the designs of the National Research Corporation of Mass., U.S.A. who have built more high vacuum furnaces now in successful operation than any other firm in the world. The Model 2904 Vacuum Furnace is a self-contained unit for high-temperature operation at high vacuum or under controlled atmosphere. It is heated by a tungsten resistance heating element with molybdenum heat shields in a water-cooled stainless steel sleeve.

This permits:

- Close control of temperature
- Good heat distribution
- Long life
- No outgassing or contamination from refractories

FOR MELTING • POURING • SINTERING
ALLOYING • HEAT-TREATING • ANNEALING

Vacuum Arc and Vacuum Induction Furnaces
Vacuum Analysis Equipment • Vacuum Diffusion Pumps

STANDARD EQUIPMENT

- High vacuum pumping system with Wild Barfield-NRC oil diffusion pump and Gas Ballast mechanical pump.
- Metal cabinet base, overall dimensions 35" x 43" x 34" high.
- Pyrex bell jar, 18" diameter x 12" long, protected with a wire mesh guard, or optionally a stainless steel bell jar.
- Water-cooled basin to shield the bell jar and to catch spilled metal.
- Feed-through for thermocouple wires or heater leads for special work.
- 15 kW. power supply, controlled with a variable auto-transformer Power is supplied to the split tungsten sleeve through water-cooled coaxial leads.

* NRC *is the trade-mark of the National Research Corporation, registered in the United States Patent Office.*

APPOINTMENTS VACANT

MARINE BIOLOGICAL ASSOCIATION OF THE UNITED KINGDOM

The Council of the Marine Biological Association invite applications for a post at the Plymouth laboratory to do research on the adsorption of chemical substances on to fine particles in the sea. Candidates should have had experience of chemical and physico-chemical methods, preferably those involving the use of radioactive materials, and should be capable of relating the work to biological problems. Candidates should have had at least two or three years research experience and the appointment will be in the equivalent grades of Scientific Officer or Senior Scientific Officer of the Civil Service according to age and experience The appointment will be for two years, renewable annually, in the first instance

Forms of application may be obtained from the Secretary of the Marine Biological Association, The Laboratory, Citadel Hill, Plymouth, and should be returned to him in quadruplicate not later than May 31, 1962.

SCHOOL OF TROPICAL MEDICINE

(UNIVERSITY OF LIVERPOOL)

Research Assistant with a degree in biochemistry or physiology required to work on various aspects of tissue metabolism in relation to parasitic diseases. Suitable study for higher degree. Salary according to age and qualifications.

Please apply to the Dean, Liverpool School of Tropical Medicine, Pembroke Place, Liverpool, 3.

CENTRAL ELECTRICITY GENERATING BOARD

SOUTH-EASTERN REGION
NORTH THAMES DIVISION

MATHEMATICAL ASSISTANT AT BRADWELL GENERATING STATION

A vacancy exists for a young mathematics graduate at this Nuclear Power Station. The work will be varied in nature, involving analysis and calculations based on physical measurements made on the nuclear reactors, in order to ensure their safe and efficient operation. Opportunities to write programmes for a large modern computer (I.B.M. 709) will arise, and a period of training for this type of work will be provided.

The salary for this position will be in accordance with N.J.C., Grade 2, £700 to £775, depending on age and qualifications.

Applications, giving details of age, education, qualifications or experience, should be sent to the Assistant Regional Personnel Officer, Central Electricity Generating Board, North Thames Division, West Farm Place, Chalk Lane, Cockfosters, Barnet, Herts, to arrive not later than May 12, 1962

F. W. SKELCHER,
Assistant Regional Director.

MANAGER, AGE ABOUT 35 YEARS, REquired for Factory, South Coast (staff 100). Must be good organizer and have light engineering background Specialized knowledge optical instrument and lens production desirable but not essential —Write, full details experience, qualifications, etc, to Box No. 622, T. G. Scott and Son, Ltd., 1 Clement's Inn, London, W.C.2.

AUSTRALIA

COMMONWEALTH SCIENTIFIC AND INDUSTRIAL RESEARCH ORGANIZATION

DIVISION OF APPLIED PHYSICS

PHYSICISTS OR ENGINEERS

Applications are invited from physicists or engineers to the professional staff of the Organization's Division of Applied Physics, located in the grounds of the University of Sydney, New South Wales

The Division of Applied Physics is one of the two Divisions comprising the National Standards Laboratory and is responsible for the establishment and maintenance of standards of mechanical and electrical measurements in Australia.

The research activities of the Division generally are concerned with the application and refinement of modern developments in physics in order to achieve better standards of physical measurement The current programme of applied and fundamental research includes optical interferometry and the development of wavelength standards, the development of the cross-capacitor as a basic electrical standard, the absolute determination of g at Sydney, microwave physics and the dielectric properties of solids. It is planned to undertake the determination of other physical constants and to start work on masers and lasers.

APPOINTMENT NO.: 750/247

Several research workers are needed to take part in the above programme and there will be ample opportunity for them to develop their own research interests Those interested may obtain further details of the individual projects and the facilities available by writing directly to the Division.

The minimum qualifications required are at least a University Honours degree in Science or Engineering with Physics as a major subject together with several years' postgraduate research experience

By mutual arrangement, the appointments for the posts may be either for an indefinite period or for a fixed term of three years

Salary: Dependent on qualifications and experience within the ranges:

£A 1,541 to £A 2,296 per annum or £A 2,426 to £A 2,751 per annum.

APPOINTMENT NO.: 750/248

Applications and enquiries are also invited from graduates or diplomates in Science or Engineering or those holding equivalent qualifications who would be interested in assisting in the research programmes outlined above.

Applicants should possess a University degree in Science or Engineering with Physics as major subject or hold equivalent qualifications

Salary: Dependent on qualifications and experience within the ranges·

£A.1,101 to £A.1,651 per annum or £A.1,651 to £A 1,981 per annum but would not be less than £A.1,321 per annum.

Salary for women will be £A 188 per annum less than corresponding rates for men.

Promotion within C.S.I.R.O. is by merit and may ultimately go beyond the upper limit of the scale within which the original appointment is made.

Fares paid for the appointee and his dependent family and for fixed term appointments return fares will also be paid. Further particulars may be obtained on applications to:

Mr. P. F. Butler, Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London W.C.2,

to whom applications (quoting relevant appointment number) should be addressed by June 23, 1962

COUNTY BOROUGH OF STOCKPORT

STOCKPORT COLLEGE FOR FURTHER EDUCATION

Lecturer in Chemistry required in Science Department. Candidate must hold an honours degree of a British University Industrial and/or teaching experience is desirable. Duties to commence on September 1, 1962. Burnham Technical Salary Scale for Lecturers. Agreed Conditions of Tenure.

Further particulars and application forms from the Principal, Stockport College for Further Education, Wellington Road South, Stockport, to be returned by May 12, 1962

ROYAL COLLEGE OF SCIENCE AND TECHNOLOGY

GLASGOW

DEPARTMENT OF NATURAL PHILOSOPHY

Applications are invited for the post of Senior Lecturer on the salary scale £1,975 by £75 to £2,275. Applicants should be physicists with a Ph D degree who have extensive experimental experience in electronics and are interested in plasma physics

Application forms, to be lodged by May 31, 1962, may be obtained from the Secretary, George Street, Glasgow, C 1

INSTITUTE OF DENTAL RESEARCH

UNITED DENTAL HOSPITAL OF SYDNEY. AUSTRALIA

SENIOR BIOCHEMIST

Applications will be received until June 15, 1962, for the position of Senior Biochemist in the Institute of Dental Research. Previous experience in research is essential and a higher degree is desirable. Salary at a weekly equivalent of £A.2,457 to £A 2,782 per annum

Further information and details of travel expenses may be obtained from the Acting Director.

C. C. BOWIE,
Secretary

United Dental Hospital of Sydney,
2 Chalmers Street,
Sydney, Australia

VACANCY FOR MINERALOGIST-PETROgrapher with sound training in principles of geochemistry Opportunities for research available Applicants should have a Ph D. or equivalent Probationary lectureship for two years leading to permanent appointment. Appointment to be effective September 1, 1962. Deadline for applications, July 1, 1962.—Apply to J. W Ambrose, Department of Geological Science, Queen's University, Kingston, Ontario, Canada.

EDUCATION AND TRAINING FOR MANAGEMENT

In a valuable memorandum* submitted to the Robbins Committee on Higher Education, the Association of Teachers of Management has clarified much of the confused thinking which abounds in circles where management training is discussed.

The Association makes it clear that, before the role of higher educational institutions in management education can be considered, education and training for management must be defined. This analysis involves, first, the question of the type of institution which is appropriate and the resources which it should command. Secondly, there is the type of course, the level and nature of any awards, and the student groups at which such courses are directed. The part to be played by such activities must also be set against the total provision of education and training which can be expected in this field.

In a clear analysis of the nature of education and training for management, four main divisions are distinguished: (1) education about business organization and management; (2) education for management; (3) training in management skills; (4) training in procedures and procedural skills. There is a considerable overlap between these four divisions, and a fully comprehensive scheme for education and training must embrace all four.

Education about business organization and management is defined as the processes by which men transform scientific and technical knowledge and raw materials into wealth through organization and management. This is only partially achieved by present teaching in the relevant disciplines of economics, psychology and sociology and through descriptive treatments of commerce and engineering. "Some knowledge of these complex processes is appropriate for any educated person who may enter commerce, industry or administration and no man can be said to be properly educated without some such knowledge".

The Association defines education for management as the process of developing in a man the capacity to think out problems of management in a disciplined way. This presupposes both knowledge about management and procedures and procedural skills. At present the volume of knowledge available does not constitute an academic discipline in its own right, and for many academic people this is the main obstacle to the creation of suitable courses in management. Management is an area of interaction of a number of disciplines, economics, politics, psychology and sociology, of much that is derived from engineering practice, and of a growing body of knowledge not attributable to any of these. Even if and when a body of knowledge tantamount to a new discipline emerges, the distinction between 'education about' and 'education for' management will remain.

Considerable support would be given to the Association's views on education about and education for management. They will not escape criticism, however, for the way in which they have ignored the manager's overriding responsibility for controlling people, for getting results through them, and the need to educate himself to do this. This, in turn, should have direct bearing on the subjects studied at higher educational institutions and, even more important, the way in which they are taught. The influence of a discerning tutor may be of more importance in the education of a manager than the subjects studied.

By training in management skills the Association includes the ability to analyse situations, to use and co-ordinate procedures, and to make decisions. These skills are distinct from purely procedural skills such as work study, production planning or distribution. Higher educational institutions should be concerned with education for and about management and with training in management skills, procedures and procedural skills only in so far as such training contributes to such education.

The choice of institutions to engage in any higher education for or about management should, in the Association's view, be governed by three basic conditions. It must engage in research; the development of this field of study calls for substantially more research than is being undertaken at present. In addition, the practising manager ought to be confronted with those carrying out research at frontiers of their disciplines but who are doing so on problems of organization, administration and management. So far as possible, both students and practising managers should be involved in the research process.

The second basic requirement must be close contact with commerce, industry and public administration on the part of the staff and of the institution as a whole. Such contact is to be encouraged provided that full academic freedom is safeguarded.

Many people in industry and commerce would agree with this worthy sentiment and would have to admit that, so far, their doors have been almost completely closed to full-time university students who wish to examine their policies and practices too closely. As industry gets more experience of dealing with research students, more and more facilities should be made available.

How the process could be considerably accelerated is bound up with the Association's third basic condition about the necessity for teaching staffs to be recruited from the relevant disciplines and from relevant processional training. Such staff should be attached to departments of management studies. In the future such teaching staff ought to be recruited from three main sources: (1) the universities, for example, psychologists and economists; (2) graduates from universities and other higher institutions after research in industry and commerce; (3) graduates and others who have taken an advanced course in management, at postgraduate-level, whether at a university or other institution.

---

* *Education and Training for Management.* (Secretary, A. E. Thomas, Scottish College of Commerce, Glasgow.)

Here, surely, is the rub which indicates why existing departments of management studies carry little real weight in industry*. Unless these departments can recruit members of staff who have had actual experience of managerial conditions in industry for some time, they will continue to be regarded as academic institutions run by men of little managerial experience with untested theoretical contributions to make to industry and commerce. Salary differences, of course, make recruitment of practising managers difficult. With the increasing tendency of higher educational institutions to encourage consultancy, however, many existing managers, and especially management consultants, would accept teaching posts and could use their previous knowledge and experience to open industrial and commercial doors to research students. Equally important, they could continue to carry out part-time assignments in industry and commerce and so ensure that their teaching is constantly revitalized with examples taken from managment in practice. The Association's lament that they have little opportunity and less encouragement to undertake research and the somewhat churlish attitude to part-time consultancy may stem from the distressing fact that, at present, even in colleges of advanced technology, many teachers of management subjects have been largely drawn from comparatively minor departments of commerce and industrial administration in technical colleges where the contribution to management theory or management practice has not shown particularly distinctive features. The development of education and training for management is unlikely to make rapid progress until some kind of sandwich device which has been so successful in training doctors is used to bring about greater union between higher educational institutions and industry and commerce. The appointment of a vigorous and successful managing director to become the first Research Fellow in management studies at Balliol College, Oxford, should have considerable influence on the direction of management education in Britain.

THE RESPONSIBILITY OF SCIENCE TO SOCIETY

Science in the Cause of Man

By Gerard Piel. Pp. ix + 298. (New York: Alfred A. Knopf, 1961.) 5 dollars.

DR. PIEL is a comparatively young American thinker and writer who is publisher and editor of the *Scientific American*. In this book he has gathered together a number of papers and addresses delivered in the past ten years. This shows that Dr. Piel is thinking about the same problem as C. P. Snow, of the gap between scientists and the humanities, and on the need of communication to the general public of informed scientific reflexion. This is an extremely difficult task, and Dr. Piel's book is to be welcomed as a contribution towards solving the problem of which is he well aware. The essays discuss questions such as the history of science, the role of technology, education, disarmament, censorship, population problems, and the necessity of moral responsibility in scientists. Throughout the book there runs a note of urgency, well summed up in a comment by Lord Boyd-Orr: "Dr. Piel gives a lucid account of the forces which have put human society on a knife-edge balance between total destruction in a forty-eight-hour war and a wonderful new era of almost inconceivable wealth".

For Dr. Piel the great aim of science is to understand not only the external world but also man himself. He writes: "It is the great destiny of science not to ease man's labours or prolong his life, noble as these aims may be, nor to serve the ends of power, but to enable man to walk upright without fear in a world which he at length will understand and which is his home" (p. 111). There is a flavour of the old eighteenth-century hope in words of Dr. Piel where he admits that men have lost the old absolutes in which they once found purpose in their lives. "Science has brought forward no adequate substitute for the system of values that it has destroyed. But the demands of the human spirit cannot be denied . . . each man must have conviction in his own worth as an individual and purpose that fulfils the personal miracle of his existence." But this can only be grounded in man himself. He writes elsewhere: "There is general recognition of the idea that the cosmos is a vast impersonal system ordered by laws of mechanics" (p. 68). Dr. Piel does not realize how difficult it is to reconcile the two demands. The ruthless break between the impersonal system and the human person so easily leads to the treatment of persons impersonally. If laws of mechanics govern the cosmos they all too easily govern men, and all depends then on who possesses the power to govern. Dr. Piel has a high doctrine of man, but this impersonal system has thrown up this strange creature man and maybe is not entirely unresponsible for him. If man has no grounding for the best that is in him in any reality greater than himself, he will find all too unhappily that he has little worth in himself, and the purpose he sets before himself may well lead to a conflict with purposes other men set before themselves and destruction come on him. The appeal to rationality is not strong enough to overcome the despair of man in a system which is fundamentally impersonal and mechanistic.

But there is so much in Dr. Piel's book with which all men of good will must agree. On education he writes: "Without a grounding in science, man is cheated of full participation in the life of his century". He wants scientists and technologists to become more responsible. "They have an inescapable and direct moral responsibility for the practical uses to which their work will be put." But how to work this out he scarcely tells us. He realizes the problem of security; the danger that science will be put to uses for defence, and the use of weapons against which the conscience revolts; the danger of Government pressures, the weakening of academic freedom. But what is the poor scientist to do? He cannot dig: to beg he is ashamed; and Dr. Piel throws out the challenge but seems too little aware of what this involves, short of a general strike of scientists and technicians against all work which might be useful in war.

American writing is often turgid and heavy. Dr. Piel, however, has a lucid style and is not without wit. He is on the side of the angels, even though he rejects their reality. His book throws much light on the American scene, political and educational. His sympathy is broad, and his picture of science as both beautiful and illuminating has its attraction. His book represents the best in American scientific humanism, and opens up problems of the modern age which must engage the attention of all responsible men.

MARCUS KNIGHT

THE NATURE OF TIME

The Natural Philosophy of Time

By Dr. G. J. Whitrow. Pp. xi+324. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1961.) 42*s*. net.

TIME is probably the most fundamental observable in science, and it is curious that the idea of time is so much taken for granted. We learn how to measure it with remarkable accuracy without concerning ourselves with what it is we are measuring, and very few undergraduate courses in, for example, applied mathematics or physics, deal honestly with questions involving the nature of time. Relativity theory touches them, but even there it is assumed that every observer has a built-in clock about which he does not need to ask questions—one result of which is the now famous clock paradox.

The late E. A. Milne was probably the most eminent theoretical physicist who refused to take time for granted but asked—and to some extent answered—fundamental questions about the role of time in modern science, and since Dr. Whitrow was a student and collaborator of Milne's it is not surprising that it is from him we receive this long overdue account of the subject. Nor is it surprising that the author has devoted more than half the book to the various mathematical problems that arise in the study of primitive clocks and time-scales and the position of time in relativity theory, because it is to this part of the subject that he has made his own major contributions. Nevertheless, two very substantial chapters, of a non-mathematical nature, are given to the ideas and observations contributed by philosophy, psychology and biology to the subject, and in view of the large amount of material collected here it is to the author's credit that he has been able to present it in such an interesting way. A critical account, with adequate references, is given of the various philosophical theories and comments on the nature of time, and the more recent contributions of experimental psychology and biology are described clearly and fitted into an unfolding pattern. Even if the mathematical parts are ignored, the book is well worth reading for these chapters alone.

The remaining four chapters are concerned with the logical and mathematical aspects of the subject, starting in Chapter 3 with a study of the postulates of temporal instants, order and measurement, and going on in Chapters 4 and 5 to the study of time in the mathematical framework of relativity and cosmology. In Chapter 4 there is described a system of eleven axioms following formal definitions of the time and distance assigned by an observer to a distant event. The consequences of these are worked out without undue mathematical complication—needing in fact little more than the idea of a continuous function—and the resulting structure is compared with that of Einstein's special theory of relativity and also with that given axiomatically by A. A. Robb. In Chapter 5 there are an account and some discussion of the position of the time parameter in various standard space-times of general relativity and cosmology, and in Chapter 6 there is a brief discussion of the nature of time in modern physics, dealing particularly with asymmetry, the causal and statistical theories, the Minkowski diagram and, finally, precognition. In this second part of the book there is much to interest mathematicians and physicists as well as philosophers, and the whole book should undoubtedly be read by every scientist and natural philosopher. The printing and production are excellent.

A. G. WALKER

HIGH-ENERGY NUCLEAR PHYSICS

Kinematics of Nuclear Reactions

By A. M. Baldin, V. I. Goldanskii, and I. L. Rozental'. Translated by Ronald Peierls. Pp. xii+223+57 tables. (London: Oxford University Press, 1961.) 38*s*. net.

AT the heart of every experiment in high-energy nuclear physics, involving the collision of particles, lie two basic topics, one being the kinematics of the reaction and the other the theoretical interpretation of the reaction. This book, intended by the authors to be, primarily, for experimental physicists, deals with these two subjects. The first half is concerned with the classical theory of relativistic kinematics and contains the derivation of the mathematical equations required to solve two-body, and, under certain limiting conditions, multi-body kinematics.

This includes such topics as the Lorentz transformation, four-vectors, the Jacobian and other kinematical transformations necessary in going from the laboratory system of co-ordinates into the centre-of-mass system of the two colliding bodies. Decay kinematics of particles which decay into two others are also treated in detail. Appendix 1 contains graphical illustrations of the results of computations based on the formulæ derived in the first part, and a fair selection of the two-body reactions has been made. One might have included some graphs of decay kinematics, but, obviously, it is not practicable to cover all possibilities and still retain a book of reasonable size.

The second part is concerned with the quantum mechanical aspects of the interactions between particles and requires an introductory course in quantum mechanics for full appreciation and understanding. A discussion on the properties of the scattering (S)-matric and its applications is lucid, and topics like diffraction scattering, the optical theorem and the principle of detailed balance are dealt with in a straightforward manner. The chapter dealing with collisions of particles with spin becomes more mathematical in treatment and introduces vector coupling (Clebsch–Gordon) coefficients and the W, X and Z (Racah) coefficients. Other subjects discussed include the phenomenon of polarization and photo-reactions, such as photo-meson production and nucleon Compton scattering. In the second appendix to this part there are some 57 tables of varying complexity giving values of W, X, Z, and Clebsch–Gordon coefficients, and the work involved in the preparation of these must have been considerable.

The authors state that the first half of the book was written by two of them and the second half by the third. The result of the *troika* has been, in effect, to produce two separate books within the same cover, and an opportunity has been missed, one feels, to bridge the gap which tends to arise between theory and experiment as subjects become more and more specialized. As an experimentalist, I felt the need in the second part for more links between theory and experiment to see the full significance of the theoretical development, without having to go to other sources for this information.

One can commend the book as a reference of importance to students of the physics of high-energy particles. They may well wish to derive the equations in Part I for themselves, and it is good to have the answers set down methodically. As regards calculations of kinematics, however, electronic computers now eliminate much of the tedium of calculations, and publications like the *Oxford Kinematical Tables* (H.M.S.O.) go a long way to solving some of the two-body problems. The latter half of the book will be read more easily by physicists who have a good grounding in those topics going collectively under the name "theoretical option". The translator has been successful in turning the Russian text into freely flowing English, and the quality of reproduction is excellent. W. GALBRAITH

THE POWER OF PHYSICS

Physics and Politics

By Prof. Max Born. Pp. vii+86. (Edinburgh and London: Oliver and Boyd, Ltd., 1962.) 12*s*. 6*d*.

THE four articles that comprise this volume are, as Dr. Kathleen Lonsdale admits in her foreword, not easy reading. They demand of the reader a concentrated attention and an understanding of physical science far exceeding that required by Bagehot's earlier classic under the same title. The first of these articles, "Modern Physics: a Veteran's View", was written for the volume. The other three are lectures given during 1958–60, the last giving its title to the book, while the other two discuss the concept of reality in physics and the limits to our image of the universe. Nevertheless, though even a Nobel Prize-winner can scarcely give to so slender a book the status of Bagehot's classic, and its appeal is probably more restricted, the two books have more in common than at first appears.

Essentially, Born's book is an exposition in the context of to-day of Bagehot's main thesis of the function of discussion in the evolution—or dissolution—of society. Even in 1876, Bagehot could write: "The issues of life are plain no longer. To act rightly in modern society requires a great deal of previous study, a great deal of assimilated information, a great deal of sharpened imagination", and Born's book demonstrates the truth of this comment to-day, independently of whether his main argument is accepted or not. In brief, all four articles elaborate the view that the advent of nuclear weapons has made warfare inconsistent with survival: the choice lies between the resolution of differences by discussion and the collapse or obliteration of civilization.

On the broad impact of physical science on politics, or the practical relations between the scientist and Government he has little or nothing to say, and although he provides one encouraging example of discussion and *rapprochement* of views between scientists of differing political views, once he leaves the strict field of science itself and its image of the universe, he seldom approaches Bagehot in penetration. Less satisfying than, for example, the late Prof. A. H. Compton's *Atomic Quest*, the book is moving in its sincerity and the deep, almost passionate, concern of the scientist for the consequences of advances in nuclear physics and the intense desire through discussion and interpretation to bring home to the world of politics, to society as a whole, the implications of the situation and the necessity for reconciliation and disarmament. R. BRIGHTMAN

A PRACTICAL ACCOUNT OF REACTOR THEORY

Thermal Reactor Theory

By A. D. Galanin. Second revised and authorized edition. Translated from the Russian by J. B. Sykes. (International Series of Monographs on Nuclear Energy. Division X: Reactor Design Physics, Vol. 3.) Pp. xiv+412. (London and New York: Pergamon Press, 1960.) 100*s*. net.

THIS book compares favourably with the standard Western texts on reactor theory being, in general, more comprehensive and more frankly technological. This is appropriate, since reactor science has ceased to be a purely logical exercise and is now a technological discipline.

The book begins with a description of the slowing down and diffusion of neutrons. The customary disquisition on nuclear theory is very properly omitted, though there is a useful compilation of nuclear data in the appendixes. This section and the five which follow it (on one- and two-group theories of homogeneous reactors, on heterogeneous effects, on critical sizes, and on perturbation theory) are fairly conventional, though the treatment of resonance absorption is different from the standard Western approach. This is followed by an extensive discussion of burn-up (the time variation of isotopic composition), problems of control and stability, transport effects, thermal spectrum and the treatment of heterogeneous effects which is associated with the names of Feinberg and Galanin: much of this material is not to be found in other books. All in all, this book is perhaps more useful to those who are studying thermal reactor theory for the first time than anything else which is now available.

However, this is not the book for which practical reactor physicists are waiting. Some of its theoretical treatment is rather out of date, and it makes no mention of the vital role of the digital computer in modern reactor calculations, though there is a short section on the numerical calculation of critical size. (In fairness to Galanin, it should be said that, although the book is dated 1960, the manuscript was finished in 1957: he would no doubt write a very different book to-day). On the theoretical side, neither collision probability techniques nor finite difference methods of solving the transport equation (such as that of Carlson) are mentioned. The discussion of thermal spectrum is limited to a perturbation solution of the Wilkins and Wigner–Wilkins equations, and to a rather unrealistic calculation of mean neutron energy. The only application of this work is to the thermalization correction to the migration area.

It seems unlikely that a single book meeting all these needs will now be written, and a series of monographs is perhaps a better solution. An excellent start has been made by Dresner[1] with a text on resonance escape. There is an urgent need for further works of the same quality on subjects such as thermal spectrum, numerical techniques and methods of solving the transport equation.

The translation of Galanin's book by J. B. Sykes is impeccable and the production is adequate. The price seems very high.

D. C. Leslie

MARKOV PROCESSES AND THEIR APPLICATIONS

Elements of the Theory of Markov Processes and Their Applications

By Prof. A. T. Bharucha-Reid. (McGraw-Hill Series in Probability and Statistics.) Pp. xi + 468. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Company, Ltd., 1960.) 89*s*.

It can be said straight away that this is a most interesting work, of considerable value to those concerned with either the theory or the applications of stochastic processes.

The first third of the book covers the general theory of Markov processes. Branching and diffusion processes are treated in particular detail. Although the treatment is straightforward, and does not bring in measure–theoretic concepts, the description 'elements' errs on the side of modesty. The presentation is exact, and a number of advanced and novel topics are included. For example, there is the material on limit theorems for branching processes, which has hitherto lain rather inaccessibly in the Russian journal literature. Another welcome section is the elementary treatment of the Kolmogorov differential equations on p. 64 *et seq.*

The remaining part consists of a truly encyclopædic study of applications: biology (populations, epidemics, genetics), physics (cascades, counters, fission detectors, reactors), astronomy (brightness fluctuations, galaxy distribution, radiative transfer), chemistry (reaction kinetics), queues, telephone traffic, and machine servicing. There are more than 600 references in all.

The author has rendered a real service by combing the literature, particularly the journals, in so many disciplines and languages, and by presenting the results clearly, capably and concisely. One is also impressed by the international balance achieved: the work gives a faithful account of activity in America and in both Western and Eastern Europe.

The theoretical section of the book is fairly definitive and well rounded. This is understandably much less true of the applied section, which is virtually a report on what has been done in the various fields, rather than a digested and unified account. So, results are presented in detail, but rather baldly and indiscriminately. I, for one, would not criticize the author for this: had he done otherwise the book would never have been written. Indeed, I would be more prone to criticize him when he occasionally weakens to the encyclopædist's temptation and writes as though a subject were in a tolerably complete state when this is scarcely the case. For example, the accounts of ecological competition and of reaction kinetics tend to give a more satisfactory picture than is justified. By its nature the book is concerned with frontier subjects, the development of which is often ragged, and just herein lies a principal value of the work.

Mr. Bharucha-Reid has succeeded in an ambitious task. I warmly recommend his book to anyone, student or research worker, at all interested in random processes.

P. Whittle

NEW EMPHASIS IN THE STUDY OF FORAMINIFERA

Ecology and Distribution of Recent Foraminifera

By Prof. Fred B. Phleger. Pp. viii + 297. (Baltimore, Md.: The Johns Hopkins Press; London: Oxford University Press, 1960.) 60*s*. net.

Because of their abundance and wide distribution in marine sediments and in the plankton of past and present oceans, the shells of Foraminifera have proved valuable in stratigraphic studies and much taxonomic information has resulted. Following success in the dating of rocks, and to a lesser extent in foraminiferan taxonomy, many students of the group are now engaged in the field of palæoecology, or more specifically, in the reconstruction of fossil environments. Knowledge of the distribution and ecology of contemporary Foraminifera is of importance in such studies, and it is opportune that a book has now been written bringing together, for the first time, much of the available information on the subject.

Unlike so many papers reporting foraminiferan studies, this book includes a full account of the methods used by the author; he rightly points out that unsatisfactory methods of collection and subsequent treatment of sediment samples has rendered many published accounts less valuable.

Another obstacle to synthesizing the vast amount of previous work on foraminiferan distribution is the taxonomic confusion which exists in the group. This, of necessity, is avoided by the author, who relies on detailed studies, such as that carried out in the Gulf of Mexico, to illustrate his discussion. Nevertheless, it is unfortunate that space was not found for an appraisal of those aspects of foraminiferal distribution which would have clarified certain statements such as " . . . probably there are few benthonic species which are world-wide in distribution except those in the deep sea" (p. 45). This calls for comment; especially in a book of this title.

Interesting accounts are given of the existence of depth zones for Foraminifera, of the various faunas characteristic of different environments, of the importance of establishing and assessing the living components of a foraminiferan sample and of the contamination of faunas by displacement and currents. The least-documented part of the book appears to be that dealing with the ecological factors affecting the depth distribution of Foraminifera. It is here that the estrangement of many students of the group from their colleagues working with other marine animals is very evident. The section on food has no reference to H. Sandon's *The Food of Protozoa* in which four pages are devoted to the Foraminifera. Furthermore (p. 123), there is reference to work on the effect of pressure on marine bacteria which, the reader is told, is the only specific evidence known to the writer concerning the effect of pressure on marine organisms. There are, however, other works on this subject to which the reader's attention ought to be directed.

Prof. Phleger's book is a useful contribution in a very difficult field of study. No great criticism is implied when I suggest that now the first book on the subject has been written a second and more comprehensive one must surely follow. R. H. HEDLEY

ENDEMIC DISEASES IN THE TROPICS

The Control of Disease in the Tropics

A handbook for medical practitioners. By T. H. Davey and W. P. H. Lightbody. Pp. xii+22. (London: H. K. Lewis and Co., Ltd.) 47*s.* 6*d.* net.

SINCE the appearance of the first edition of this book in 1956 it has remained without a serious rival. Books devoted to the treatment of tropical diseases are much more numerous. Does the lack of books on the prevention of disease indicate a lack of interest in this subject in developing countries? If this is so, it is a great pity as the techniques of disease control have developed so rapidly that many of the major endemic diseases are now much more susceptible to attack.

These advances are reflected in the second edition of this book. More emphasis is placed on the treatment of tuberculosis with the new drugs now available. Wide-scale treatment by this method gives hope of eventual control without the need of expensive buildings and equipment. Similarly, the emphasis on the control of leprosy has shifted in line with the success of the sulphones; segregation is giving way to mass treatment on a wide scale.

The chapters on malaria have, perhaps, not followed the present trends quite so noticeably. A few paragraphs are devoted to the principles and practice of malaria eradication, but this seems scarcely enough for a programme that is operating in malarious countries with an aggregate population of more than a thousand million people. It may be argued that malaria eradication is operated by specialists. It is likely that its very considerable success would be even greater if the medical officer with general public health responsibilities had a better understanding of its methods and problems.

It is unwise to paint too optimistic a picture of the prospects of control of all the great endemic diseases of the tropics. No spectacular advance has been made against schistosomiasis, hookworm and filariasis; methods of control are known but have not been shown to be applicable in practice in many areas in the tropics. It would be useful for a book of this nature to indicate which methods of control are already successful and which require development for effective use on a large scale. An appreciation of this difference is essential for the rational planning of health services.

Two new chapters are included, one on poliomyelitis, which is increasingly being recognized as a problem in the tropics, and the second on health education. This subject, which forms a meeting ground between the physician and the social scientist, and which often suffers from a lack of definition, has been dealt with in a most straightforward manner; the importance of the part to be played by all grades of health workers is emphasized.

Almost every page has been revised in order to bring it up to date. There is no risk in forecasting that this edition will be as successful as the first.

M. J. COLBOURNE

HIGHLAND BRITAIN

The Peak District

By Prof. K. C. Edwards, assisted by Dr. H. H. Swinnerton and R. H. Hall. (The New Naturalist: a Survey of British Natural History.) Pp. xvi+240+28 plates. (London: William Collins, Sons and Co., Ltd., 1962.) 30*s.* net.

IN the darkest days of the War, almost as a gesture of defiance as well as of faith, began the publication of Collins's *New Naturalist Series*. The first three titles appeared in 1945 and the present volume is No. 44—apart from 18 monographs. The series was an instantaneous success, and the editorial board has never swerved from its original aim of "maintaining a high standard of accuracy combined with clarity of exposition in presenting the results of modern scientific research" to the British public. Many experienced publishers shook their heads knowingly at this deliberate refusal to 'popularize' science, but how wrong they have been proved. From the beginning it was agreed that there should be a number of regional volumes, interpreting the natural history of the area very widely, and not neglecting man and his activities. The London region was followed by Snowdonia, the Weald and Dartmoor and, in a more general view, the sea coast.

The present volume covers broadly the area of the Peak District National Park—the first to be designated as such under the Act of 1949. The days when one individual could, in the Gilbert White tradition, claim to cover adequately the whole field of natural history—including man—are past, yet a volume written by a team is apt to be irregular and to lack cohesion. The solution here is that Kenneth Edwards, professor of geography in the University of Nottingham, has acted as principal author and as editor. Two leading members of his team, nearly all closely associated with the University or with local institutions, are named on the title-page, but eight others are thanked in the authors' preface for their contributions or assistance.

For more than a quarter of a century, Prof. Edwards, from his base at Nottingham, has explored the Peak District, for the most part on foot. As a well-known field-man, he has guided successive generations of youth hostellers and members of the Ramblers' Federation and many field societies as well as his own students to appreciate the influence of a varied physical environment both on wild life and on man.

As an island of 'Highland Britain' surrounded by industrial England, the outcrops of the Millstone Grit, the Coal Measure sandstones and shales, the massive Carboniferous limestones and the old volcanic 'toad stones' have afforded sharply contrasted land forms and habitats—from intimate wooded dales to windswept moorland heights and boggy hollows. Man's interest has varied with the passing of time, and to-day competing interests are strong—from mining and quarrying, through farming, grazing and forestry to the needs of water supply, sport, recreation and nature conservation.

In a well-balanced text, supported by numerous maps and diagrams and a fine selection of pictures, the authors are to be cordially congratulated in giving due consideration to each of these varied and often conflicting interests.

L. DUDLEY STAMP

THE NEW CAMBRIDGE RADIO TELESCOPE

By Prof. M. RYLE, F.R.S.
Mullard Radio Astronomy Observatory, Cavendish Laboratory, Cambridge

THE Department of Scientific and Industrial Research has recently announced the award of a grant for the construction of a new radio telescope which has been designed at Cambridge. Like the two existing large telescopes[1,2], the new instrument will make use of the principle of aperture synthesis[3] and will enable a further increase in resolving power and sensitivity to be achieved.

The instrument has been designed primarily: (*a*) to obtain detailed information on the structure of the more intense radio galaxies; (*b*) to extend the statistical information concerning the number-flux density relationship to considerably weaker sources; (*c*) to investigate any non-uniformities in their angular distribution; these observations are aimed particularly at the further investigation of the cosmological problem. It will also be used in high-resolution studies of the emission from the Galaxy, and in exploring the detailed structure within galactic sources.

In the design of an instrument having a resolution of the order of 1 min. of arc, the limits set by the ionosphere make it necessary to operate at higher frequencies than that used in the present large interferometer (178 Mc./s.). Until recently, receiving amplifiers for these higher frequencies have had comparatively poor noise performance; but the development of new types of amplifier now allows the operation of 'unfilled apertures' of the Mills Cross[4,5] or synthesis type with adequate sensitivity.

Although the cylindrical parabolic reflectors which have been used as the individual aerial units in the present Cambridge instrument have been shown to provide a very inexpensive form of construction, there are difficulties in extending the same technique to the higher frequencies now envisaged. These difficulties arise partly because of the attenuation inherent in providing a line feed, and partly in the mechanical design of closely spaced wire reflector surfaces. The first limitation can be overcome by using a large number of independent pre-amplifiers in the manner proposed for the Benelux Cross[5], but the maintenance of sufficiently accurate phase equality involves considerable technical problems.

An alternative two-dimensional form of synthesis has therefore been adopted in which the relative positions of two small circular aerials are altered to occupy, in turn, all the positions present in the synthesized aperture[3]. One method of achieving such a two-dimensional synthesis is by the use of transit observations with the two elements mounted on mutually perpendicular railway tracks; this system is, however, inconvenient to use since the observations, of necessity, provide information concerning a complete declination strip of the sky, and a very large number of observations must be completed before a map of any part of it is available.

In the new instrument a single railway track is used to provide a variable spacing in an east–west direction. Since the rotation of the Earth carries this axis through one complete revolution in 24 hr., extended observations of a given area of sky at each separation of the elementary aerials allow the sampling of those components of a large aperture contained within a ring (Fig. 1). By combining the observations made with different separations of the elementary aerials, it becomes possible to synthesize a complete elliptical aperture, which may be regarded as the projection of a circular aperture the plane of which is normal to the Earth's rotation axis. The symmetry of the system is such that observations are needed for only 12 hr. at each spacing of the elementary aerials.

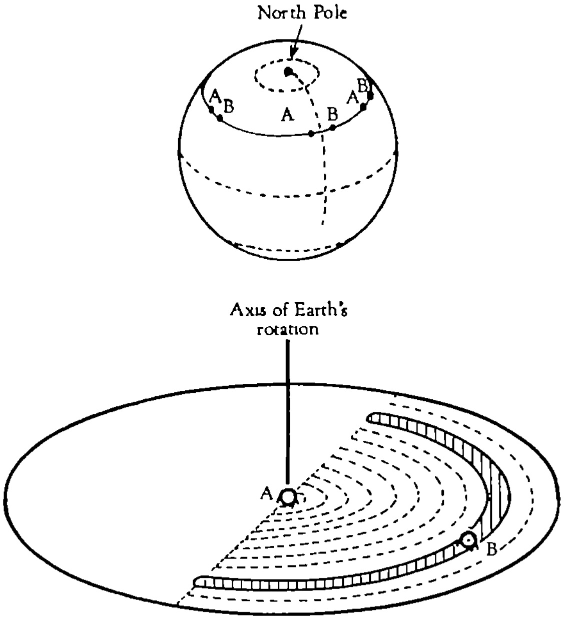

Fig. 1. Diagram to illustrate the change in relative positions of two aerials on an east–west axis during a period of 12 hr. and how observations with such an instrument provide one ring of the complete aperture

As with all methods of synthesis the signal-to-noise ratio obtained when a given area of sky is scanned in a given total observing time depends on the relative areas of the elementary aerials and the synthesized aperture; the new method has the considerable practical advantage over two-dimensional synthesis using transit observations that the observations over a particular period of time relate only to the small area of sky selected by the reception pattern of the elementary aerials. The system only requires the construction of a single railway track, and the total area of ground occupied is very small since it is contained within a narrow strip the length of which is equal to the diameter of the synthesized aperture.

The use of observations over a range of hour angle in order to provide differing projections of the interferometer axis on the sky was first applied by O'Brien[6], who synthesized a two-dimensional grating which he used for observing the distribution of radio brightness across the Sun. The method was afterwards applied to the observation of radio sources by Högbom[7], who

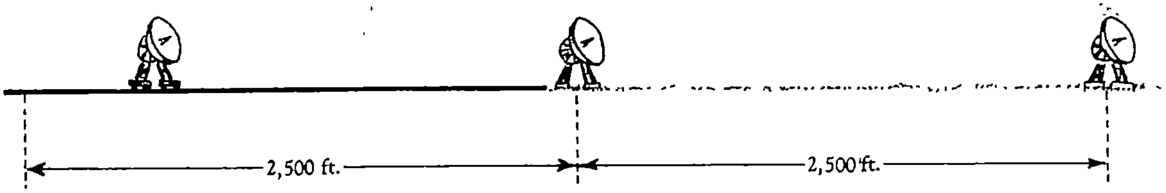

Fig. 2. Arrangement of the three paraboloids

used two small aerials at a wave-length of 3·7 m. to obtain a resolution of 2°.

The first attempt to provide an instrument of large resolving power by this method was made by Ryle and Miss Neville[8], using sections of the 178-Mc./s. interferometer to provide different spacings along an east–west line. Since, in this case, the individual sections of the aerial could not be moved in hour angle, observations were restricted to an area around the North Pole, 8° in diameter. This system provided a pencil beam response the width of which was 4·5 min. arc to half intensity, a resolution equivalent to that of a circular aperture 3,400 ft. in diameter. Observations were made for 12 hr. at each of the element spacings, and provided successive circular strips in the full aperture as illustrated in Fig. 1.

When the method is used for declinations away from the North Pole, provision must be made for tracking the individual aerials to observe the selected area of sky for 12 hr.; the synthesized aperture is now an ellipse, with the minor axis diminished by the sine of the declination.

The arrangement of the new Cambridge instrument is shown in Fig. 2; the signal from a rail-mounted aerial will be combined with those from two fixed ones arranged on an east–west axis, and the output from the two interferometers will be recorded separately. This arrangement compares favourably in cost with the use of a longer railway track and a single fixed aerial, and the observing time is halved.

Each of the three aerials will be an equatorially mounted paraboloid 60 ft. in diameter. As with the present instrument the signals will be recorded digitally on punched paper tape[9], so that they can be passed directly into *Edsac* for the synthesis computation. At high declinations the resolving power is equivalent to that of a circular aperture 5,000 ft. in diameter, and at declination 25° to an elliptical aperture 5,000 ft. × 2,000 ft. The sensitivity can conveniently be defined in terms of the equivalent aerial which would achieve the same signal-to-noise ratio when a given area of sky is observed in a given total time; it should be approximately the same as that of a paraboloid of diameter 750 ft. The overall performance, taking account of both resolving power and sensitivity, can be compared with that of a conventional paraboloid 1,250 ft. in diameter, and having a sufficiently accurate surface to allow it to operate on a frequency four times that used in the Cambridge instrument.

It is planned to use the instrument initially on a frequency of 408 Mc./s., with an expected resolution of 1·5 min. of arc. If the necessary phase stability can be achieved at 1,420 Mc./s., the resolution should be 25 sec. of arc.

It is hoped that work on the foundations will start within the next few months.

HIGH-FREQUENCY, HIGH-POWER, PULSE SIGNALS FROM AN AUSTRALIAN TRANSMITTER

By DR. J. F. WARD,
Department of Physics, Royal Australian Air Force Academy, University of Melbourne

BETWEEN September 1961 and February 1962, observations were carried out in various countries of an experimental pulse emission at 25·760 Mc./s. from a high-power transmitter in southern Victoria, Australia. The object was to seek anomalies of propagation which are to be expected when high-intensity irradiation occurs at the ionospheric *F* layer from an aerial with a low launching angle in the vertical plane. The peak pulse-power available was 50 kW. and the rhombic transmitting aerial, elevated 2·5 wave-lengths above the ground plane, had a gain with respect to a dipole computed to be greater than 17 db. with the peak of the main lobe in the vertical plane at an angle of approximately 6° to the Earth's surface. The azimuthal true bearing of the main lobe of the aerial was 312°, which meant that central south-east Asia, Europe and the United Kingdom were potential targets. 2 or 4 msec. pulses were used with a repetition period of either 40 or 80 msec. Radar back-scatter observations were first carried out in Melbourne, followed by observations of the forward transmitted pulse trains at locations in various parts of south-east Asia—mainly Singapore—and later in the United Kingdom. The relatively high frequency of transmission selected was intended to show up propagation anomalies during unstable or transitional conditions of the ionosphere. For a similar reason, operating schedules of 01.00–03.00 U.T. and 03.00–06.00 U.T. were adopted.

An aerial array of a new form was constructed for the reception of the back-scattered signal. This array will be described in a separate communication; but its essential property for the purpose of this present experiment was that it yielded some effective

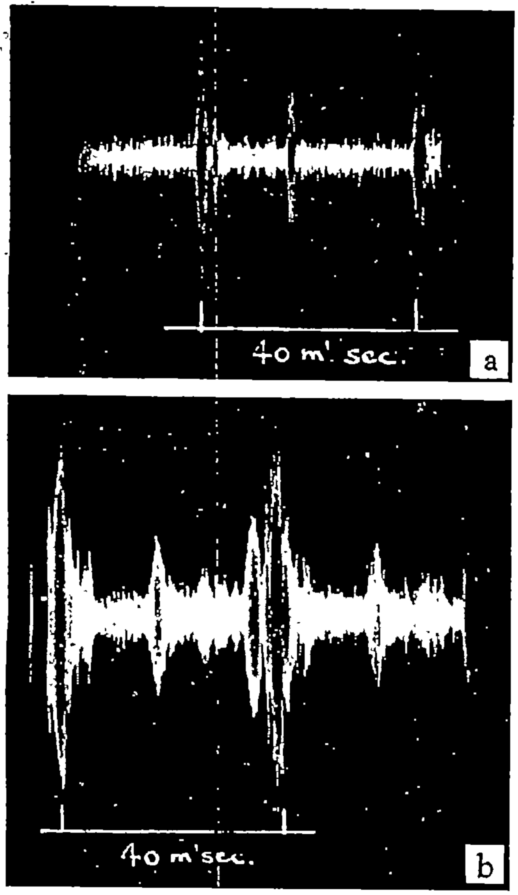

Fig. 1*a*, Radar back-scatter at Melbourne from north-west Australia, Multipath low—2 msec. pulse-length, 40 msec. repetition period. 01 30 U.T., October 19, 1961. *b*, Radar back-scatter at Melbourne showing multipath and other degradation—4 msec. pulse-length, 40 msec. repetition period. 02.15 U.T., October 19, 1961

pick-up at the lowest angles of down-coming radiation. The interesting results from Singapore on the forward pulse train were obtained by the use of rhombic aerials of high gain and high elevation for which the peak of the main lobe in the vertical plane occurred at an angle of approximately 7° to the Earth's surface.

Fig. 1*a* (01.30 U.T. on October 19, 1961) and Fig. 1*b* (02.15 U.T. on October 19, 1961) are typical of the normal radar back-scatter signals received at Melbourne on practically all the twice-weekly occasions of observation. A single-scattered pulse group of normal delay of the order 16–20 msec. indicates a target in north-western Australia. Frequently, during the latter part of an observation period for which this simple pattern had persisted, the delay period would increase to perhaps 25–30 msec.

On a large number of occasions, of which Fig. 2 is typical, double pulses appeared, often with multipath degeneration of the pulse shape—with a further delay for the additional echo of perhaps 5–10 msec. These are explained probably as two-hop back-scatter modes with target regions—depending on the delay time recorded and so on the angles of fire—in either Indonesia or northern Malaya.

When the incident pulse train was observed systematically at Singapore the anticipated simple pulse pattern with a 40 or 80 msec. repetition period was found to be the exception rather than normal. Fig. 3 (Singapore 01.00 U.T., November 16, 1961) gives an example of a single spurious echo of delay of the order of 20 msec. This was a fairly stable mode and could persist for most of a transmission schedule of duration 2 hr. Fig. 4, photographed 10 min. after the exposure of Fig. 3 on November 16, 1961, illustrates the well-defined type of second spurious echo which exhibits an additional delay of about 6 msec. While patterns of the type shown in Fig. 3 and Fig. 4 could be expected to occur frequently, there were occasions when extremely complicated echo displays would arise, and although these usually persisted for minutes only, they were reported by several independent observers to remain at times for periods up to 1 hr. Fig. 5 (Singapore 02.38 U.T. on January 9, 1962), which is derived from a long-exposure colour photograph at a time when the repetition period had been lengthened to 80 msec., includes unfortunately two sweeps of the time-base. The patterns can be differentiated by eye, however, and the existence of echoes throughout the repetition period of 80 msec. can be noted with a positively identifiable group of apparent delay of the order of 60 msec.

It is known that delays of the order of a few msec. can be experienced from signal components reflected from either side of the great circle propagation path[1]. Likewise signals scattered from regions of the Earth's surface illuminated by the minor lobes of the transmitting aerial could be expected to make contributions; but a delay of 16 msec., or more, as illustrated in Fig. 3, is difficult to explain. Although the evidence is not conclusive, it can be shown that a signal propagated from Victoria by the long great circle

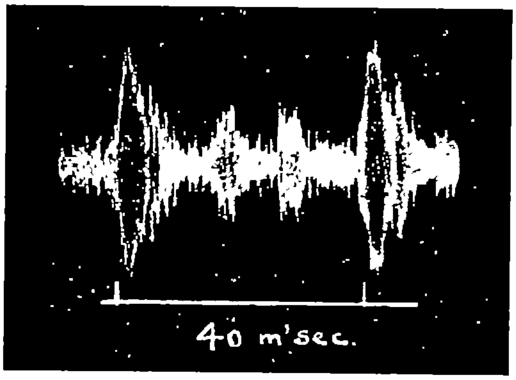

Fig. 2. Radar back-scatter at Melbourne showing scattering from both one- and two-hop target areas in South-East Asia.

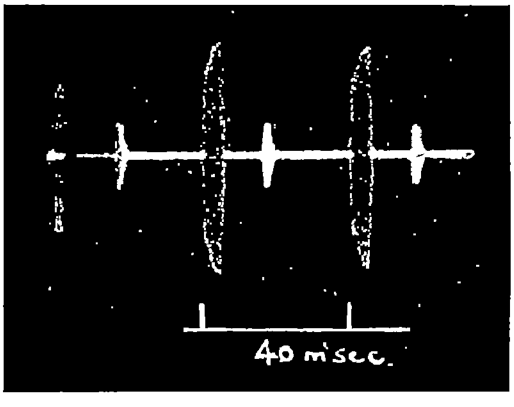

Fig. 3. Pulse train received at Singapore with a stable, delayed echo of about 16 msec. 01.00 U.T., November 16, 1961

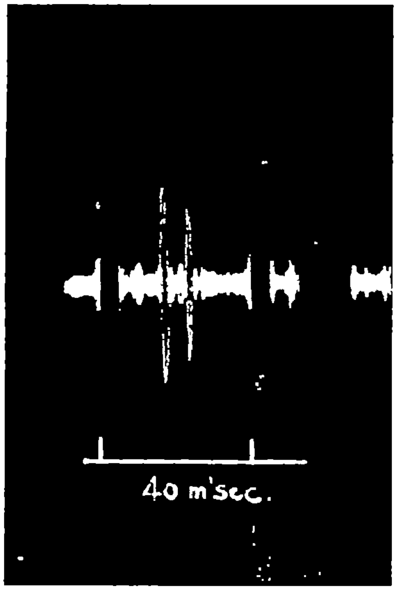

Fig. 4. Pulse train received at Singapore with a pair of delayed echoes. 01.10 U.T., November 16, 1961

path could appear, by running through the 40-msec. time-base of the display, as a virtual 16-msec. delay. If this was the explanation, then the second delayed pulse of Fig. 4 could be considered to arise from the same mechanism of propagation but with a slightly higher-order mode structure, or even, as demonstrated by Shearman[2], from a mode pattern set up by the high angle, on bearing, secondary lobe of the transmitting aerial. In view of the high power of transmission, and the rather poor front-to-back ratio typical of a terminated rhombic, say, 12 db., there is a distinct possibility that long great circle transmission could have occurred. On the other hand, a careful examination of the corresponding oscillograph display when the pulse repetition interval was increased from 40 to 80 msec. appeared to confirm that an echo round the world in the desired direction of transmission was not the explanation of the pulse-time distribution experimentally obtained. Irradiation of the Earth's surface one hop to the rear of the transmitting aerial gives the possibility of scattered forward transmission along the short great circle path via Victoria to Singapore. This mechanism could account for an apparent delay of 16 msec. at Singapore.

No satisfactory explanation of the mechanisms represented by Fig. 5 can be advanced at this stage although, in this particular case, the existence of round-the-world echoes cannot be excluded. Such a transmission, as also that postulated for the long great circle case relating to Fig. 4, would have to occur over long-range paths in darkness for which the maximum usable frequency, as predicted traditionally, would be less than 25 Mc./s. even for 4,000-km. hops. In an attempt to confirm the presence of such modes, observations were carried out at the Radio Research Station, Slough, England, during February 1962, but no pulses were received.

The results demonstrate that if the *F* layer of the ionosphere can be illuminated by high-frequency radiation launched at a low angle with respect to the Earth's surface, complicated signal paths and mode patterns are established[3,4]. The overall effect of these various uncontrolled contributions is deleterious to high-frequency speech communication and almost intolerable for transmission of digital data. Such complexity suggests also that the distortion of speech thus transmitted, thought to be primarily a function of selective fading over the modulation band-width, might be due also to the partial destruction of the fundamental pitch frequency of voiced sounds by the spurious contributions of long (that is, greater than, say, 10 msec.) delay. The fact, however, that such paths can be established for long-range transmission at a frequency of 25 Mc./s. emphasizes that for low angles of fire and reception, established concepts for the prediction of maximum usable frequencies are unreliable. A new relationship between ionospheric critical frequency, maximum usable frequency and vertical angle of launching must be established for the case when this angle is less than 5°. Such a study has particular relevance to the problem of high-frequency communication during the present period of low sunspot activity and so of lowered critical frequencies.

If the complex pulse patterns exhibiting long delays as demonstrated can be shown to arise from ray contributions from the minor lobes of the transmitting and receiving aerials used—and these were typical of the best usually available for world-wide communications—the ineffectiveness of such aerials is obvious and the need for a more fundamental approach to the design of high-frequency aerial array is highlighted.

The final interesting conclusion arises from the fact that the present criteria of minimum spacing of aerials in space diversity along the transmission path are based on experience with existing types of aerials. It appears clear from Fig. 5 that the destruction of the correlation between the incident, radio-frequency energy contributions is not related, as now believed, merely to the imposition of the ionospheric fluctuations on the main (or any single) energy-carrying mode, but, on the other hand, to the effect of the uncorrelated, substantial energy contributions from other modes. The correlation coefficient, therefore, as at present understood, is a function of the aerial polar patterns (both transmitting and receiving) rather than of the ionospheric variability alone. Since the former are controllable, a new possibility appears to exist for the design of array groups for wide-aperture interferometry operating at high frequency.

The field work discussed here forms part of a larger programme of research directed towards the improvement of long-distance, high-frequency radio communication during the prevailing period of low sunspot activity. The essential mechanism to any such improvement is believed to be the selective initiation and reception of only the low angle of fire, long range, minimum hop, ionospheric *F* layer mode[5,6].

This presupposes launching and reception at vertical angles well below five degrees. The aerial design and propagation aspects of this work, together with the correlation experiments referred to above, are continuing at the University of Melbourne.

Extensive help for this world-wide project has been given by a number of organizations, and of these the contributions particularly of the following are acknowledged: Postmaster General's Department, Australia; Royal Australian Air Force; Cable and Wireless, Singapore; Department of Scientific and Industrial Research, Singapore and Slough, England; and the South-East Asia Treaty Organization. This programme of research at the University of Melbourne is supported in part by a grant from the Australian Radio Research Board.

INITIATION OF CONTINENTAL DRIFT

By Dr. R. W. GIRDLER

Department of Geology, University of Durham, Durham City

During the past few years, geophysicists have revived interest in the possibility that the continents may have drifted relative to the poles and relative to one another. The revival of interest is largely due to the results of work on palæomagnetism[1,2]; but it is significant that contributions have been made by workers in other fields such as oceanography[3], palæoclimatology[4,5] and crustal structure[6,7].

Recently, Runcorn[8] invoked the idea of a large-scale pattern of convection currents in the mantle to explain the present position of the continents. Following Urey[9], he supposes that the core of the Earth is growing and, in accord with the theoretical work of Chandrasekhar[10] and Vening Meinesz[28], as the core grows the higher harmonics for a convective motion in the mantle becomes more and more important. The continents are broken and moved by the horizontal motion of sub-crustal convection currents and come to rest over the descending currents, the rising limbs of the currents being near the centres of the ocean basins.

Independent support for this idea comes from the nature and position of the world-wide ridge-rift system. In general, the ocean basins are characterized by median ridges[11] and these often have rift valleys or fracture zones near their crests. The rifts are frequently seismically active[12,13] and measurements suggest they are characterized by high heat-flow[14]. In fact, they are features which might be expected over the rising limbs of convection currents[15]. According to Runcorn's hypothesis, there should be phases of continental break-up as each time the convecting pattern changes to a higher harmonic uprising currents must somewhere evolve under continents. Chandrasekhar[10] has shown that for a core of the present radius ($0{\cdot}55R$) the $n = 3,4,5$ harmonics are almost equally likely to be excited at marginal stability. We might therefore expect to find some places on the Earth's surface where new, rising convection currents are beginning to occur under or near to the continents. Fig. 1 shows a map of the world ridge–rift system, and it is immediately seen how well the distribution fits a large-scale convective pattern as visualized by Runcorn and supported by Chandrasekhar's calculations. It is also seen that there are at least two regions where the ridge–rift system intersects the continents; these are via the Gulf of Aden and Red Sea and via the Gulf of

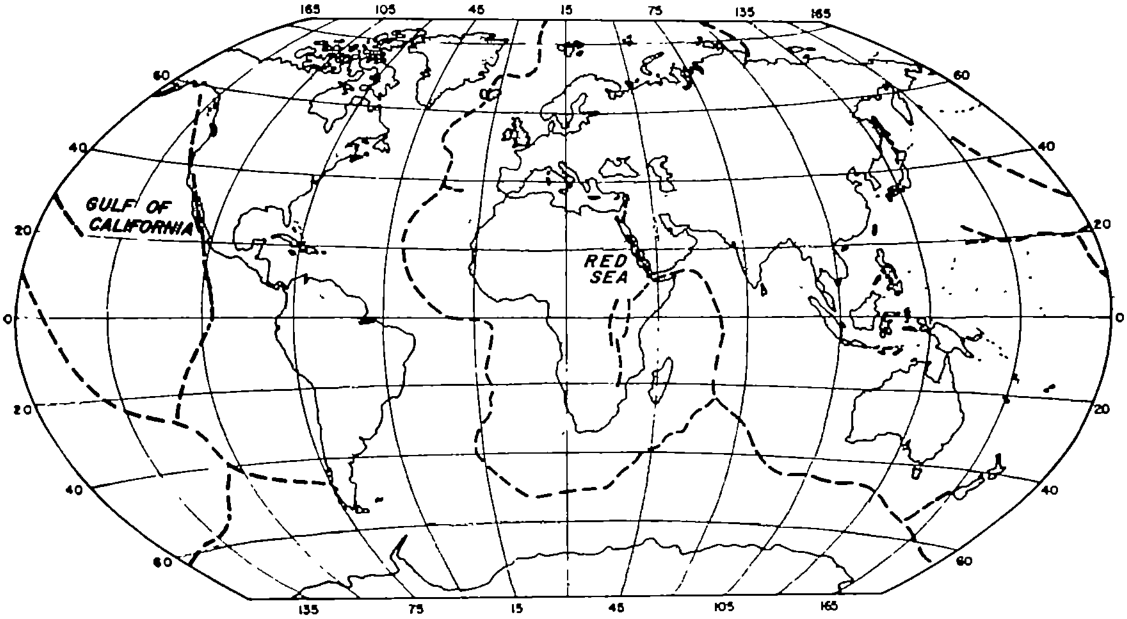

Fig. 1. Map showing the approximate location of the world ridge–rift system and associated features

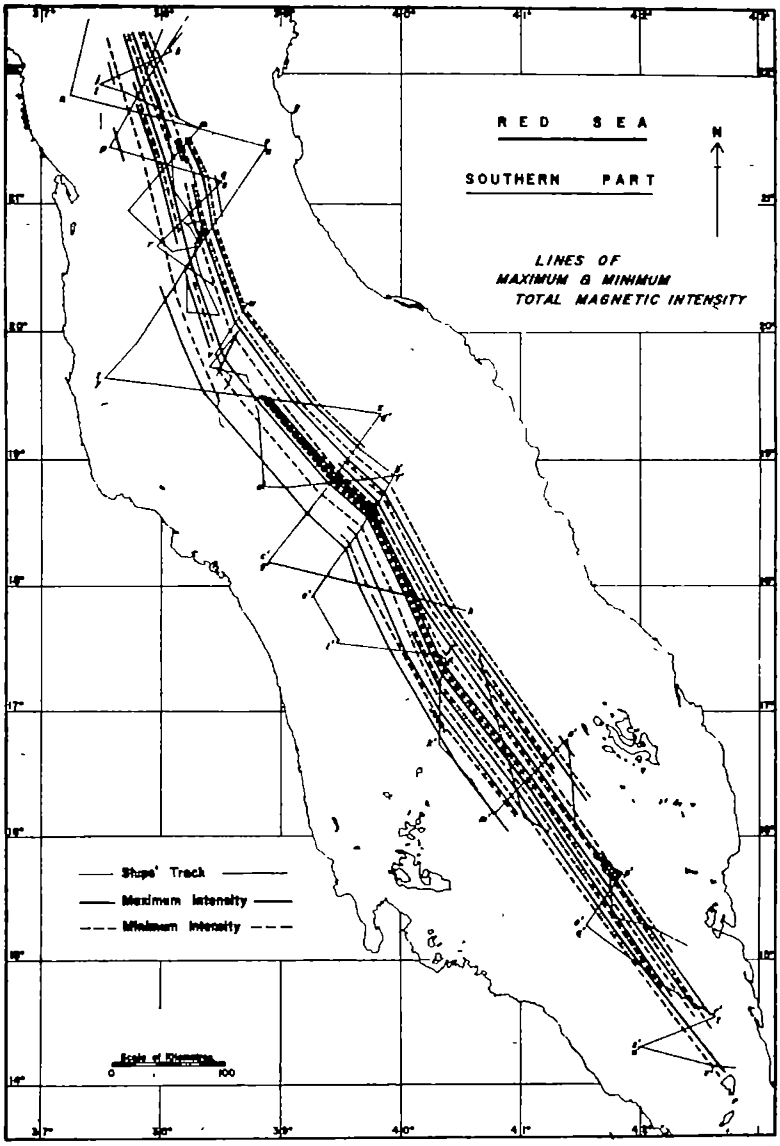

Fig. 2. Distribution of large magnetic anomalies in the southern part of the Red Sea

California. It is suggested that these two regions may give a clue as to how continental drift begins.

Recently, much geophysical work has been carried out in the Red Sea and Gulf of Aden[14-18]. A deep, axial trough under the centre of the Red Sea is characterized by large, positive Bouger gravity anomalies and these seem to be largest where the water is deepest. In 1957, I[19] interpreted this gravity maximum as being due to a basic mass, intruded through the downfaulted basement rocks, the large volume of intrusive material probably coming from beneath the Moho. More recent geophysical work supports this interpretation; for example, seismic refraction profiles by Lamont Geological Observatory, Columbia University[17], near the centre of the Red Sea show that a 7·1 km./s. layer is found at a shallow depth of 4·04 km. This is overlain by 2 km. of lava flows and sedimentary rocks, 0·45 km. of sediments and 1·5 km. of water. The crustal structure under the deep water therefore tends towards oceanic character and it seems that a strip of ocean reaching widths of up to 50–60 km. is in process of being formed in the centre of the Red Sea between the African and Arabian continents.

The areal extent of this recent oceanic crust may be mapped from the distribution of magnetic anomalies. Measurements of the total intensity of the Earth's magnetic field have been made by the Lamont Geological Observatory[17] and by Dr. T. Allan[20], lately of Cambridge. The anomalies over the deep, axial trough of the Red Sea have amplitudes of up to 1,200 γ ($1\ \gamma = 10^{-5}$ oersted) and gradients up to 200 γ/km. The large gradients make it difficult to contour the data, and lines of maximum and minimum total magnetic intensity have been plotted (Fig. 2) by correlating the features of the anomalies from profile to profile. It is seen that the trend of the anomalies is almost exactly parallel to the sinuous shore-lines of the Red Sea, suggesting that the continental crust has been torn apart leaving room for the intrusion of basic igneous rocks which give rise to the large magnetic anomalies.

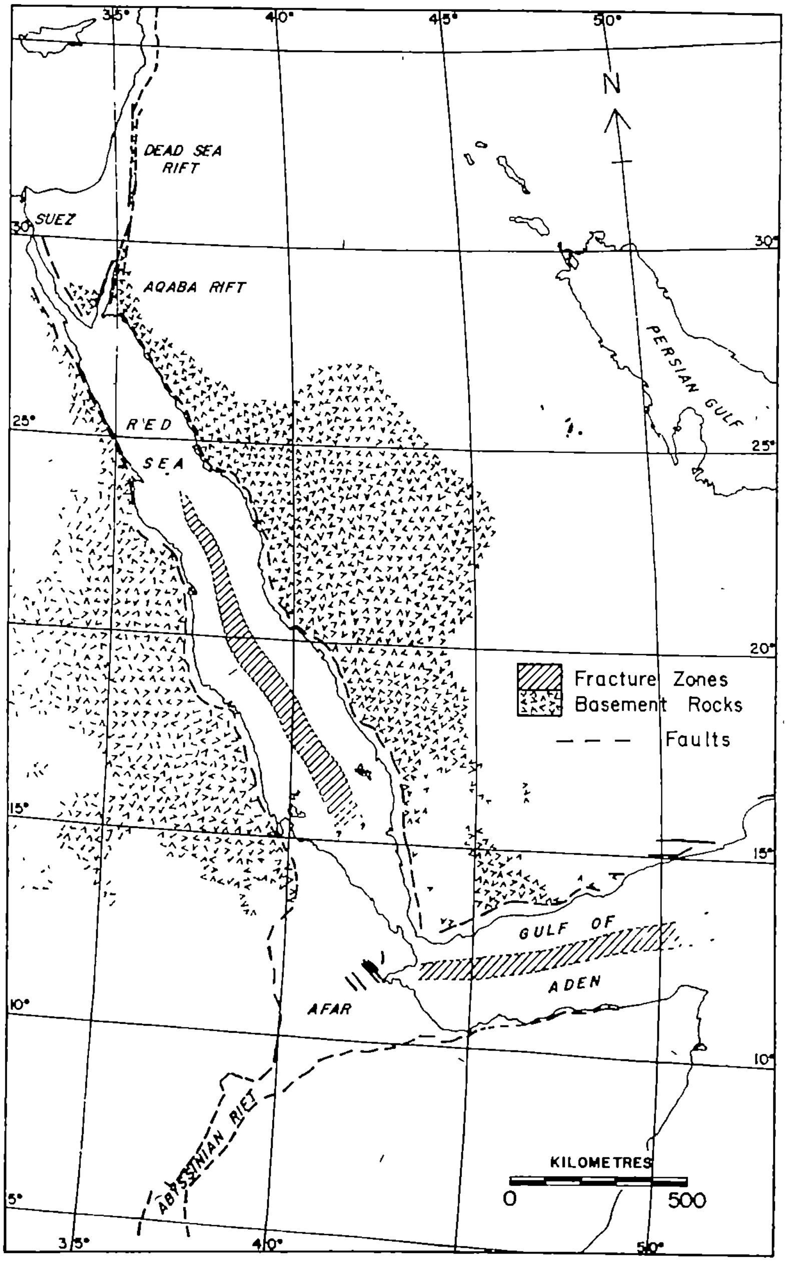

Fig. 3. Map of the Red Sea area showing the approximate location of the axial fracture zone, along which oceanic type crust seems to be forming

Large magnetic anomalies have also been observed along the centre of the Gulf of Aden[18,21] and these similarly trend parallel to the shore-lines. The possible extent of the fracture zone leading to the formation of the oceanic type crust is shown in Fig. 3, and it is seen that the tension crack opens up towards the south, suggesting a relative rotation of Arabia and Africa and the splitting apart of the continents. The Red Sea and Gulf of Aden form part of the East African Rift System, and it seems likely we now have geophysical evidence which might suggest that the Arabo-African continent is breaking up along the rift faults. The fact that the East African rift system forms part of the world ridge–rift system suggests that a new convection current may exist beneath the continental rifts giving a mechanism for their formation.

It appears likely that the Gulf of California has somewhat similar structure to the Red Sea and Gulf of Aden. Here, part of the world ridge–rift system (Fig. 1) intersects the North American continent via the East Pacific Rise. Geological evidence[22] indicates that the Baja Peninsula was once situated 480 km. to the south-east and formed part of the mainland; it has since rifted away by oblique tension across the San Andreas fault system. Gravity measurements[23] indicate that the southern part of the Gulf is in approximate isostatic equilibrium, and the deep water is underlain by heavy material. A seismic profile[24] in the axial deep at about 27·5° N. shows 0·4 km. of sediment and the Moho to be only about 6 km. beneath the sea floor or 8–10 km. below sea-level; the structure is therefore oceanic in character. Farther north, the

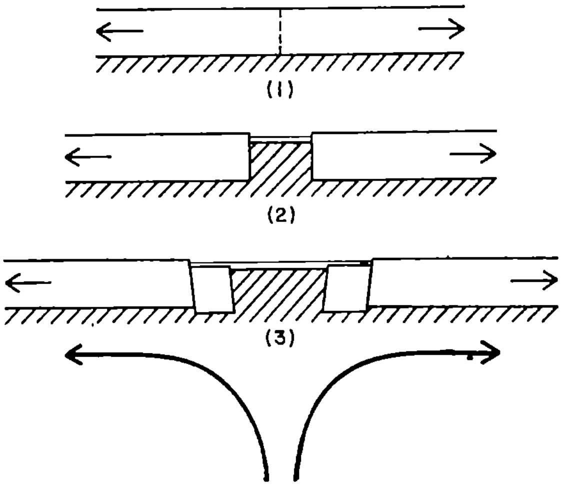

Fig. 4. A possible mechanism for the break-up of continental crust resulting in the formation of new oceanic type crust

structure of the Gulf is intermediate between continental and oceanic types with 5 km. of low-velocity sediments, 5 km. of rock with sialic velocity overlying material with velocity 7·5 km./s. Heat-flow measurements in the southern part of the Gulf[25] give values many times above normal. The Gulf is continued to the south by the East Pacific Rise which Menard[26] considers to be a very youthful part of the world ridge–rift system which is seismically active but as yet shows no median rift valley. Menard uses a rising convection current to explain the East Pacific Rise and it seems likely that the same current is causing a split of the Baja Peninsula from the mainland and the formation of oceanic structure along the rift zone.

Thus, we have two examples of what might be considered the earliest stages of continental drift, and it remains to consider a mechanism by which new oceanic crust may form. Fig. 4 is a diagrammatic representation of a possible mechanism based on the author's[19] mechanism of formation of the Red Sea structure. Tensional forces cause a crack in the Earth's crust, for example along what is now the centre of the Red Sea and Gulf of Aden (Stage 1). The tensional stresses were large enough to cause a separation of the continental crust and basic, igneous material is intruded into the tensional crack until hydrostatic equilibrium is obtained (Stage 2); the hydrostatic pressure of the magma is not sufficient for the intrusive material to reach the level of the continental crust, a consequence of its higher density. The filling of the crack causes subsurface movements which may result in faulting of the continental margins (Stage 3). The tensional stresses could be due to a rising convection current which is causing a separation of the continental crust with the formation of new oceanic crust in between. This gives a very simplified picture; the actual structure under the centre of the Red Sea is complicated and the axial, deep water is probably underlain by a series of wide, parallel fissures filled with basic, igneous rock[27].

In conclusion, it can be seen that a study of the world-wide ridge–rift system gives observational support to the theory of continental drift recently proposed by Runcorn. Besides satisfying a world-wide convection pattern, the presence of a possibly new current under the East Pacific Rise suggests a recently changing pattern as there a rising current is close to an Alpine fold-mountain belt; if convection is also used to explain fold mountains then the pattern must have changed within the past 3 × 10^7 years. Further, it is tentatively suggested that the regions where the ridge–rift system intersect the continents may show how continental drift is initiated with the formation of new oceanic crust depending on the degree of extension.

RAINFALL INITIATION BY METEOR PARTICLES

By PER B. STOREBØ

Division of Physics, Norwegian Defence Research Establishment, Kjeller, Norway

THE hypothesis that meteor particles could initiate rainfall was suggested by Bowen[1] in 1953. He investigated rainfall as a function of day of the year, and found peaks in mean rainfall records approximately 30 days after annually fixed meteor showers had occurred over the Earth. But neither the statistics in his first paper nor those in later and more sophisticated treatments[2–4] have convinced sceptical critics. On the other hand, no one has been able to show that he is wrong. New examinations[5] of rainfall records tend to show peaks on the dates where Bowen found them; but disagreement exists about the significance of the deviation.

No acceptable explanation of how meteor particles can initiate rainfall has been presented. Based on a theory about rainfall formation put forward earlier by Bergeron[6], Bowen indicated that the particles might work as ice-forming nuclei. The idea is that very many clouds do not yield precipitation because the small cloud droplets aggregate too slowly to form raindrops before the life-cycle of the cloud is terminated. In a cloud of supercooled droplets, however, an ice particle may grow rapidly. The vapour pressure is lower over ice than over water, and this causes transfer of water from the droplets to the ice particle. The upper layers of clouds often consist of supercooled droplets, and the ice particles may grow into snowflakes, which later may melt to form raindrops.

Closer investigation[7] has so far failed to support the hypothesis that meteor particles act as ice-forming nuclei. Neither the iron–nickel alloy nor the rock material of which meteors are predominantly composed, seems to have appreciable ice-forming tendencies.

There are other obstacles. Based on his world-wide investigations, Bowen states that the rainfall peaks lag about 30 days after the meteor showers, and that there is a spread of about ± 2 days between stations. Free fall is the only suggested mechanism of world-wide transport from the heights where the particles are suddenly decelerated by the atmosphere down to cloud heights. Calculations[8] show that this corresponds to a meteor particle diameter of about 10μ, with a range of about $0{\cdot}7\mu$.

Theoretical treatment of particle entry into the atmosphere shows that 10-μ particles are about the largest ones which can enter without catching fire and vaporizing. There is, however, no lower size limit. Therefore, an acceptable theory for meteor influence on rainfall must, through the mechanism involved, stipulate a lower limit very close to the 10-μ upper limit.

No such lower limit is suggested by the ice-forming nuclei theory.

However, the fact that meteors are made up of heavy material suggests another way of influencing droplet agglomeration. The 10-μ particle has a terminal velocity of fall greater than cloud droplets, and may therefore collide with them. The resulting droplet has a heavy core and therefore a greater fall velocity than the other droplets, and new collisions may occur. In this way water is accreted into one drop, and this is the first step towards rain formation.

It looks obvious that this mechanism must work best for the largest meteor particles so that a lower limit for the effect may be established. This question will now be examined in more detail.

A typical cloud droplet has a diameter in the range 10–20μ, and the meteor particle in question has a diameter about 10μ. The fall velocity of the meteor particle is higher than that of the droplet, and it should therefore catch up with the droplet. It is, however, very complicated to calculate the capture efficiency of the meteor particle. It is of a similar size to that of the droplet, and the influence of both bodies on the air stream must therefore be considered. No solution of the hydro-dynamical equations has yet been presented for this case, and only approximate calculations can be made.

Langmuir[9] has computed the collection efficiency of a fixed sphere for small spherical particles in the stream around it. He found the efficiency to depend on a parameter K, which may be modified for particles in Stokes's régime falling through the air to:

$$K = \frac{4 \cdot g \cdot \rho_2 \cdot r^2(\rho_1 \cdot R^2 - \rho_2 \cdot r^2)}{81 \cdot \eta^2 \cdot R}$$

where R and ρ_1 are radius and density of the fastest droplet or particle, r and ρ_2 those for the slowest, η is the viscosity of the air, and g is the acceleration of gravity.

The collision efficiency E_L was found to be:

$$E_L = 0 \text{ for } K \leqslant 1{\cdot}214,$$

$$\text{otherwise } E_L = \left[1 + \frac{3}{4}(\ln 2K)/(K - 1{\cdot}214)\right]^{-2}$$

The formulæ above have been criticized because the slowest droplet or particle in some respects was treated as a point. In order to overcome this deficiency Ludlam[10] applied a rough correction:

$$E = \left[E_L{}^{1/2} + \frac{r}{R}\right]^2$$

This formula has been used for computing the behaviour of a meteor particle entering a cloud composed of droplets. It is thus applied beyond the régime for which it was introduced; but for the purpose of this article the errors are probably acceptable.

In order to evaluate the hypothesis, the time and distance of fall from the moment the meteor particle enters the cloud until enough water is accreted to form a drop with a diameter of $\geqslant 60\mu$ were computed. The size 60μ is somewhat arbitrarily chosen. It is, however, felt that Stokes's formula can be used up to this size with acceptable errors, and that the meteor particle will have only a minor influence on the further growth of the drop, which already is well above the average cloud droplet in size.

Some details of the computation should be mentioned. The cloud droplets were assumed to be of uniform size, and the liquid water content of the cloud was set to $0{\cdot}3$ gm./m.^{3}, so that each droplet resided in a certain specific volume. E was computed from the formula presented here, and a collision was assumed to occur when, in a co-ordinate system fixed to the cloud droplets, the volume swept over by the particle times E was equal to the specific volume of the droplet. It was assumed that the collision resulted in a new droplet with weight and volume equal to the sum of those of the colliding bodies. The process was repeated with the new composite droplet taking the place of the particle. The computation was terminated when the droplet diameter was $\geqslant 60\mu$.

The calculations were carried out for a number of different configurations of particle sizes and droplet sizes, and for two specific weights of the particle, namely, 5 and 8. The viscosity of the air was set to $1{\cdot}53 \times 10^{-4}$ gm. sec.$^{-1}$ cm.$^{-1}$, a number appropriate for the upper troposphere. The calculations therefore apply to the top cloud-level.

The results are given in Fig. 1. The straight, heavy line in the lower part of each diagram (top and bottom) rising towards the right indicates the configurations where meteor particle and water droplet have the same velocity, and along this line no collisions should occur. Below this line the first collision occurs because the cloud droplet overtakes the particle; but the calculation is otherwise very similar to the method already described.

It should be noted that the diagrams in Fig. 1 can easily be applied to other liquid water contents,

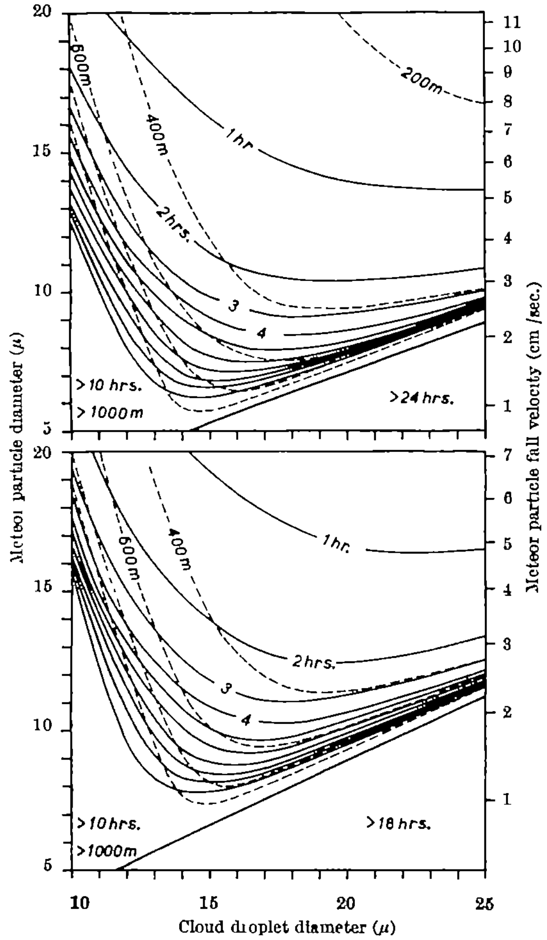

Fig. 1. Growth of a drop initiated by a meteor particle colliding with cloud droplets in a cloud with a liquid water content of 0·8 gm./m.^{3} The solid lines show the time of growth until a diameter of 60 microns is reached. The time-interval between the lines is 1 hour. The broken lines show the corresponding distance of fall; the interval between the lines is 200 metres. Along the straight, heavy line rising towards the right no growth occurs. The particles in the top diagram have a density 8 gm./m.^{3}; those in the bottom have a density 5 gm./cm.^{3}

because time and distance of fall are inversely proportional to the water content.

The diagrams in Fig. 1 indicate that large meteor particles among average-sized cloud droplets may grow by collision to 60μ size in a fairly short time, and that this time increases rapidly as the particle size decreases. It was mentioned earlier that due to the world-wide spreading of rainfall peaks, a variation in particle diameter of 0·7μ was tolerable. The calculations indicate that a decrease in particle size from 10μ to 9·3μ implies between 25 and 35 per cent increase in growth-time in clouds with droplet size in the range 15–20μ.

In a meteor shower with a broad-size spectrum such a sharp gradient in the rate of water accretion may well set a lower limit to the size of the particles with which the suggested mechanism will work well enough to be discernible in rainfall statistics. If, in addition, an upper limit of about 10μ is set by the vaporization during atmospheric entry, a narrow size-range remains for meteor particles capable of growing to raindrops.

The highest specific weight used for the particles in the computation is 8, corresponding fairly well to an iron–nickel composition. Particles composed of lighter material may be present in meteor showers. Comparing the two diagrams in Fig. 1 it is seen that the particles with specific weight 5 may act as rain nuclei at lower speed than the heavier ones. If the meteor showers differ in composition, it is possible that the time-lag of about 30 days differs somewhat from one shower to another.

It is also questionable if the time-lag necessarily must be the same all over the Earth. The fall velocity and the parameter K depend on the viscosity of the air, and because this quantity increases with temperature, the meteor effect may show a latitudinal variation and, at higher latitudes, a seasonal variation. A high cloud temperature requires larger particle size than a low cloud temperature for the same effect. This should be kept in mind when a statistical analysis of rainfall data is made.

The calculations terminated with a drop diameter of 60μ, which is far from the typical raindrop size of 1,000–2,000μ. As indicated in Fig. 1, the drop has already fallen some hundred metres, and in order to grow to raindrop size it must fall very many thousands of metres. A cloud of this depth will probably produce rain without any help. Simple scavenging is therefore scarcely the way meteor particles work.

There seem, however, to be more potentialities for influencing weather situations which in any case would produce rain. In order to discuss this problem, we may divide the development of a rain cloud into suitable stages. First comes the build-up of the cloud, when the small cloud droplets are formed. Then follows the ripening stage, during which aggregation and larger droplet formation take place. The third stage starts when updraught and condensation are fully developed and drop formation occurs rapidly owing to some kind of chain reaction, so that rain results.

Meteor collection will of course not have any influence whatsoever during the rainfall stage, because raindrops are formed in any event. But during the ripening stage the very thing is happening that meteor particles may initiate. They may therefore shorten this stage somewhat. The meteors may even work as ripening agent during the build-up stage, so that the total time from the cloud starts to form until rain starts to fall may be shortened considerably.

This hypothesis implies several possibilities for extra rain production, depending on the thermodynamical conditions for cloud formation. Where the clouds are formed in some daily cycle, and the resources of energy and moisture are not otherwise limited, the extra time added to the rainfall stage will increase the total amount of precipitation. Where the resources are limited in such a way that one cloud has a certain life-cycle during which it drains a certain area for energy and moisture, but at the same time suppresses cloud formation over a larger area by subsidence, the shortened life-time will give other clouds better opportunities to grow into rain clouds afterwards. More rain will fall because more cloud cycles are completed.

In a number of cases the cloud development stops without entering the rainfall stage. For clouds about to give precipitation, the extra push which meteor particles possibly give may bring the clouds into the rainfall stage. In such cases rain clouds are formed which would otherwise not have been formed. One may speculate on whether this can even cause the further development of weather systems which would otherwise subside.

The computations presented indicate that meteor particles may act as raindrop initiators in clouds by the simple process of collision with cloud droplets. The semi-theoretical formulæ used indicate that a lower size limit for this effect exists close to 10μ diameter. Combined with an upper size limit for particles occurring after a meteor shower of about 10μ, this may give a narrow size range for drop-forming particles. The hypothesis therefore supports Bowen's findings by statistical methods.

It is an open question if such an influence will increase the rainfall over a long period. Rainfall peaks on certain days may drain the moisture sources somewhat and cause reduced precipitation the following days. The mean rainfall curve for the world presented by Bowen really seems to suggest this. It is interesting to note that such an effect would tend to suppress the effect of possibly active nuclei after the first front of particles has arrived and make rainfall peaks sharper than the initiating meteor particle peaks.

The hypothesis outlined in this article lends itself to experimental tests, and it is to be hoped that such work will be taken up.

CONTROL OF INTRODUCED DEER IN NEW ZEALAND

By M. J. DANIEL

Forest Research Institute, New Zealand Forest Service, Rotorua

THE situation that exists to-day in New Zealand with regard to the many species of introduced mammals must surely be unique. Excluding the introduction in the fourteenth century of the Polynesian rat (*Rattus exulans*) and the Polynesian dog (*Canis familiaris*) by the Maori settlers, between 1779 and 1913 no less than 51 species of mammals were introduced[1]. Of these, only about 30 species became established[1]. These include 10 species of deer, which have no natural predators and, in contrast to many other parts of the world, do not seem to be limited by climatic factors. For these reasons the deer have attained pest proportions.

The red deer (*Cervus elaphus*), with more than a hundred liberations[2], is the most widespread over both islands and causes the greatest economic concern. Other species causing extensive damage to watershed protection forests and to pastureland are the Japanese deer (*Cervus nippon*) and the fallow deer (*Dama dama*) respectively.

During 1851–1930 the red deer was afforded partial or complete protection in most areas of the Dominion. As early as 1922, botanists and foresters were becoming gravely concerned at the rapid increase of the herds and of the damage being caused in watershed protection forests and planted pine forests[3]. Protection was altogether removed in 1930, and deer control was undertaken by professional hunters. Since then between 2–3 million deer have been shot by these hunters and by sportsmen[2].

The damage caused by deer in indigenous watershed protection forests, planted pine forests and in the vulnerable montane scrublands and sub-alpine tussock grasslands has been well documented by such botanists as Cockayne[4] and Zotov[5] and, more recently, by the forest ecologists carrying out the national forest survey[6–8]. This animal problem not only involves the several species of deer, however. Chamois (*Rupicapra rupicapra*), Himalayan thar (*Hemitragus jemlaicus*), pigs, goats, hares, rabbits and opossums are also very serious pests in some places. The last-named species, the Australian brush-tailed opossum (*Trichosurus vulpecula*), was introduced and liberated in many places during 1858–1921 for skin production, and it spread rapidly. It appears that by itself the opossum does not constitute a threat to the indigenous forests[9]. But when these canopy feeders are present in forests already containing numbers of ground browsers such as deer, goats and pigs, the resulting damage is very serious[8]. Some idea of the numbers of opossums in the forests can be obtained from the fact that 12 million were killed in the 10-year period 1951–61.

Although the large herds of the 1930's and 1940's have been reduced by hunting pressure, the deer problem in many parts of the country is still acute. It can be seen from Fig. 1 that the deer are widely distributed in New Zealand. The areas marked free of deer are either those most intensively farmed or otherwise unsuitable, such as the high glaciated region around Mt. Cook (3,860 m.).

The use of 1080 (sodium fluoroacetate) for domestic rodent control[10,11], the control of field rodents and coyotes in North America[12,13] and the control of rabbits in Australia and New Zealand is well documented[14–16]. This attempt by the New Zealand Forest Service to control deer with 1080 is a new use for this versatile poison, although Rudd and Genelly report[17] that about 160 mule deer were probably poisoned by 1080 laid in grain for squirrels in California.

In New Zealand as early as 1927 small trials were held to determine whether fallow deer could be controlled by using strychnine in salt-licks and in carrot. The results were inconclusive[1]. In 1956 it was found that red deer would accept branches of palatable trees sprayed with 1080 solution.

In 1957 a series of baiting trials was started on fallow deer[18], in the Caples Valley of South Island (Fig. 1). On either side the mountains rise to over 1,880 m., the dominant vegetation being *Nothofagus* forest. The valley floor has several grassy clearings which, being used by the deer, were ideal for such trials. More than 80 baiting trials were carried out in 14 months using root vegetables, fresh and dried fruits, hay, natural vegetation, salt-licks and lures. Although a statistical analysis of the trials cannot be made, it appeared that carrots and natural vegetation were the most acceptable. The majority of the baits were disturbed or eaten by opossums. The lures, such as oil of lime and aniseed were effective for the opossums but not for the deer.

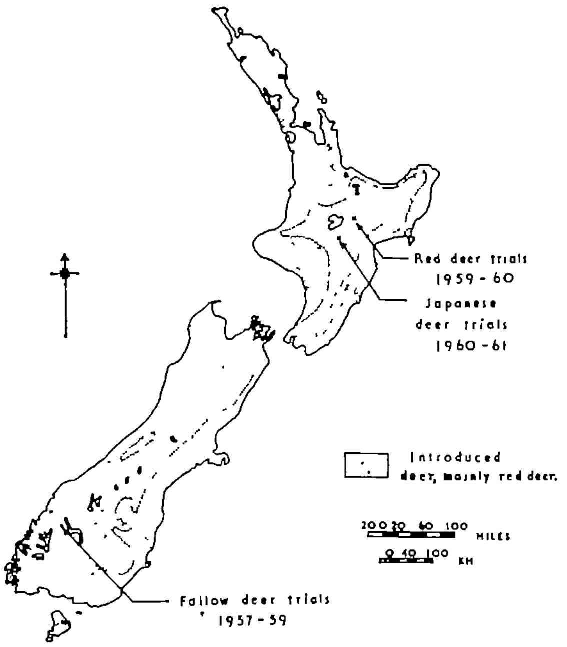

Fig. 1. Distribution of introduced deer in New Zealand and location of poison trials, 1957–61 (modified from Wodzicki, 1961)

Following these trials, three poison trials using 1080 in 1,100 kgm. of chopped raw carrot at a rate of 0·23 kgm. per 227–455 kgm. of bait were carried out. For effective distribution the bait was dropped by plane over the clearings. The total number of deer found dead was 247, representing kills of 60–90 per cent of the deer on the clearings at the time. None of the deer was found more than 280 m. from the poison line. The amount of bait in the rumen varied from a trace to more than 1·80 kgm. In the second poison trial, in which 70 deer were killed, the mean amount of bait eaten by the bucks was 1 kgm. and for the does only 0·5 kgm. Bleeding at the nostrils occurred in 33 per cent of the bucks and 10 per cent of the does. This difference is significant at the 2½ per cent level of probability. Taking the lethal dose for deer to be similar to that for sheep, 0·45 mgm. per 1 kgm. of body-weight, and the average weight for this species as 45–55 kgm., the amount of 1080 for a lethal dose would be 20–25 mgm. At the dosage used this amount would be contained in about 40 gm. of bait[19]. Some of the deer had consumed more than 30 lethal doses, causing severe bleeding at the nostrils and death within 2–3 hr. without convulsions. An examination of heart, liver and muscle tissue was made, and it was concluded that secondary poisoning from human consumption of deer meat poisoned with 1080 at the level used could not occur[19]. Other mammals poisoned in the trials included several red deer, rabbits, hares and opossums. No native birds were found dead.

These trials were followed by similar ones in the North Island on red and Japanese deer. Those on red deer[18] were held on the eastern boundary of Kaingaroa planted pine forest (Fig. 1). Poisoned carrots were distributed from a truck along several miles of road with scrub on one side and ponderosa pines on the other. A total of 61 red deer were poisoned in 6 trials. Success varied from 0 to 75 per cent in the trials. Disturbance by shooters and abundant spring growth lowered the expected kill. The trials on Japanese deer[20] were held along grassy river terraces and in the adjacent *Nothofagus* forest about 940 m. up on the central plateau of North Island (Fig. 1); 192 deer were poisoned on the grassy clearings and 42 in the forest. Probably many more were poisoned but not found. These represent about 80 per cent of the deer feeding on the areas at the time. This was the first indication that deer could be poisoned in indigenous forest.

From these trials considerable experience has been gained in handling and distributing large quantities of poisoned bait by plane. The knowledge that concentrations of deer on grassy clearings can be effectively and economically reduced is valuable. Further trials will have to be undertaken on goats, opossums and deer to determine whether a root bait or a pollard bait is the most effective for the different seasons in various localities. Also, knowledge of movements and concentrations of deer when attained will be of immense help in poisoning operations against deer in densely forested country. The question as to whether deer, goats, pigs and opossums can be effectively controlled by these methods, in many hundreds of square miles of mountainous and forested country, remains the problem of the future.

OBITUARIES

Colonel P. A. Clayton

COLONEL PATRICK ANDREW CLAYTON died on March 17 at the age of sixty-five. He was educated at University College School and went on to the University of London. But, in 1915, his studies were interrupted by the First World War and, with the Royal Field Artillery, he saw service in Greece and Turkey. On demobilization, he joined the Survey of Egypt and his next few years were spent mapping the plateau of El-Tih in Central Sinai, which, rather unexpectedly, was found to attain a height of more than 5,000 ft. In 1927, he became surveyor to a Boundary Commission on the Egypto-Italian frontier and demarcated it by a line of 187 cairns (replaced in 1938 by concrete pillars) running south for 200 miles from the Mediterranean deep into the Sand Sea.

Later in that year he was associated in the contouring of the great Qattara Depression which his colleague G. F. Walpole had just shown to lie below sea-level and so to be a potential source of hydro-electric power. Next, Egypt's southern frontier claimed his attention and, in 1930–31, he extended the Nile Valley triangulation net for 350 miles to the extreme south-west corner of Egypt at 'Uweinat, observing 143 stations in 171 days. At 'Uweinat, he found and repaired a car which Major Bagnold's private expedition had abandoned and filled it with starving refugees, mostly women and children, who had already covered 200 waterless miles in a panic-stricken flight from the Italian bombing of Kufra Oasis. For their rescue King Fuad rewarded him with a gold medal *pour actes méritoires*. Among these activities Clayton found time for a bold reconnaissance of the west side of the Gilf Kebir, a great sandstone plateau the east side of which had first been sighted by Prince Kamal el-Din in 1926. A cave with rock paintings was found and, from the Sheb-Tarfawi area 100–150 miles west of Wadi Halfa, he brought back numerous querns, hand-axes and pottery sherds of neolithic and protodynastic age.

In 1932, Clayton took leave to accompany a private ground and air reconnaissance of the Gilf Kebir. His companions were the Hungarian Count Almasy, Sir Robert Clayton East Clayton (no relation) and Squadron-Leader Penderel. From the air various wadis were seen to dissect the plateau, and Almasy at once proclaimed that they had found "the lost oasis of Zarzura". In 1933, back with the Survey, Clayton set out from 'Ain Dalla and not only succeeded in reaching one of these wadis, Wadi 'Abd el-Malik, on the ground, but also actually made his way through the whole Sand Sea to Kufra. This passage was to prove of inestimable value to the Long Range Desert Group in the War to come.

That same year Orde Wingate had set out from Dakhla Oasis with a camel caravan to find Zarzura. After days of battling through a monotonous landscape of sand he at last sighted something dark on the western horizon which mirage exaggerated to a row of palms. But, as he got nearer, it dwindled again until it became a model *T* car, one of Clayton's, perched on a dune. There was a camp beyond but the mercurial Wingate never saw this. Instead, he turned straight back and made for Dakhla. His tracks, however, gave him away and that night the pursuing Clayton overtook him and made friends.

On the same expedition, scattered in the troughs of the Sand Sea, near the western frontier, Clayton picked up many tektites, weathered lumps of silica glass. This excited so much interest that a second trip was made to the site in company with Dr. L. J. Spencer and Dr. O. H. Little, the head of the Egyptian Geological Survey. Many museum specimens were brought in, some of which had been fashioned by Acheulean man into beautiful transparent hand-axes.

Italy's attack on Ethiopia in 1936 sounded a warning note, and both Clayton and Walpole were sent to commence what was to end up as a comprehensive survey of the 50,000 square miles of desert over which the Eighth Army and the Afrika Corps were to meet in battle. That, however, was accomplished by other hands. 'Egyptianization' overtook both Clayton and Walpole and they left the Survey in 1938—Clayton to join the Survey Department of Tanganyika.

In 1940 he was recalled from this to join Bagnold's Long Range Desert Group and was soon in his beloved Libyan Desert again, thrusting through the gap discovered in 1933 to raid the Italian communications between Jalo and Kufra. In January 1941, in command of *G* and *T* patrols of the Long Range Desert Group, he made contact with a small Free French force under Col. d'Ornano. On January 11 they raided the oasis of Murzuk, 1,100 miles from their base in Cairo. Three aircraft were destroyed on the ground; but two of the raiders were killed, one of them d'Ornano. A bloodless victory was scored next day at Traghen; but other posts proved too strong and had to be left alone. On January 31, Clayton with *T* patrol met a slightly stronger Italian motorized party at Gebel Sherif, 60 miles south of Kufra. The intervention of three Italian aircraft turned the tide of battle, and three of his cars were set on fire Clayton with two men were wounded and taken prisoner.

While a prisoner in Italy Clayton learnt of his promotion to Lieut.-Colonel with the award of a D.S.O. The Royal Geographical Society also honoured him with its Founder's Medal in 1941 "for surveys in the Libyan Desert and his application of this experience to desert warfare".

With the Italian collapse in 1943 Clayton escaped but was soon retaken. He spent the rest of the War in a German Stalag where his great skill as a draughtsman made him popular as a forger of passes for would-be escapers. After the War he was employed by the War Office in their Hirings Department, first as a serving officer and, after his retirement in 1953, as a civilian. He died on the day of his namesake, St. Patrick, March 17. His widow and a son survive him.

G. W. MURRAY

Mr. C. L. Hinton

CYRIL LANGLEY HINTON, formerly superintendent of research of the British Food Manufacturing Industries Research Association, died on March 15, at the age of seventy. He had retired from the Association's staff at the end of 1958 after nearly thirty-nine years of service.

Hinton was one of the three original members of the staff, the other two being the director, T. Macara, and L. E. Campbell. At that time the Association was connected primarily with the confectionery and jam trades, and his work on variations in the melting point of cocoa-butter, on the manufacture of fondant, and on the composition of fruits and jams will be long remembered. He became an authority on sugar analysis and was the author of the Department of Scientific and Industrial Research Food Investigation Special Report No. 48 on pectin and of a paper on the polyuronides in the *Annual Review of Biochemistry*, 1951. At various times he was chairman of the Technical Commission of the International Association of Confectionery Manufacturers, and therefore largely responsible for the work leading up to the publication of *Methods of Analysis* by that body. For many years he was a member of the Society for Analytical Chemistry's Sub-Committee for the determination of metallic impurities. He had a flair for foreign languages and became an acknowledged authority on international food legislation.

In his retirement C. L. Hinton found much to occupy his time and was author of the first number in Food and Agriculture Organization Food Additive Control Series *Food Additives Control in the United Kingdom*. He was up to the time of his death engaged on another work for the Food and Agriculture Organization on the utilization of sugar.

U.S. NATIONAL ACADEMY OF SCIENCES

New Officers

PROF. FREDERICK SEITZ, head of the Department of Physics in the University of Illinois, has been elected president of the U.S. National Academy of Sciences in succession to Dr. Detlev Bronk, president of the Rockefeller Institute, who has held office as president of the Academy for an unprecedented period—since 1950.

Two new members of Council of the Academy have also been elected: Dr. Roger Revelle, on leave from the University of California at San Diego to serve as science adviser to the Secretary of the Interior; and Dr. W. Barry Wood, jun., of the School of Medicine, Johns Hopkins University.

New Members

The following new members of the Academy have been elected:

Prof. L. H. Aller, professor of astronomy, University of Michigan;

Prof. W. A. Arnold, principal biologist, Oak Ridge National Laboratory;

Prof. V. C. Boekelheide, professor of chemistry, University of Oregon;

Prof. R. W. Briggs, professor of zoology, Indiana University;

Prof. H. Brooks, professor of applied physics, and dean, division of engineering and applied physics, Harvard University;

Prof. J. M. Buchanan, professor of biochemistry and head of the division, Massachusetts Institute of Technology;

Prof. G. F. Chew, professor of physics, University of California;

Prof. A. H. Coons, visiting professor of bacteriology and immunology, Harvard Medical School, and career investigator of the American Heart Association;

Prof. M. Doudoroff, professor of bacteriology, University of California, and professor, Miller Institute for Basic Research in Science;

Dr. A. E. Emerson, professor of zoology at the University of Chicago, and research associate, American Museum of Natural History and Chicago Natural History Museum;

Dr. S. E. Forbush, chairman, section of theoretical geophysics, Department of Terrestrial Magnetism, Carnegie Institution of Washington;

Dr. H. Friedmann, director, Los Angeles County Museum of History, Science, and Art;

Prof. R. M. Garrels, professor of geology, Harvard University;

Prof. D. A. Glaser, professor of physics, University of California, Berkeley;

Prof. D E. Green, co-director, Institute for Enzyme Research, and professor of enzyme chemistry, University of Wisconsin;

Prof. P. Herget, professor and director of the Observatory, University of Cincinnati;

Prof. H. L. James, professor of geology, University of Minnesota;

Prof. M. D. Kamen, professor of biochemistry and chairman of the Department of Biophysics, Brandeis University;

Prof. S. S. Kety, professor of psychiatry and psychiatrist-in-chief, Johns Hopkins University;

Prof. P. J. Kramer, James B. Duke professor of botany, Duke University;

Prof. Chia-Chiao Lin, professor of mathematics, Massachusetts Institute of Technology;

Prof. F. A. Long, professor of chemistry, Cornell University;

Prof. G. J. F. MacDonald, professor of geophysics, University of California, Los Angeles, and staff associate, Geophysical Laboratory, Carnegie Institution of Washington;

Prof. G. W. Mackey, professor of mathematics, Harvard University;

Prof. G. A. Miller, professor of psychology, Harvard University;

Prof. C. B. Morrey, jun , professor of mathematics, University of California, Berkeley;

Prof. A Pais, professor of physics, Institute for Advanced Study, Princeton;

Prof. W. H. Pickering, professor of electrical engineering, and director, Jet Propulsion Laboratory, California Institute of Technology;

Prof. I. Rouse, professor and chairman of the department of anthropology, Yale University;

Prof. E. L. Smith, professor of biochemistry and research professor of medicine, University of Utah;

Dr. P. Sporn, president and director, American Electric Power Co.;

Dr. T. D. Stewart, curator, division of physical anthropology, U.S. National Museum;

Prof. W. L. Straus, jun., professor of anatomy and physical anthropology, Johns Hopkins University;

Prof. S. Warren, professor of pathology, Harvard Medical School, and chief pathologist, New England Deaconess Hospital;

Prof. J. D. Watson, professor of biology, Harvard University.

Medal Awards

The Academy has awarded the following medals:

The *J. Lawrence Smith Medal* to Prof. Harold C. Urey, professor-at-large in the University of California in San Diego, "for outstanding achievement in the investigation of meteoric bodies".

The *Charles Doolittle Walcott Medal* to Dr. A A. Öpik, since 1947 Cambrian stratigrapher and palæontologist in the Federal Bureau of Mineral Resources, Canberra, "for outstanding contribution to the knowledge of Cambrian geology and palæontology".

The *Public Welfare Medal* to Dr. J. A. Shannon, director of the National Institutes of Health, Bethesda, Maryland, "for eminence in the application of science to the public welfare".

The *Jessie Stevenson Kovalenko Medal* to Prof. G. H. Whipple, professor of pathology and dean emeritus in the University of Rochester School of Medicine and Dentistry, "for contributions to medical knowledge".

The *Kimber Genetics Medal* has been awarded to Dr. M. Demerec, formerly director of the Department of Genetics of the Carnegie Institution of Washington, "in recognition of his many contributions to the understanding of the genetics of various plants, *Drosophila*, bacteria and viruses, and especially for his leadership in the investigation of unstable genes, the mutation process, genetics of micro-organisms and the genetic fine structure of the gene".

NEWS and VIEWS

Foreign Members of the Royal Society

The following have been elected foreign members of the Royal Society of London: Prof. D. Bovet, head of the Laboratory of Therapeutic Chemistry, Istituto Superiore Di Sanita, Rome, distinguished for his contributions to therapeutic chemistry; Dr. F. A. Lipmann, member of the Rockefeller Institute, New York, distinguished for his contributions to biochemistry, especially to enzymology and cell metabolism; Prof. J. R. Oppenheimer, director and professor of physics, Institute for Advanced Study, Princeton, distinguished for his contributions to modern quantum theory; Prof. V. Prelog, dean of the School of Chemistry, Swiss Federal Institute of Technology, Zurich, distinguished for his contributions to the development of modern stereochemistry.

Rothamsted Experimental Station:

Dr. G. W. Cooke

The Lawes Agricultural Trust Committee has appointed Dr. G. W. Cooke, head of the Chemistry Department at Rothamsted Experimental Station since 1956, deputy director of the Station in succession to the late Dr. A. Muir (see *Nature*, 194, 135; 1962). His work and writings have established him as the acknowledged authority on crop nutrition, a subject to which his recent book, *Fertilizers and Profitable Farming*, was a notable contribution. Cooke's training and interests give him an unusual ability to combine science with practice. The son of a Nottinghamshire farmer, he went from Loughborough Grammar School to the University College at Nottingham, where he graduated in chemistry in 1937. After a year in which he did biochemical research with Prof. J. M. Gulland at Nottingham, he obtained a research scholarship of the Ministry of Agriculture and Fisheries and with this went to work with Dr. E. M. Crowther at Rothamsted in 1938, where he was appointed to the staff in 1941. He first studied chemical methods of measuring the proportion of plant nutrients in soil that is available to plants, but during the War and afterwards, in collaboration with the Agricultural Advisory Services, he organized an extensive series of field experiments with phosphatic fertilizers. These had the dual purpose of finding alternatives to superphosphate when this was scarce, and of improving the use of fertilizers. Other experiments showed the benefits to be gained with some crops from placing the fertilizer near to the seed or roots. His more recent work has been concerned mainly with nitrogen fertilizers, comparing different forms and finding the best time to apply them. Along with these immediately practical problems, he has also done much to elucidate the form in which plant nutrients occur in soil and the changes they undergo there.

Chemistry at Glasgow :

Prof. D. W. J. Cruickshank

The University Court has recently founded a third chair in chemistry and named it after Joseph Black, who was the University's lecturer in chemistry during the period 1756–66. The first occupant of the chair, as from September 1, is to be Dr. D. W. J. Cruickshank, who, after taking a London degree with honours in engineering from Loughborough College in 1944, and then engaging in work for the Services, became research assistant in 1946 in the Chemistry Department, the University of Leeds. This directed his interests towards the potential applications of mathematics to chemistry and led to his spending three years at Cambridge, where he gained his B.A. in 1949, became a wrangler in Part 2 of the mathematical tripos and in 1950 gained distinction in Part 3. He then returned to Leeds as lecturer in chemistry and, in 1957, became reader in mathematical chemistry. He was awarded the degrees of Ph.D. at Leeds in 1952, and M.A. and Sc.D. at Cambridge in 1954 and 1961, respectively. Dr. Cruickshank's earlier work was in X-ray crystallography. In determining the structures of molecules from the X-ray diffraction patterns given by their crystals, the observational data, though of limited accuracy, are usually in large numerical excess over the structural parameters to be derived. Thus, mathematical and computational techniques can be of immense value in indicating best values for the parameters and in assessing their precision. In this field Cruickshank did pioneer work from the early days of the *Mark I* computer at Manchester, and his numerous papers have won him international reputation. His work on the thermal movement of molecules in the solid state is a beautiful example of combined X-ray and infra-red spectroscopic methods. Recently he has also turned his attention to the electron-diffraction method for studying molecular structure in the gaseous state, and more particularly to the quantum theory of chemical bonding.

European Launcher Development Association

In a written answer on April 16 the Minister of Aviation, Mr. P. Thorneycroft, stated that the Convention for the establishment of a European Launcher Development Association, drafted at the Lancaster House Conference last December, had now been signed by the Governments of Australia, Belgium, France, the Federal Republic of Germany, Italy, the Netherlands and the United Kingdom. The initial programme, which was now proceeding, provided for development of a launcher; using *Blue Streak* as the first stage and a French rocket as the second stage. The third stage would be developed under the leadership of the Federal Republic of Germany. The design, development and construction of the first series of satellite test-vehicles would be carried out under the leadership of the Italian Republic, the equipment for the ground guidance stations under the leadership of Belgium, and of the long-range telemetry links under the leadership of the Netherlands. Development firings of the first stage and of the complete three-stage launcher would be carried out at Woomera. In a written answer on April 17, Mr. D. Freeth stated that the Preparatory Commission for the European Space Research Organization had proposed that an inter-governmental conference should be held in May for signature of a Convention and other documents. It was not proposed that any of the establishments should be in the United Kingdom.

Nuclear Reactors for British Universities

In a written answer on April 17 the Parliamentary Secretary for Science, Mr. D. Freeth, said that one low-power nuclear reactor was being built for the use of the Royal College of Science and Technology, Glasgow, all the Scottish universities and Queen's University, Belfast. The Government had agreed in principle to make grants for the provision of two further reactors, one in Lancashire and one in the London area. A request for a second reactor at the University of London had been deferred and several universities had been told that there was no early prospect of grants being made. A grant of up to £255,000 had been made for the reactor for the Scottish universities and he hoped that the two further grants, totalling more than £500,000, would be announced later this year.

Air Pollution by Diesel Fumes

The Diesel Fumes Bill, which received a second reading in the House of Commons on April 6, was withdrawn after the Parliamentary Secretary to the Ministry of Transport, Mr. John Hay, assured the House that the Bill added little to the wide powers which the Ministry already possessed to deal with the problem under Section 64 of the Road Traffic Act. Already the Minister had power to prescribe densities of smoke and visible vapour and to prescribe that additives must be used in all Diesel engines. However, he suggested that Mr. R. Speir should propose an amendment to the Road Traffic Bill with the effect of Clause 3. This Clause allows Diesel-engined vehicles not already subject to special provisions about inspection to be tested at the roadside when reliable measurement is possible. Earlier, Mr. Hay referred to the very wide programme of research into air pollution which had been and was still being carried out by the Medical Research Council. Research work has not revealed any specific threat from Diesel fumes alone in the concentration in which they are found in city streets. Petrol engine exhausts are likely to be the main hazards, and the results of research in the United States in such fields are being watched as the problem there is far more acute. Mr. Hay repeated that extensive tests by the Department of Scientific and Industrial Research have established that a well-maintained and properly driven Diesel-engine vehicle does not normally emit any more than a slight puff of smoke. Neither fuel additives nor filter devices are as fruitful a field for reducing dark smoke as proper maintenance and adjustment of the engine. Mr. Hay said that during 1960–61 there were 1,875 prosecutions, and it was difficult to ensure that enforcement of the existing powers could be much improved although various possibilities were being examined. Furthermore, the law has recently been strengthened by a new regulation which from January 1, 1962, forbids the misuse by the driver of a Diesel-engined vehicle of the excess-fuel device, which in certain circumstances can provide extra power at the cost of black smoke. The regulation also requires control for the device on new vehicles to be such that it cannot be operated when the vehicle is moving and older-vehicles have to be modified in this respect by July 1.

The British Aerosol Manufacturers' Association

The first annual report of the British Aerosol Manufacturers' Association, covering the year ended December 31, 1961, records the provisional approval of a draft specification for metal containers for aerosol dispensers (Pp. 12. London: British Aerosol Manufacturers' Association, 1962). These specifications are to be considered by a technical committee of the British Standard Institution before circulation to industry for comment. The Executive Committee also recommended during the year that all aerosol containers filled by members should bear precautionary wordings. Detailed statistics of the aerosols filled by member firms during 1960 and 1961 have been collected and are listed. It is still open for discussion whether membership of the Association should be extended to include manufacturers of equipment and machinery.

Pollution by Agricultural Wastes

Although pollution of rivers is usually attributed to sewage or to discharges from factories, agricultural wastes cause trouble in many areas. This is emphasized in the seventh annual report of the Tweed River Purification Board, where it is pointed out that farm effluents, such as drainage from silage pits or piggeries, may be very strong and may overload a sewage works if they are discharged to a sewer (Pp. 46. Newtown St. Boswells: Tweed River Purification Board, 1961). The presence of traces of toxic insecticides or herbicides can also interfere with biological processes of sewage treatment. In an appendix to the report, information is given on the volume and composition of waste waters from a relatively new and rapidly expanding agricultural industry—poultry packing—obtained as the result of an investigation at a packing station in south-east Scotland. To give some idea of their polluting character, they are compared with those from a slaughter-house; on the basis of the demand for biochemical oxygen, the waste liquor from processing 12·5 turkeys or 32·3 chickens is equivalent to that from slaughtering one pig.

The Case Against Decimalization

Prof. A. C. Aitken, in a pamphlet entitled *The Case Against Decimalisation*, presents very skilfully the case against decimalization in general, starting with a lucid and cogent historical review (Pp. 22. Edinburgh and London: Oliver and Boyd, Ltd., 1962. 2*s*. 6*d*.). He is less persuasive, however, in arguing for the duodecimal system, adoption of which in coinage, with a pound of twelve shillings, he suggests. He claims that this is a much more efficient system than the decimal system and that its adoption offers substantial advantages on practical as well as on arithmetical grounds.

Committee on the Problem of Noise

The Committee set up in April 1960 by the Minister for Science under the chairmanship of Sir Alan Wilson has now fixed May 15 as its closing date for receiving written evidence concerning the nature, sources and effects of the problem of noise, and further measures which can be taken to mitigate it. Organizations and persons who intend to submit written evidence should send it to the secretary of the Committee, Mr. R. S. Matthews, at the Ministry of Health, Savile Row, London, W.1.

The Ciba Foundation

The report of the Ciba Foundation for 1961 records the holding of seven general international symposia on very varied subjects as well as a colloquium on the detection and assay of hormones by immunochemical means, and the fourteenth meeting in the series of colloquia on endocrinology. Four study groups were arranged, dealing with progesterone and the defence mechanism of pregnancy; biological activity of the leucocyte; the mechanism of action of water-soluble vitamins; and curare and curare-like agents; while seven discussion meetings were also arranged. At the three Dunant Coterie dinners the subjects of discussion included the Yeti 'scalp', medical education and research in Africa and Asia, the barrier function of the small intestinal mucous membrane, and some implications of the use of food additives. In the winter a series of film sessions, besides prize-winning medical films from abroad, French films on tropical medicine and an international selection of recent medical films, were shown. The thirteenth Ciba Foundation lecture, delivered by Prof. E. Katchalski, dealt with synthetic macromolecules as protein models. Three Anglo-French bursaries were awarded by the British Selection Committee and two by the French Selection Committee. Besides lists of publications in print or in preparation and accessions to the library, full details of the symposia and colloquia are appended to the report.

Scottish Field Studies Association

It is regrettable that the strong student support given to the Scottish Field Studies Association has not been matched by similar financial support. The annual report describes the fine work the Association is doing in Scotland, and makes it clear that no real progress can be made until the Association has a Field Centre of its own and enough money to make tidy administration possible (*The First Ten Years*. By B. W. Ribbons. Annual Report, 1961. Glasgow: The Scottish Field Studies Association). The modest sum required would not seem to be beyond the resources of industrial and charitable organizations in Scotland. Details of the courses available in 1962 and how help can be given to the Association are obtainable from the Secretary, 179 West Regent Street, Glasgow, C.2.

Sir John Hammond: a Pioneer in Modern Farm Animal Breeding

The February issue of *Animal Production* (4, Part 1; 1962) is devoted to the jubilee of Sir John Hammond, the pioneer of the modern outlook on the breeding of farm animals in Britain and a world leader in the physiology of fertility. Elizabeth O. Cockburn has contributed a most interesting account of his career and there is a characteristic photograph of him arriving with his bicycle for the dinner in his honour. Steeped in agriculture and of an old-established veterinary family in the eastern counties, he intended to qualify and become a third generation in the profession, but not having done Latin at school, the need to study it for the entrance examination led almost fortuitously to a change in programme and he entered the then new Agricultural Department of Cambridge, with results that have so fortunately influenced much of the quality of farm livestock. To-day, Hammond's pupils and collaborators are found in all or most of the countries with strong livestock interests. The achievement in 1958 of the breeding of ten million cattle by artificial insemination under the auspices of the British Milk Marketing Board can be traced to his pioneer activities. No less remarkable is the wide range of physiology explored and developed from Cambridge in the course of researches on the reproductive system, following, of course, on the foundations laid by the late F. H. A. Marshall. A selected bibliography accompanies this biographical note. The *Journal of Reproduction and Fertility* (3, No. 1; 1962) is concurrently marking Hammond's contribution to the study of reproductive physiology.

Irish Journal of Agricultural Research

The first number of the *Irish Journal of Agricultural Research*, issued by An Foras Talúntais (Agricultural Institute), Dublin, which became available in 1961 (1, No. 1; October 1961. Pp. 82. Published twice yearly. Annual subscription, 20*s*.; 3 dollars. Single number, 10*s*.; 1.50 dollars), provides a means whereby research workers in all branches of agricultural science including soils, plants and animals, engineering, economics and sociology can publish the results of their researches and will appeal primarily to scientific workers in agriculture. The first number contains papers covering a wide field ranging from soil analysis, cereal root eelworm, tomato culture, management of bogland, supplementary feeding of lambs and marketing of agricultural output.

The British Journal of Social and Clinical Psychology

The British Journal of Social and Clinical Psychology is to be devoted to social psychology and abnormal and clinical psychology (1, Part 1; February 1962. Pp. 80. Edited by Michael Argyle and Jack Tizard. Published three times per annum. Subscription price per volume, 50*s*.; 8.50 dollars. Separate parts, 20*s*.; 3.50 dollars. London and New York: Cambridge University Press). Papers on industrial, gerontological and sociological matters, such as delinquency, are to be included so long as they deal with psychological questions. This seems an excellent programme, and the first issue sets a good example which it is to be hoped will be followed by those to come. There are two papers on schizophrenia, one on personality questionnaires, another on space concepts in the mentally subnormal. Others are on institutionalism in mental hospitals, maternal attitudes to child socialization, and the attitudes of teachers to education. There is also a study of performance of tests of memory and learning in elderly patients. There are to be book reviews, and the books reviewed in this issue are given adequate notices. In the past, journals of this nature have tended to be either entirely clinical or else devoted to pure psychology, so that papers on the application of such things as psychological tests on abnormal patients have been pushed into odd corners. Now, with this new journal, they will be certain of reaching those who are interested in them, and the writers will not feel that they are being published on sufferance by editors who would prefer to devote their space to different matters. Everyone interested in psychology and psychiatry will welcome this journal and hope that it will have a long and successful career.

Association of Applied Biologists

The following honorary officers were elected for 1962–63 at the recent annual general meeting: *President*, Prof. H. G. H. Kearns; *Vice-President*, Dr. J. S. Kennedy; *President-Elect*, Prof. A. H. Bunting; *Treasurer*, Dr. F. Raw; *General Secretary*, Dr. F. T. Last (Glasshouse Crops Research Institute, Rustington, Littlehampton, Sussex); *Programme Secretary*, M. J. Way; *Editor*, R. W. Marsh; *Assistant Editor*, Dr. I. Thomas. New members of Council elected were: Prof. J. Colhoun, Dr. S. H. Crowdy, J. E. E. Jenkins, R. M. Lister and A. H. Strickland.

National Vegetable Research Station Association Scholarship

A HEINZ scholarship tenable at the National Vegetable Research Station, Wellesbourne, Warwick, was announced in *Nature* of April 28, p. 339. Another scholarship, which, apart from the name, is identical, is also tenable at the Research Station. This scholarship has been established by the National Vegetable Research Station Association (a body of growers and others interested in horticulture). Further information can be obtained from the Secretary of the Station. Closing date for applications is May 31.

University News: Cambridge

THE following have been elected to Fellowships in Churchill College:

Title A: Dr. D. B. A. Epstein, Trinity College, College lecturer and director of studies in mathematics; Dr. C. P. Wroth, Emmanuel College, University lecturer in engineering, College lecturer in engineering; G. R. Nicoll, University lecturer in engineering, College lecturer in engineering.

Title F (*Overseas Fellowships*): Dr. R. W. Clough, professor of civil engineering in the University of California (for 1963–64); Dr. J. A. K. Quartey, lecturer in chemistry in the University of Ghana (for 1963–65); Dr. G. Feinberg, assistant professor of physics in Columbia University (for 1963–64); Dr. R. Blankenbecler, assistant professor of physics in Princeton University (for 1963–64); Dr. J. Eells, jun., associate professor of mathematics in Columbia University (for 1963–64).

Announcements

MR. JOHN HEREWARD PITCHFORD, chairman and managing director of Ricardo and Co., Engineers, Ltd., has been elected president of the Institution of Mechanical Engineers in succession to Sir Kenneth Hague. Mr. Pitchford was elected a vice-president of the Institution in 1959, and he is also chairman of its General Purposes Committee.

DR. R. E. PARKER, lecturer in organic chemistry in the University of Southampton, has been appointed secretary and registrar of the Royal Institute of Chemistry, in succession to Dr. H. J. T. Ellingham.

THE 1962 Standards Laboratory Conference will be held at the Boulder Laboratories of the National Bureau of Standards, Colorado, during August 8–10. Further information can be obtained from Alfred E. Hess, Circuit Standards Division, National Bureau of Standards, Boulder, Colorado.

THE thirty-seventh annual conference of the Electrical Association for Women will be held in Buxton, Derbyshire, during May 14–16. Further information can be obtained from the conference secretary, Miss G. Shaw-Mackenzie, Electrical Association for Women, 25 Foubert's Place, London, W.1.

A SUMMER school, sponsored by the North Atlantic Treaty Organization, will be held in the University of Ghent during July 23–August 4. The topics to be treated concern the optical properties of semiconductors and insulators. Further information can be obtained from Prof. W. Dekeyser, Laboratorium voor Kristallografie en Studie van Vaste Stoffen, Rozier 6, Ghent.

Two postgraduate courses on "X-Ray Diffraction Techniques" and "Recent Advances in Non-destructive Testing" will be held in the Department of Metallurgy of the College of Advanced Technology, Birmingham, during July 9–13 and July 16–20, respectively. Further information can be obtained from Dr. I. G. Slater, Department of Metallurgy, College of Advanced Technology, Gosta Green, Birmingham 4.

A POSTGRADUATE course on "Nuclear Power" will be held in the Department of Mechanical Engineering, Imperial College of Science and Technology, commencing in autumn 1962 and lasting one year. The course will comprise lectures, practical work and a special project, and is intended for students holding a good honours degree in mechanical, civil, electrical or chemical engineering, or applied scientists who have graduated in physics or metallurgy. Further information can be obtained from the Registrar, Imperial College, London, S.W.7.

AN international symposium on "Food Regulations in Relation to International Trade", which will follow the first international congress of food science and technology, is to be held in London on September 24. Subjects under discussion will include: the present chaotic position; food-additive regulations; food-labelling regulations. Further information can be obtained from the the Honorary Secretary, The Food Group, 14 Belgrave Square, London, S.W.1.

THE 1962 national symposium of the Institute of Radio Engineers' Professional Group on Microwave Theory and Techniques will be held in Boulder, Colorado, during May 22–24. The programme will include ten technical sessions: microwave frontiers, theory, wave-guide properties; theory, wave-guide discontinuities; filters; high power; measurements; components; limiters; parametric amplifiers; future of microwave and solid state. Further information can be obtained from Mrs. Barbara Patterson, 1962 PGMTT National Symposium, Boulder Laboratories, National Bureau of Standards, Boulder, Colorado.

A SUMMER course on "Biological Servomechanisms", organized by the Massachusetts Institute of Technology, will be held at the Institute during July 9–20. The course will be divided into three sections: the general theory of dynamic feedback systems, linear and non-linear; the problem of modelling biological systems and interpreting their behaviour in terms of the general theory of dynamic systems; experimental sessions to demonstrate the behaviour of biological systems. Further information can be obtained from the Director of the Summer Session, Room 7–103, Massachusetts Institute of Technology, Cambridge, Massachusetts.

ERRATA. The title of the communication "Absorption-Elution Grouping of Modifications and Development of Bloodstains" by R. A. Outteridge (*Nature*, April 28, p. 385) should read: "Absorption-Elution Grouping of Bloodstains Modifications and Development".

IN the article entitled "Release of Hydrocyanic Acid from Crushed Tissues of All Stages in the Life-cycle of Species of the Zygaeninae (Lepidoptera)", by David A. Jones, John Parsons and the Hon. Miriam Rothschild, appearing in the January 6 issue of *Nature*, it is stated on p. 53, right-hand column, line 16, that "Blowfly larvæ . . . (were) found to be free of rhodanese activity". The authors state that the blowfly (*Calliphora vomitoria* L.) is, in fact, positive for rhodanese; unfortunately, the authors' proof did not reach *Nature* office in time for this correction to be made.

SHORTAGE OF ENGINEERS IN THE UNITED STATES

THE U.S. Engineering Manpower Commission reported that, for the fourth consecutive year, college freshman enrolments in engineering in the autumn of 1961 declined compared with the year before (*Interim. Sci. and Tech.*, February, 1962). The percentage of engineers in the total college population is also declining. In 1957, engineering students numbered 10·8 per cent of the total freshman class; in four years, this has dropped to well below 7 per cent. The result, according to the Commission, is that "the nation will have to make do with fewer engineering graduates for the next four to six years". Engineering graduates have fallen from 52,700 in 1950 to 37,800 in 1960. It now appears that, by 1965, the annual total will sink further to some 32,000.

In contrast, a report from the National Science Foundation indicates that the demand for engineers continues to soar. The American economy requires a little less than a million engineers today : by 1970 this will rise to nearly 1·5 million. To meet this, the annual output of new engineers over the next decade must be 81,000, or more than twice as many as anticipated.

Why is the engineering manpower supply not keeping pace with the demand? Are increased science enrolments the reason for the slump? Carl Frey, of the Engineering Manpower Commission, states that engineering enrolment actually rose a little—2·5 per cent—in those schools offering both science and engineering, while science enrolments in those schools were up by 24.4 per cent. The 'glamour' sciences are probably drawing away some students who might otherwise have elected to read engineering, but "it hardly seems possible that this alone accounts for the drop in the relative standing of engineering freshmen". The Engineering Manpower Commission report concludes that, "the need is not to take from science and give to engineering, but to increase engineering enrolments while maintaining science at its present level of growth". During the 1960's the Engineering Manpower Commission anticipates that engineering graduates will number about 35,000 annually, while graduates in the sciences, according to estimates by the Natural Science Foundation, will number some 80,000 annually.

If the sciences do not account fully for the slump in engineering, what does? The real cause, according to M. H. Trytten, director of the National Academy of Science, Office of Scientific Personnel, is the inadequate preparation of sufficient young people for careers in engineering: about half the high school students in the United States attend schools which are too small to provide proper training for college work in engineering and science. Trytten believes that the National Science Foundation forecast of the demand for engineers is too conservative, because neither the demands of the space programme nor the need for engineers in the American-sponsored programmes abroad is included in the forecast. "The only way out of the shortage is through stronger programmes of public school preparation 'down into the grades'."

New educational programmes are bringing improvements in the teaching of public school science and mathematics. But Trytten and others, including Prof. J. Conant, insist that these must reach deep into areas of educational neglect such as those now served only by the small rural school and those whose productivity of scientists and engineers is low, particularly in the South. In times when the demands were less severe, these deficiencies were less apparent. With science and technology in such dominant positions in society, there is deep concern that the United States is neglecting the education of one-half of its potential students.

GEOLOGY IN THE U.S.S.R.

ACADEMICIAN D. V. NALIVKIN discusses in the October issue of *Priroda* the future prospects of geological work in the Soviet Union (*Priroda*, 10, 67; 1961). He notes the existence of a very large number of geologists carrying out prospecting work for finding new deposits of economic minerals and ores and emphasizes the enormous work done in geological cartography in the production of petrographic, stratigraphic, palæontological, geophysical, metallogenic and other types of maps. For example, palæographical maps will be collected in two large atlases which will be exhibited at the International Geological Congress in India in 1964. Another important feature of Soviet geology is the establishment of fundamental boreholes, aimed at elucidating important geological successions. The author notes four important problems facing the modern Soviet geologist, namely: (1) synthesis of minerals in laboratories and on the industrial scale; (2) problems of tectonics (here he mentions the establishment of a new branch of science—"astrogeology"—which studies the influence of cosmic factors on terrestrial events); (3) absolute age of sedimentary and igneous rocks, which provides a new chronological scale in geology; and (4) the problem of the so-called 'underground rocket', a boring apparatus of a new type, which will make possible boring to a depth of 12 km. for the study of the deeper zones of the Earth and for extended prospecting.

Geological age. A new method of determining the age of rocks and meteorites is briefly described by G. F. Komovsky (*Priroda*, 5, 90; 1961). It is based on the measurement of the relative heights of the peaks of thermoluminescence of rocks heated to 400° C. This method, however, despite its simplicity, can provide only an approximate date.

Geological folds. Field tectonics and experimental studies lead V. V. Belousov (*Priroda*, 6, 14; 1961) to postulate the following types of crustal folds: (1) block folds, produced directly by vertical movement of the crust; (2) folds of compression—folds produced in the incompetent (plastic) strata, forming either domes or rolls and due to the attempt to re-establish equilibrium lost during movement of the crust; (3) deep-seated folds, usually occurring in metamorphic or ultra-metamorphic rocks; (4) folds of general compression resulting in widespread linear folds. The general mechanisms of folding are discussed in the article.

Earth's mantle. The project of the study of the Earth's mantle, accepted by the International Union of Geodesy and Geophysics in the summer of 1960, is briefly discussed by V. A. Magnitsky (*Priroda*, 6, 46; 1961). Naturally, this study will be applied only to the upper part of the mantle. A deep boring through the Mohorovičić discontinuity is projected, together with associated seismological, magnitometric, gravimetric and thermal flow studies.

Iron and manganese in ocean deposits. One of the scientific results of the Soviet research vessel *Vityaz* is the mapping of the concentration of iron–manganese concretions in the deposits of the Pacific Ocean, a brief account of which is given by N. L. Zenkevich and N. S. Skornyakova (*Priroda*, 2, 47; 1961). The average amount of these concretions in the area of their concentration is 8,600 tons/km.^{2}. Submarine photographs reveal a very high proportion of the oceanic bottom rich in concretions. These results agree with the findings of H. W. Menard and C. J. Shipek (*Nature*, 182, 1156; 1958).

Applied geochemistry. Geochemical landscapes, geochemical maps, dispersion aureoles and other problems of applied geochemistry are discussed by A. I. Perel'man (*Priroda*, 9, 98; 1961) and by A. A. Saukov and A. I. Perel'man (*Priroda*, 10, 59; 1961).

Transformation of a desert. An article by V. N. Kumin (*Priroda*, 9, 61; 1961) gives a succinct account of the important irrigation scheme encompassed in the construction of the large Karakum Canal, which carries the waters of the River Amu-Daria over 100,000 hectares of fertile desert lands. Various irrigational and biological problems are discussed.

Palæoclimatological maps. G. I. Bushinsky (*Priroda*, 8, 54; 1961) describes palæoclimatological maps constructed on the basis of detailed analysis of lithogenesis by N. M. Strakov, who subdivided lithogenesis into four main types: humid, arid, glacial and volcanological-sedimentary. These types are mapped out on the world map as definite zones for the successive geological periods.

Stromatoliths as indicators of Polar wanderings. A. G. Vologdin (*Priroda*, 11, 102; 1961) reports that, in collaboration with Chinese geologists, he was able to study in detail stromatoliths (banded algal limestones) of Sinian age (1,200–600 million years) in the region of Zisyan Mountain, 110 miles east-north-west of Peking. It was discovered that these platy formations exhibited on their upper surface convexities which were assumed to be due to the heliotropism of the algae. Previous measurement of the orientation of the convexities of stromatoliths in this region and in the Enisey range showed a displacement of the pole by 40° during the whole of the Sinian period. This method is considered to be adjunct to the usual palæomagnetic methods in the study of polar migration.

S. I. TOMKEIEFF

EXPORT MARKETING

THE reasons why export marketing has not aroused the same enthusiasm in Britain as in, for example, Germany, the United States, or the U.S.S.R. are discussed in a recent issue of *Planning* which has been prepared from material supplied by N. A. H. Stacey, economic adviser of the General Electric Co.*.

The relative decline in British exports has often been attributed to the post-war resurgence of Western Germany and Japan, but the report suggests that the length of time which has now elapsed since the end of the Second World War considerably reduces the strength of this contention. Apart from this, two explanations are generally advanced. The first is that Britain has failed to adapt the commodity structure of its exports to changing world needs, and the second that it has failed to adapt its traditional export market pattern to new developments in world trade, in particular to the rapid increase in trade between highly industrialized nations since the War.

Where do the deeper faults lie, and how can they be remedied ? The broadsheet concentrates on what is believed to be one of the major reasons for Britain's lack of success in the world's export markets, namely, the British manufacturer's use of obsolete marketing techniques resulting from a neglect of market research.

The neglect of the marketing function by British industry must be attributed, paradoxically, to the long, unbroken success of British manufacturing industry. Since Britain was the supplier for more than a century and a half of immense quantities of manufactured goods to the nations of the world, the notion that the process of manufacturing was the foundation of sound business gained an unwarranted sanctity. The corollary to this was the belief that distribution, even if not unproductive, was not as valuable as manufacturing.

Such an attitude was justified while Britain was the sole mature industrial nation, as it was until the 1880's. Now it has to share this position with a dozen or more industrial nations. The increased uniformity in the technical performance and efficiency of the goods made by reputable manufacturers in many of the industrial countries has meant that the effort needed for making a sale has assumed much greater importance.

The most important part of successful export effort in the competitive conditions of to-day is sound knowledge of the overseas markets. Familiarity with buyers' requirements, with the needs of the country, the preference of its population, and knowledge of its recent economic and social development are the determinants of import requirements both to-day and to-morrow. It is part of intelligent marketing to discern requirements and to anticipate needs. Sound marketing is based on the assiduous collection of information to answer two questions. These are: (1) In what (new) markets can the manufacturer sell his existing range of products (with or without modification) or extend his sales ? (2) What new products should be made for which there is a demand in his existing markets ?

The neglect of marketing, based on systematic marketing research overseas, is a dominant cause of Britain's present-day export predicament. To find out customers' preferences, to define the characteristics of the market, to estimate the volume of sale, to obtain information on products and prices of the competing manufacturers, to check on the efficiency of publicity, to secure economic information on likely developments in the future, these uses of marketing research have not been properly considered by many British manufacturers.

---

* *Planning*, Vol. 28, No. 459 (February 19, 1962) Problems of Export Marketing. Pp. 19–38. (London: Political and Economic Planning, 1962.) 3*s*.

Why is this so ? The explanation is to be found in Britain's past successes. Until recently, certain traditional markets were considered a prerogative of British industry, which led to institutional thinking instead of entrepreneurial action in overseas trading. For German, French or American firms evaluation of overseas markets in the post-war period was a necessity if they were to compete successfully with the already well-entrenched British manufacturers. Foreign manufacturers had to gain markets rather than find them—with the result that their marketing methods had an aggressiveness about them lacking in those of British markets.

The rest of this admirable broadsheet gives practical advice on how companies can develop vigorous marketing policies.

OPERATIONAL RESEARCH AND THE HEALTH SERVICES

FOR some time the Nuffield Provincial Hospitals Trust has been alive to the potentialities of the application of scientific method and modern management techniques to the planning and administration of the National Health Service. In recent years it has particularly encouraged the development of operational research studies in the socio-medical field. The full scope of the work being carried out is not well known, and during December 14–15, 1960, the Trustees arranged a symposium of interested persons for a general review of progress in the field*.

The conference was attended by most of the leading authorities on operational research in the fields of hospital and public health as well as representatives of the Ministry of Health, the Department of Health for Scotland and the Ministry of Health, Northern Ireland. At the same time, most bodies at present in a position to sponsor such research were represented.

The papers presented to the symposium were commissioned with the object of setting out the opportunities and the realities. The plan consisted of portraying the main issues as seen by a medical administrator, and of contrasting these with known operational research applications in the field and, as an astringent epilogue, of presenting accounts of two recent studies actually carried out.

Among the points brought out by the chairman, Prof. M. G. Kendall, in his concluding remarks were that there are widespread opportunities for the useful application of operational research techniques in studies of the National Health Service; such an application can be made at various levels of administration, and the number of operational research studies should be increased as soon as possible. Such studies could profitably examine not only the possibility of the National Health Service as it now exists but also the possibility of modification. The field to be covered is so vast that it would be difficult to specify an order of priority of importance in topics to be studied, but it should prove possible to draw up a classification. Recognizing that research on these matters may proceed in a number of locations, under a number of different administrations, there should be some arrangement to encourage inter-communication between the research units concerned. In particular, there should be periodic conferences of interested persons, and some form of centralized information service, to ensure that the nature and existence of present-day research is brought to the notice of all those who are likely to engage in it and use it.

The desirability of encouraging interest among hospital and local authorities in the possibilities of operational research in the National Health Service field should be recognized, and can be brought about by conferences, lectures or case-studies and direct encouragement from Central Government authorities. Recognizing the shortage of expert operational research personnel, Prof. Kendall suggested that there should be encouragement in universities and elsewhere for the formation of operational research units, the members of which could be made available for consultation or could provide leadership to authorities engaging in operational research studies.

CALCUTTA SCHOOL OF TROPICAL MEDICINE

IN the annual report of the Calcutta School of Tropical Medicine and the Carmichael Hospital for Tropical Diseases, 1959–60*, the director, Dr. R. N. Chaudhuri, describes some of the more important observations made during that period.

A new technique, devised for experimental studies on amœbiasis, was successfully utilized in guinea pigs to produce a condition simulating chronic and recurring amœbiasis in man; this permitted direct studies on the evolution of the disease-process, and *in vivo* evaluation of amœbicidal drugs, without killing the animals. Human experiments have shown that asthmatic symptoms with high eosinophilia may result from ingestion of embryonated eggs of dog ascarids. This supports previous observations based on animal experiments and suggests a probable parasitic role in the ætiology of tropical eosinophilia.

Four types of protein malnutrition were categorized and follow-up studies showed the probability of one passing into another, indicating that the clinical pattern in them all resulted from the same ætiological process, namely, protein cum caloric deficiency, aggravated or precipitated by infection. Plant proteins, though not quite so good as milk, have been found useful in deficiency-states, and a pulse–cereal–green vegetable gruel sweetened with jaggery has produced encouraging results. It has the advantage of simple preparation at low cost and may considerably replace milk. The supply of vegetable proteins by a "supplementary feeding" programme to infants and young children in the low socio-economic group of the population may hold the promise of a prophylactic against this condition. Protein-rich biscuits were also prepared from protein hydrolysate of pulses and fish-protein hydrolysate. Clinico-pathological and experimental observations were also made on the nature and extent of hepatic involvement in diabetes mellitus.

---

* Annual Report of the Calcutta School of Tropical Medicine, and the Carmichael Hospital for Tropical Diseases, 1959–60. Pp. 131. (Calcutta: Calcutta School of Tropical Medicine and the Carmichael Hospital for Tropical Diseases, 1961.)

As had been previously shown, the percentage of *Staphylococci* resistant to prevalent antibiotics remained high, namely, 70 per cent, though they were uniformly sensitive to erythromycin. Resistance of *Escherichia coli*, from cases of urinary infection, to sulphonamides, streptomycin and tetracycline was found to be on the increase.

Work on the survival of smallpox virus in a non-pathogenic form in the brain of infant mice is in progress with the view of finding the LD_{50} in different passage-levels of the variola virus. Studies are still being carried out to determine the normal antibody titre in random population samples, and especially among young children, against variola virus.

Leucoderma skins receiving ultra-violet radiation, compared with a non-irradiated control, on histological examination showed an increase of melanocytes with proliferation of dendrites and abundance of melanin. To substantiate previous observations that counter-irritant drugs, commonly applied locally, are apt to produce hard erythematous and reactionary patches, ultimately resisting any form of treatment, a number of patients with leucoderma were treated with psoralen ointment in a soothing base. The results have been encouraging, and further work is in progress.

Histamine reaction in cases of non-lepromatous leprosy showed significant quantitative difference when compared with that on the normal skin. Studies on serum protein in the two polar types of leprosy revealed an increase of γ-globulin fraction in sera of lepromatous cases. Formation of leishmanial granuloma was demonstrated in the spleen of drug-resistant kala-azar. Biochemical observations of interest were made on the liver of animals infected with *Trypanosoma evansi*.

A new species of *Dioscorea* yams, obtained from the Darjeeling area, was found to contain as much as 4 per cent diosgenin. The glycoside content of *Digitalis* was found to reach its maximum when the plant was about 1½ years old. Three compounds of indigenous drugs were prepared for clinical trial, namely, arborine hydrochloride, aegelin and psoralen. A volatile oil derived from the seeds of *Nigella sativa* was shown to have a mosquitocidal property; its chemical composition was determined. Four new compounds were synthesized for possible use as insecticides and insect repellants.

A number of new drugs was also subjected to clinical trial to evaluate their therapeutic efficacy, particularly against amœbiasis, leishmaniasis, helminthiasis, and skin diseases, including superficial mycosis and leprosy.

CANCER SERVICES IN EUROPE

A PAPER prepared by Dr. A. Chaklin, chief of the Cancer Division, World Health Organization, Headquarters, Geneva, and Dr. J. Mosbech, Office of Medical Statistics, Danish National Health Service, served as a background document for the technical discussions held during the eleventh session of the World Health Organization Regional Committee for Europe at Luxembourg in September 1961. The main points have been brought together in an article in the *WHO Chronicle* (16, No. 3; March 1962). While the ætiology of most forms of cancer is still unknown, many of them can be effectively treated. For this, well-organized services are essential. There are considerable differences in the organization of cancer control in the various countries of Europe. In the Scandinavian countries cancer falls within the province of the family doctor and the general hospital. In the United Kingdom, also, there is no separate speciality for malignant disease, all treatment being carried out on a regional basis within the ordinary facilities of the National Health Service. There are, however, certain hospitals and clinics reserved for cancer treatment, and a number of homes for the care of incurable cases.

The situation in the U.S.S.R. and the countries of eastern Europe is quite different. A network of cancer services with a high degree of independence, staffed by doctors especially trained in the detection, treatment and prevention of the disease, was established by Government decree in the U.S.S.R. after the Second World War.

This network consists of cancer stations, cancer dispensaries, and hospital cancer departments. At the cancer stations, the public is offered advice and education for the prevention and early detection of malignant disease, while mass screenings are organized, cancer cases registered and patients put in touch with expert facilities. Every doctor is required to refer any patient with an obviously or possibly malignant lesion to one of these stations. The cancer dispensaries, concentrated in the larger towns, are highly specialized and well-staffed institutions the functions of which include not only the application of the surgical and other treatment required but also the assembly and the analysis of data, the training of medical and allied staff, the education of the public and general collaboration with public health authorities in cancer control. The hospital cancer departments concentrate mainly on the purely medical aspects of cancer treatment at a specialized level.

Thus, although in both the U.S.S.R. and in the United Kingdom it is the general practitioner or his equivalent who makes the first contact with a case of malignant disease, the subsequent procedure is very different; in the former country the patient will be treated by a specialized service while, in the latter, he is most likely to be dealt with in the local general hospital with appropriate facilities. The differences between the two services may eventually become less because of the trend in many countries towards the centralization of hospital services. As knowledge increases, the collaboration of many specialists becomes necessary and the cost of equipment mounts; these factors favour the concentration of cancer patients in a few hospitals at regional, or even at national level.

Efficient cancer services cannot be planned or operated without valid statistics, which must relate to morbidity as well as mortality. Thus, some form of cancer registration is essential. A registration or notification system, particularly if combined with an analysis of treatment and survival statistics, is of the greatest value in providing not only an index of therapeutic efficiency but also important material for epidemiological research. In a small, closely knit country such as Denmark or the Netherlands, a single national registry for all forms of malignant disease is possible. In others it may be necessary to work from several national registers; or there may be separate national registers dealing with particular types of tumour such as bone sarcoma. It is from such statistical information as that concerned with the rapid increase of morbidity and mortality from lung cancer in men that ætiological conclusions—and preventive action—may develop.

The prevention of cancer has found its most obvious application in many countries in the attack on causative occupational and industrial factors. Many different carcinogens are encountered in the chemical industry, mining and other occupations; and certain components of polluted air in cities and food additives are known or suspected to be carcinogenic. Ionizing radiation is another potential source of malignancy. Measures to prevent the pollution of air, particularly by benzpyrene, and to limit the hazards of radiation are now established elements of public health service practice in many countries.

Another approach to prevention is through the mass screening of the population to detect precancerous lesions. In most countries of western Europe, such screening is carried out by particular industries or professional groups on a private basis. In eastern European countries and the U.S.S.R., however, more and more extensive examinations of both working and non-working populations are performed each year; this has resulted in the detection of precancerous lesions—particularly of the uterine cervix, breast, skin and stomach—and the early recognition of actual neoplasms. Experience in the U.S.S.R. has demonstrated the importance of planning such surveys carefully. Examinations of persons more than 30–35 years of age are conducted by teams of specialists, and other diseases are looked for simultaneously. Regular radiographic examinations of the chest, and sometimes of the upper gastro-intestinal tract, is also a feature.

In some countries the approach is through examination of all patients attending factory or hospital out-patients clinics for whatever reason. The mass gynæcological examination of women in factories and hospitals is also valuable in connexion with tumours of the cervix and pelvis. In some areas, cytological diagnosis is being practised on a large scale, and this method holds great promise.

One of the greatest problems in obtaining good results from cancer treatment is that of seeing patients at a sufficiently early stage of the disease. Only too often delays constitute a formidable handicap to success. The time-interval between the earliest symptoms and radical treatment may be several months, even for the common cancers of the breast and stomach. In many cases cerebral tumours do not come to operation for a year or 18 months after the first headache. Early diagnosis is achieved partly by educating the public (and the general practitioner) to be aware of, and willing to report, possible symptoms; and partly by providing suitable facilities for diagnosis. A number of European countries has special diagnostic centres, appropriately equipped, attached to hospitals; and in the U.S.S.R. there are the designated cancer dispensaries or polyclinics. A widespread application of the technique of cytological diagnosis may perhaps prove a valuable aid to early diagnosis. This has already shown itself, in some parts of the world, to be of first importance in detecting early cancer of the cervix by means of a simple vaginal smear.

A general development of mass screening and early diagnostic measures depends on sound education of the general public in the issues at stake; yet this is often neglected. Controlled surveys have shown that public attitudes can be changed by campaigns, particularly those directed against specific tumours, the most important effect often being to overcome a feeling of hopelessness about cancer treatment in general. In the U.S.S.R. and in eastern European countries such education is a responsibility of the Ministry of Health; there are institutes of health education, and mass examinations are carried out in factories, all propaganda media being harnessed for the purpose. In other countries this task is left to national societies dealing either with cancer in general or with particular lesions. Cancer of the lung is one of these, and many unofficial bodies are now aiming at the prevention of smoking in school-children and young people. It is interesting to note that, while a leading British authority stresses the risks of imparting too much clinical information to laymen, the view in the U.S.S.R. is that clear and detailed information on every aspect of the problem is the best way of avoiding cancerophobia.

In most countries there is no special legislation governing cancer diagnosis and treatment facilities. In some, where the problem is handled at ministerial level, appropriate regulations exist, for example, in Czechoslovakia and France, where notification is compulsory. Whether special legislation is required is mainly determined by the adequacy of the existing general health legislative framework. In all cases, the objects must include efficient prevention, diagnosis, treatment, after-care and rehabilitation irrespective of economic status; the accumulation of reliable statistics; and the provision for cancer research.

COMPOSITION OF 'PEARLS'

By Prof K. VOZOFF, R. M. ELLIS* and Prof. G. D. GARLAND
Department of Physics, University of Alberta

RECORDS of micropulsations of the Earth's magnetic field at times exhibit 'pearls' which appear to result from mixing two sinusoidally varying magnetic fields having slightly different frequencies and roughly equivalent amplitudes. Typically these frequencies lie in the range 0·2–2 c.p.s. and may differ from one another by 0·01–0·1 c.p.s. An identical wave form could be obtained through amplitude modulation of a single oscillator.

In the course of our magnetotelluric investigations a recording containing about 1 hr. of impure pearls was analysed. The recording of the two horizontal electric components and the three magnetic components was made between 1430Z and 1520Z, on September 7, 1961, at a location 20 miles north of Edmonton, Alberta. The average zero crossing period of the pulsations was about 1·4–1·5 sec. Their modulating envelope appeared to be a sinusoid of about 26 sec. period which was itself being modulated. There was a pronounced tendency for the entire pattern to repeat itself at periods of about 145 sec., or after 10 'pearls'. The entire pattern was superposed on much slower variations. Polarization in the horizon-

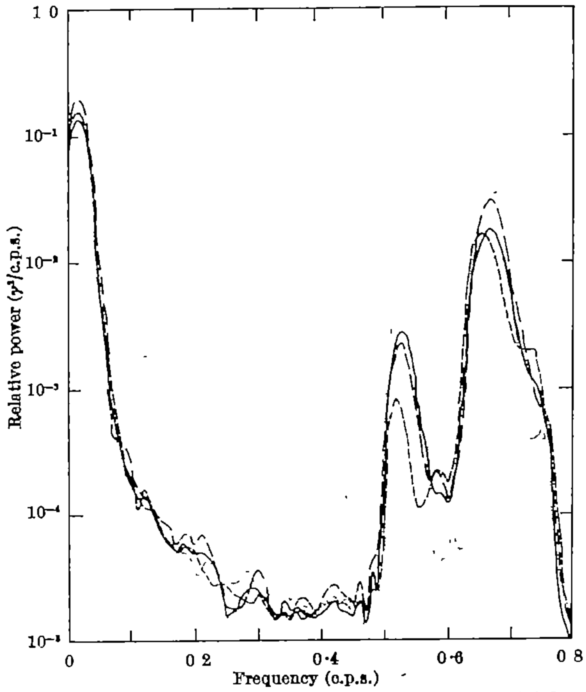

Fig. 2. Partial H_x spectra. . . ., First third; —·—, second third; — — —, last third; —, entire record

tal plane was at times elliptical, at other times linear. The directions of linear polarization varied through 135°. Maximum peak-to-peak amplitude was about 0·5γ.

The character of the signals underwent a gradual transition during the recording interval. Consequently, after the average spectra were computed for each component, the records were split in thirds and re-analysed.

It is apparent from either of the average horizontal spectra (Fig. 1) that the majority of energy is concentrated in three bands: two, relatively narrow, centred at 0·53 c.p.s. and 0·67 c.p.s. respectively, and the much broader low-frequency band. In these average spectra the amplitude of each band appears to be about the same in the X as in the Y direction. The vertical (Z) component must obviously be treated separately. The beat period which one would expect from mixing 0·53 c.p.s. and 0·67 c.p.s. is not an obvious feature of the records except in the first third, because the 0·53 band is generally somewhat smaller in amplitude. Most of the character is due to structure within the 0·67 c.p.s. band.

When the records are re-analysed by thirds (Figs. 2 and 3), it becomes evident that there occurred drastic changes in the directional orientation and amplitudes of the 0·53 c.p.s. components. Average amplitudes in the other two peaks vary by less than 50 per cent through the hour. Regardless of the picture one uses to explain the fields, it would appear that the sources of the 0·53 c.p.s. and 0·67 c.p.s. peaks must be independent of one another.

We noted that our two major peaks lay very close to a possible pair of modes predicted by MacDonald[1] for this magnetic latitude (60° N.). For this reason we obtained as many other observations for the period as we could. On only two of those we obtained could pulsations in this frequency range be seen. These were recorded at Austin, Texas (*EERL*, University of Texas) and at Reykjevik, Iceland, in one of Prof. Benioff's observatories. The charts were not suitable for analysis at these frequencies. However, the Texas record did show very small sinusoidal fluctuations of about 0·5 c.p.s., superposed on much larger, long period oscillations. The Iceland chart showed pronounced 0·3 c.p.s. pulsations with a weak recurrence tendency of roughly the same period as seen on the Alberta records.

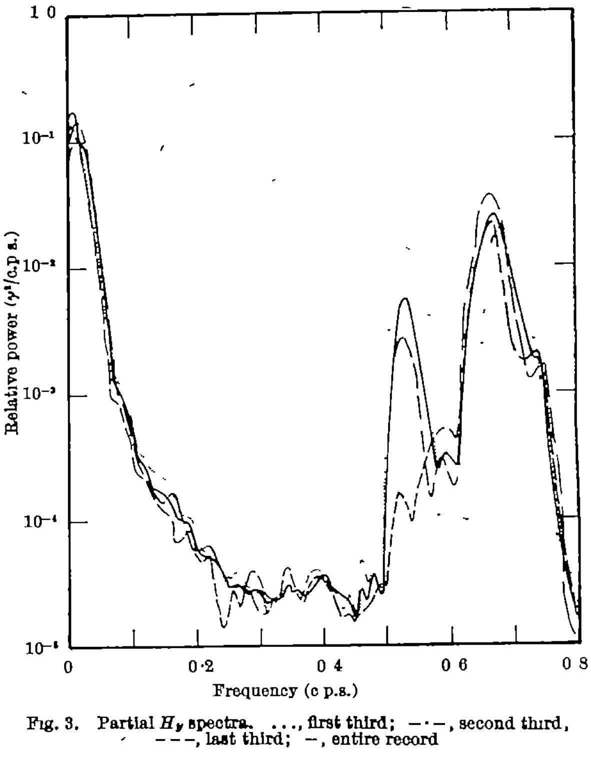

Fig. 3. Partial H_y spectra. . . ., first third; —·—, second third, — — —, last third; —, entire record

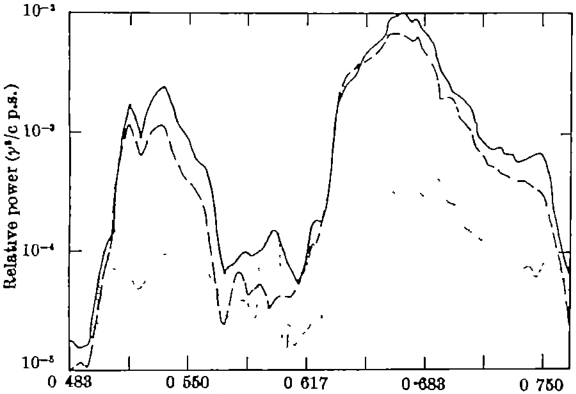

Fig. 4. Expanded spectra. —, H_y, – –, H_x; . . . ., H_z

The frequencies observed on our records 0·53 c.p.s. (1·9 sec. period) and 0·67 c.p.s. (1·49 sec. period) would correspond to the third and fourth trapped modes in MacDonald's high-density model at this latitude (60° N.). The 0·5 c.p.s. pulsation on the Texas record would correspond to the fourth trapped mode in the same model at that latitude (40° N.). The 0·3 c.p.s. pulsation on the Iceland record does not appear to be a permissible mode of the model at that latitude (67° N.). It should be noted that it was mid-afternoon in Iceland but early morning in western North America when the observations were made.

Re-analysis of the Alberta tapes with greater frequency resolution (Fig. 4) partially resolved the 0·53 c.p.s. band into a pair of bands at 0·517 and 0·536 c.p.s. Slight shifts in the location of this peak in Figs. 2 and 3 suggest that this may be due to a frequency change about two-thirds of the way through the record, rather than to splitting. Individual peaks were not apparent within the 0·67 c.p.s. band, but the spectra, particularly in Z, were suggestive of several closely spaced bands which also shifted slightly with time. Re-synthesis shows that most of the observed characteristics of the records can be accounted for by the calculated spectra. An exception is the 145-sec. recurrence pattern, which must almost certainly appear in the spectra as persistent structure within the 0·67 c.p.s. band.

Physically, the recurrence pattern is suggestive of an amplitude modulation. This might be explained by a disturbance travelling in the free mode, and exciting the trapped modes each time it enters (or leaves) the velocity channel. The calculated first free-mode period in this model is 185 sec.

We conclude that the changes, in time, of the relative amplitudes and orientations of the two major bands imply that the source oscillations can be excited independently. If we assume that any filtering which occurs between source and observer is unable to distinguish between frequencies so close together, we must conclude that relative amplitude and orientation changes arise at the sources. There is a suggestion that the oscillations are of the trapped V-type predicted by MacDonald[1], possibly excited by the free-mode disturbances of the same type.

This work was aided by grants from the Petroleum Research Fund, the American Chemical Society and the National Research Council of Canada. We thank the groups that made records available to us, as well as the Pacific Naval Laboratory, Miss G. Baril and particularly to Mr. M. D. Burke for considerable assistance in this programme.

VIBRATIONAL SPECTRUM OF A TWO-DIMENSIONAL DISORDERED LATTICE

By M. D. BACON and DR. P. DEAN

Mathematics Division, National Physical Laboratory, Teddington, Middlesex

A PROBLEM fundamental to any investigation of the lattice vibrations of disordered atomic systems is that of the determination of the frequency spectrum. Investigations into various aspects—the thermodynamic effects of vibrations, optical and infra-red absorption, electron–phonon interactions—these and others depend on at least some knowledge of the spectrum. The history of research into the spectra of disordered systems has reached the stage at which exact information is now available for certain classes of one-dimensional models[1–3]. However, two- and three-dimensional systems have received little serious attention. In this article we present the spectrum for a disordered two-dimensional lattice which we believe is the first to be obtained for a disordered system other than the linear chain. Although the spectrum is based on calculations on small sections (16 × 16) of lattice, it shows points of considerable interest when compared with the one-dimensional results, and we can draw some conclusions which are probably of wide validity.

Our model of a disordered lattice is one in which the sites of a square lattice are occupied randomly, with equal probability, by one or other of two kinds of atom, light (L) and heavy (H). The atoms interact with nearest neighbour central and non-central forces as in the monatomic and periodic analogues of the system, used by other authors[4]. Such a model does not, of course, represent any particular physical system. It is essentially a mathematical model which nevertheless is extremely valuable for the insight it provides into more realistic systems.

The method of calculation of the density of normal mode frequencies is a modification of one outlined by Dean and Martin[5]. Following the text and notation of that paper we see that: (1) the frequency problem transforms to the eigenvalue problem of a symmetric matrix $S - \omega^2 I$ of block triple-diagonal form; (2) a process based on the 'negative eigenvalue theorem' is given for the calculation of the matrix eigenvalue spectrum. The theorem states that the number of negative eigenvalues of $S - \omega^2 I$ is equal to the sum of the numbers of negative eigenvalues of matrices $U_1 = A_1 - \omega^2 I_{l_1}$, $U_j = A_j - \omega^2 I_{l_j} - B_j^T U_{j-1}^{-1} B_j$ ($j = 2, 3, \ldots N$) where A_j and B_{j+1} are, respectively, the jth diagonal and off-diagonal blocks of S, and I_{l_j} is the unit matrix of the same order as

A_j. In this communication we use a particularization of this result. We decompose our dynamical matrix $S - \omega^2 I$ into just two U-matrices, the first of which is of unit order and is thus the top left-hand element ($=a_{11}$) of $S - \omega^2 I$. U_2 is a matrix of order one less than that of S. The essential point in this reduction is that the number of negative eigenvalues of $S - \omega^2 I$ can be obtained from the number in U_2 and the sign of a_{11}. If now U_2 is regarded as a matrix to be decomposed (into U_1' and U_2') in precisely the same way as $S - \omega^2 I$ the process can be repeated until, finally, the number of negative eigenvalues is simply the number of negative terms in the n unit matrices $U_1 = a_{11}$, U_1', U_1'', . . . , n being the order of S. This procedure of counting negative eigenvalues of $S - \omega^2 I$ yields the proportion of squared frequencies smaller than ω^2—in other words, the integrated spectral function $M(\omega^2)$. The derivative of this function, $D(\omega^2) = dM(\omega^2)/d\omega^2$, is the usual density or spectrum of squared frequencies.

Computations (using the *ACE* of the National Physical Laboratory) were performed on sections of lattice of size 16 × 16; thus the dynamical matrix was of order 256. Toroidal boundary conditions were imposed on each section in one direction and, for mathematical convenience, rigid walls in the other. $M(\omega^2)$ was calculated throughout the whole range of the spectrum at intervals in ω^2 of 1/8. The mass ratio chosen was 4 : 1 and the ratio of central to non-central force constant taken to be unity. (In the notation of Dean and Martin[5] the parameters of the system are $k = k' = 1$; $m_H = 4$; $m_L = 1$.)

Curve (*a*) of Fig. 1 is the integrated spectrum of squared frequencies obtained for one particular disordered lattice section. Results for other sections show precisely the same features and hence curve (*a*) can be taken as typical. Curve (*b*) is the integrated spectrum for the infinite monatomic lattice of heavy (*H*) atoms[6]. Curve (*c*) is the result for the infinite diatomic periodic ('chessboard') array:

$$[D(\omega^2) = (2\omega^2-5)(4+4y)^{-1/2}K(k),$$

$$k^2 = (3+2y-y^2)/(4+4y),$$

$$-1 \leqslant y = (5/2-\omega^2)^2 - 13/4 \leqslant 3,\ M(\omega^2) = \int_0^{\omega^2} D(\omega^2)d\omega^2,$$

where $K(k)$ is the complete elliptic integral of the first kind. The programme used for the main calculations produced results which followed very closely the analytical curves (*b*) and (*c*) when applied to small sections of the relevant lattices.

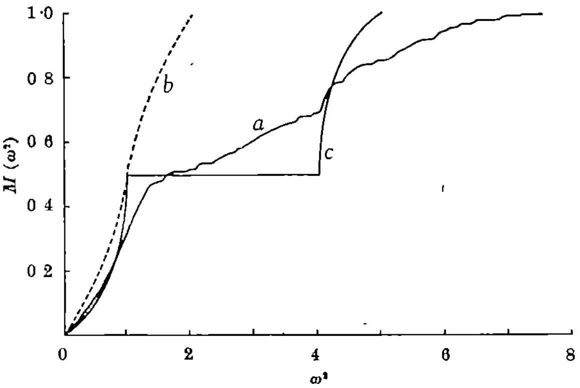

Fig. 1. Integrated spectra for two-dimensional lattices. *a*, the disordered lattice; *b*, the infinite *H*-monatomic lattice; *c*, the infinite diatomic alternating array

The form of the integrated spectrum for the disordered two-dimensional lattice is significant when compared with the known results for the linear chain. The spectrum of the linear system has two distinct parts: in a region corresponding approximately to the band of the *H*-monatomic lattice it is smooth and continuous; at higher frequencies it becomes extremely complex and has been shown to be essentially a weighted sum of the frequencies of numerous highly localized 'defect' modes which are associated with various kinds of short-range chain structures[2]. Curve (*a*) suggests that the situation is similar for the two-dimensional disordered systems examined in this article. The step-like nature of the function $M(\omega^2)$ in the region $\omega^2 > 1{\cdot}5$ approximately, shows the density of frequencies to have numerous peaks of different intensities. We conjecture that these peaks correspond to localized modes which are associated with particular kinds of small-scale lattice structure. If this conjecture is valid, and proof (or disproof) should soon be forthcoming, then the evidence for the spectra of disordered three-dimensional lattices being of the same kind will be overwhelming. It should then be possible to determine the main features of the spectra of realistic alloy systems from a study of the highly localized modes which can occur in these systems.

The work described here was carried out as part of the research programme of the National Physical Laboratory and this article is published by permission of the Director of the Laboratory.

FORMATION OF SPHERULITES IN POLYETHYLENE

By W. BANKS, J. N. HAY*, A. SHARPLES and G. THOMSON

Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian

REFERENCE has frequently been made (for example, ref. 1) to the ease with which polyethylene crystallizes to form spherulites which can be readily observed in the optical microscope (that is, of dimensions in the region of 10^{-2}–10^{-1} cm.), and indeed one of the first papers to suggest that spherulite formation might be a general phenomenon in high polymers was concerned with a study of polyethylene[2]. Most of the previous work has involved thin

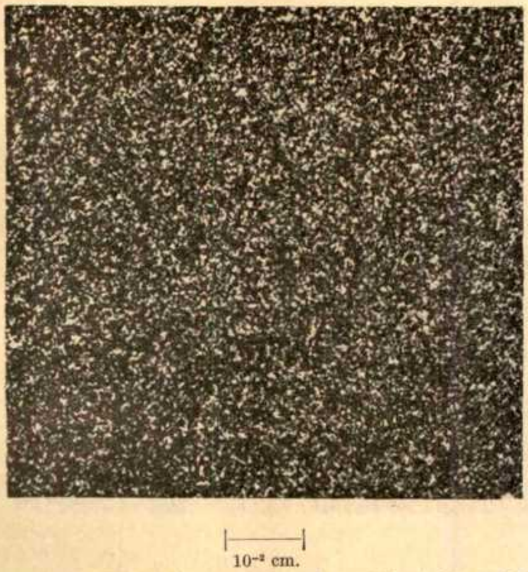

Fig. 1. Ziegler-type polyethylene ($M.I. = 0{\cdot}22$) heated to 200° C. for 5 min. and crystallized at 115° C.

films of polymer crystallized between glass surfaces, although on occasions sections from larger samples have been examined[3], and their appearance has supported the view that the behaviour of thin films is characteristic of that of the bulk material. Recent work in this laboratory, however, has indicated that although resolvable spherulites may be formed under certain conditions, the characteristic structure of a wide variety of crystallized polyethylene samples is not obviously spherulitic.

The samples studied included various types of low and high pressure polyethylenes, copolymers with butene and propylene, a polymethylene and fifteen fractions of molecular weights ranging from 3,000 to 500,000, obtained from two Phillips-type low-pressure products. In general, after heating between cover-slips at various temperatures up to as high as 300° C., the birefringent structures formed on subsequent cooling contained no resolvable spherulites, and were of the appearance shown in Fig. 1. The fact that the samples were invariably birefringent indicated that oriented regions were present of dimensions at least of the order of the wave-length of light, and it is reasonable to suppose that the structures observed contained distinct entities, possibly even spherulites, but of a size less than that capable of being resolved by the microscope. In the present case, careful observations during crystallization established that growing centres separated by distances greater than 2×10^{-4} cm. would have been detected; this is two orders less than the dimensions quoted for typical spherulites. Exceptions occurred to this general behaviour, and, for example, with a Phillips-type homopolymer, spherulites were occasionally detectable in the unresolvable background (Fig. 2). Also three of the fractions examined (molecular weights 9,800, 18,700 and 52,000) gave resolvable nuclei on slow growth, and in some areas the nucleation density was low enough to enable spherulites of about 10^{-2} cm. diameter to be formed (Fig. 3). Even in such cases, however, spherulite formation was not uniform throughout the sample.

The possibility of spurious nucleation at the glass surfaces was ruled out as a result of experiments using mica, and also from observations on sections cut from samples crystallized in bulk. In addition, the persistence of nuclei from previous crystallizations[4] seemed unlikely for several reasons, among which was the fact that in kinetic studies[5] all previous history was found to be removed at less than 1° C. above the melting point. Finally, it was shown that unresolvable structures resulted whatever the rate of crystallization, when the time scale was changed from a fraction of a second to several days.

Although resolvable spherulites similar to those previously recorded[1,2] were not observed on normal melting and cooling, it was found that they could be produced by a variety of methods involving heat and

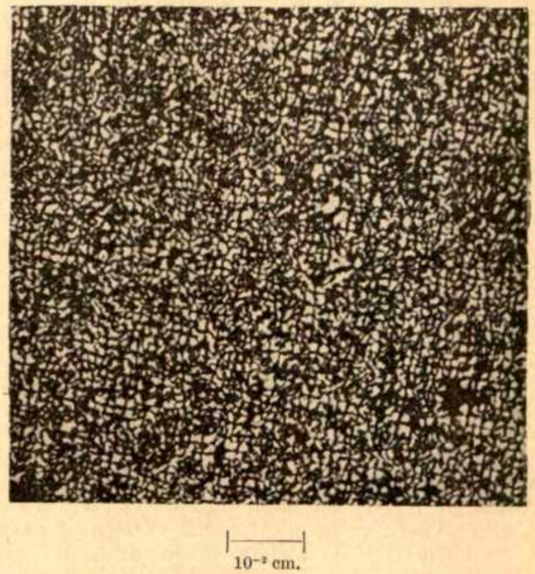

Fig. 2. Phillips type polyethylene ($M.I. = 0{\cdot}67$) heated to 170° C. for 5 min. and crystallized at 123° C.

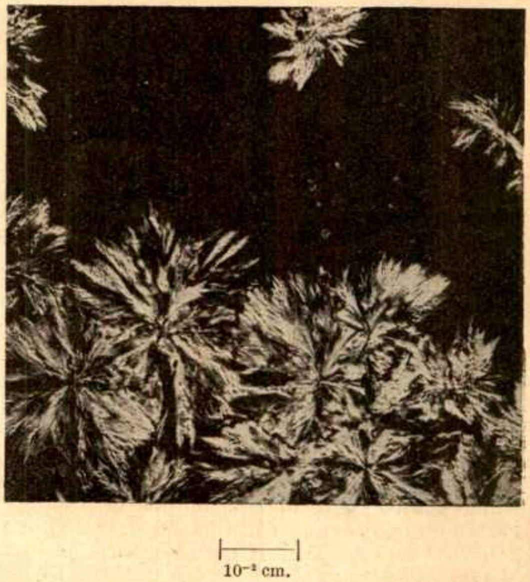

Fig. 3. Polyethylene fraction ($\bar{M}_v = 18{,}700$) heated to 200° C. for 5 min. and crystallized at 128° C. for 6 hr.

solvents, of which the following is an example. The Ziegler-type polyethylene used to give Fig. 1 was heated at 320° C. between cover-slips for 10 sec. and cooled, after which it produced spherulites of diameters up to 10^{-2} cm. without difficulty (Fig. 4). Similar treatments produced similar results for all samples examined, and it is considered likely that the polyethylene spherulites which have previously been reported resulted from treatments which produced states not characteristic of the original material.

In view of the fact that spherulite formation is the basis of existing theories of polymer crystallization[6], it is of considerable importance to establish the conditions under which they are formed. In addition, as the above experiments suggest that spherulite size can be modified by suitable treatments, presumably involving a reduction in the numbers of nucleating centres, it is also of practical interest to determine the nature of the process, as spherulite size is known to be correlated with optical and mechanical properties[7]. In the experiment reported above, the conditions used to produce resolvable spherulites were also conducive to thermal degradation. However, the unchanged melting point of the sample suggested that no significant change in molecular weight had occurred. Also, work to be reported in detail elsewhere indicated that homogeneous thermal degradation of the bulk material is unlikely to be the reason for the observed effects, as, for example, in the case of the treated Ziegler polyethylene (Fig. 4), the original appearance could be restored simply by dissolving and removing the solvent *in situ*. Subsequent melting and cooling produced structures similar to that given in Fig. 1. In addition, various thermal treatments of the larger samples failed to convert them to states capable of producing large spherulites.

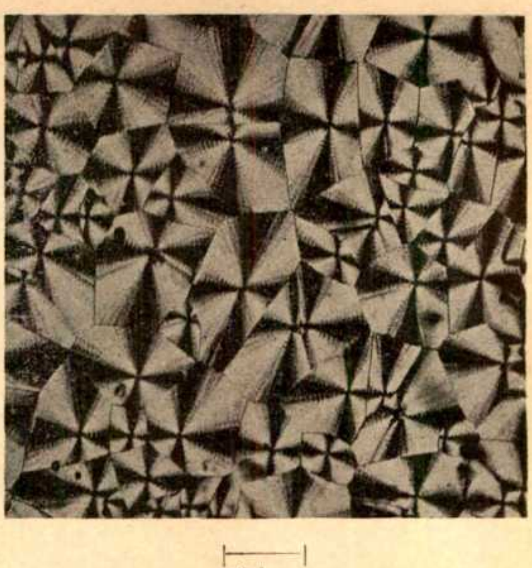

Fig. 4. Ziegler-type polyethylene ($M.I. = 0{\cdot}22$) heated to 320° C. for 10 sec. and crystallized at 110° C.

Although no detailed explanation is at present available to account for all the observations, it would seem unlikely that homogeneous modification of the whole material by any specific chemical reaction is involved. This receives support from experiments with other chemically different polymers, such as polyesters and polyamides, which, although normally appearing again in the form of unresolvable birefringent structures, can also be converted by suitable thermal treatment to forms where large spherulites can be observed. It is more probable that growth occurs from heterogeneities, and that the effective number of these centres is reduced during treatment either by chemical modification or by some physical process such as aggregation.

We are grateful to B.P., Ltd., for financial assistance in this project.

VASCULAR ACTION OF ACTEINA: ACTIVE CONSTITUENT OF *ACTAEA RACEMOSA* L.

By PROF. E. GENAZZANI and L. SORRENTINO

Department of Pharmacology, University of Naples

THE hypotensive action of the liquid extract of the rhizome and roots of *Actaea racemosa* L. is well known[1,2]. We have investigated the effect of various fractions of this extract on arterial pressure when injected intravenously in unanæsthetized rabbits.

Following our experimental results, that is purifying the most active fractions, Panizzi *et al.* (personal communication) have obtained certain crystalline substances with different melting-points.

The results so obtained (Table 1) suggest that the hypotensive effect of the extract of rhizome and roots of *Actaea racemosa* L. is due to the resinous part, insoluble in water and mainly to that constituent of it, called 'acteina', which is soluble in chloroform.

Pharmacological investigations have shown that acteina does not provoke acute toxicity (Table 2) or stimulate any local effects; it does not affect the heart or spontaneous movement in animals.

The hypotensive effect of acteina on unanæsthetized rabbits or on urethanized (1 gm./kgm.) cats is shown even with doses of 1 mgm./kgm. and reaches its maximum with doses of 10 mgm./kgm.; an increase in such doses does not provoke further decrease.

On the other hand, this effect, even with doses of 5 mgm./kgm., is not constant in unanæsthetized or chloralosed (1 gm./kgm.) dogs. There is no effect on a conscious human being—either normal or hypertensive subjects.

In man, acteina provides an increase in peripheral blood flow even at 0·5 mgm./kgm. Such a dose is effective also in subjects affected by peripheral arterial disease (Fig. 1).

Experiments on the vasal action of acteina have shown that: (1) It does not affect the periphery or the ganglionic synapses of the somatic nervous system. (2) When injected intravenously in the rabbit, it decreases the vasomotor reflexes caused by clamping and unclamping the common carotid arteries. (3) When injected in the thyroid artery in dogs, it has no effect on the chemoreceptors of the carotid sinus. (4) When injected by means of a catheter in the right atrial cavity, it has a hypotensive effect in rabbits even with doses (4 μgm./kgm.) which are inefficient when injected in the marginal vein of the ear. (5) When injected in the common carotid artery, it has a hypotensive effect in the cat even with doses (30 μgm./kgm.) which produce no effect when injected in the jugular vein. (6) When injected in the peripheral circulation in the dog it provokes peripheral dilatation.

Table 1. EFFECT OF THE LIQUID EXTRACT OF *Actaea racemosa* L. AND OF THE VARIOUS FRACTIONS OF IT ON THE CAROTID BLOOD PRESSURE OF UNANÆSTHETIZED RABBITS

Substances intravenously administered at a dose of 1 mgm./kgm.	Decrease of the pressure values (*m* ± *S.E.*) per cent
Fluid extract	10±2·2

Table 2. MINIMUM LETHAL DOSES OF ACTEINA*

Animal used	Route of administration	Doses (mgm./kgm.) Single	Doses (mgm./kgm.) Administered daily for 30 days
Rabbit	Gastric	—	>6
	Hypodermic	—	>3
	Intravenous	>70	—
Mouse	Intraperitoneal	>500	>10
Rat	Gastric	>1,000	—
Dog	Hypodermic	—	>6

* On groups of 10 animals.

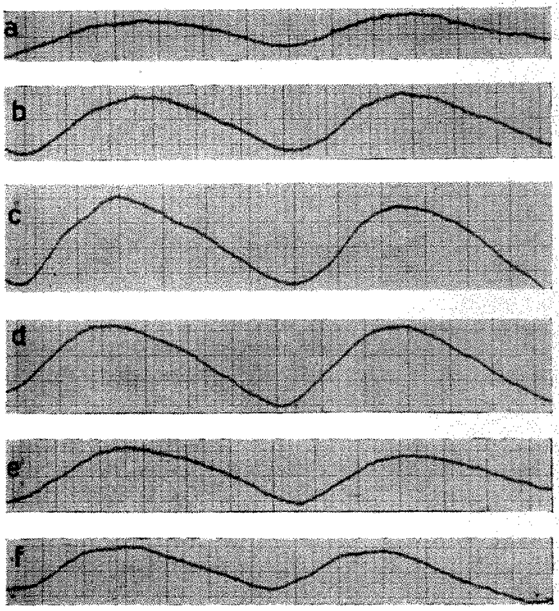

Fig. 1. Photoplethysmographic records of a man, forty-nine years old, affected by peripheral artery disease, treated with 1 mgm./kgm. of acteina. *a*, Basal record; *b*, *c*, *d*, *e*, *f*, records 30 min., 1, 2, 3 hr. after injection. Calibration: 1 cm.=0·5 mV.

Furthermore, it must be emphasized that in almost 70 per cent of cases, the interruption of the vagus nerve on the neck inverts the hypotensive effect due to acteina; in such cases even the hypertensive reflexes of the carotid sinuses become normal again.

Therefore we conclude that acteina affects the function of the vagus, having a hypotensive effect in unanæsthetized rabbits and anæsthetized cats.

Its effect is discontinuous so far as its hypotensive effect on the unanæsthetized dog is concerned, even if it clearly shows a peripheral vasomotor effect.

It probably acts on the vasomotor centres, provoking inhibition of some of them and excitation of others, through either direct or reflected central mechanism.

In man this drug has no hypotensive effect, though its peripheral vasodilatory effect is evident.

FURTHER INVESTIGATIONS OF THE CARBOHYDRATE METABOLISM OF COCK SPERMATOZOA

By DR. P. E. LAKE*, DR. F. W. LORENZ, and WINIFRED D. REIMAN

Department of Poultry Husbandry, University of California, Davis, California

LORENZ[1] reported that fructose accumulated in a phosphate buffer medium whenever cock (*Gallus domesticus*) spermatozoa were incubated in the presence of glucose or mannose; the reverse reaction could not be clearly demonstrated. We have examined this observation further in an attempt to elucidate the metabolic pathway for the conversion, using paper chromatographic and autoradiographic techniques.

Semen, free from transparent fluid[2], was collected from New Hampshire cocks and quickly diluted with 3 parts of a buffered avian Ringer phosphate, *p*H 7·25, containing 4 mgm./ml. of either glucose, fructose or sorbitol. On separate occasions 1 μc. of either uniformly labelled D-[^{14}C]-glucose or D-[^{14}C]-fructose was added to the final mixtures containing the same sugar. In each experiment initial aliquots were taken and the remainder incubated for 1 or 3 hr. at 37° C. either aerobically or semi-anaerobically as described previously[1]. After incubation the diluted semen

* Present address: Agricultural Research Council, Poultry Research Centre, King's Buildings, West Mains Road, Edinburgh 9.

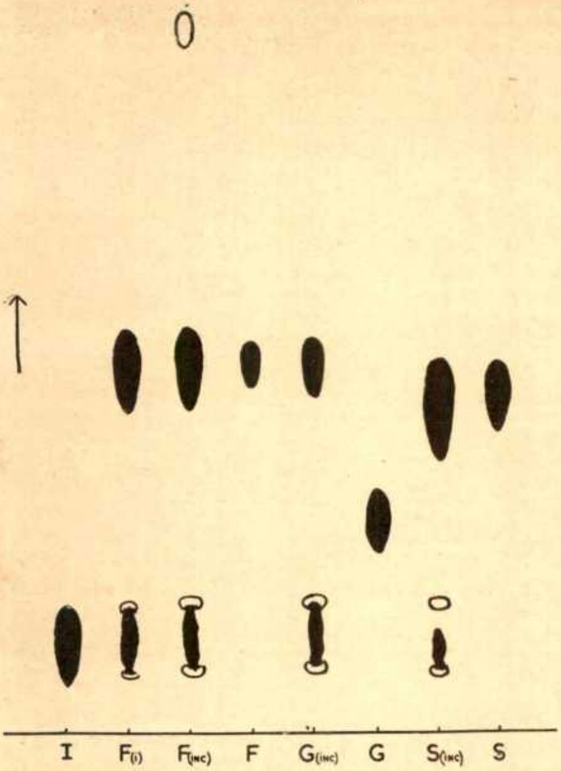

Fig. 1. Chromatogram of extracts of cock semen incubated aerobically for 3 hr. at 37° C. separately with glucose, fructose and sorbitol. Descending (run off end of paper), 48 hr., 27° C. Silver nitrate-alcoholic sodium hydroxide location reagent. Solid spots stained brown or black after treatment with alcoholic sodium hydroxide solution. Outlined spots remained as white areas after this treatment; the foremost spot was unidentified, but the two slow-running spots proved to be fructose-6-phosphate, glucose-6-phosphate and other phosphorylated compounds. These latter were present in unincubated semen and increased in amount during incubation (though more irregularly than suggested here) whether or not the semen was incubated with added carbohydrate. $F_{(i)}$, semen with fructose before incubation; F(inc), semen after incubation with fructose; G(inc), semen after incubation with glucose; S(inc), semen after incubation with sorbitol; *I*, *F*, *G* and *S*, authentic marker spots of inositol, fructose, glucose and sorbitol respectively

samples were deproteinized, using barium hydroxide and zinc sulphate followed by freezing and thawing. The supernatant fluids were passed consecutively through ion-exchange resins 'Dowex 50' (H^+ form) and 'Amberlite *CG* 45', type 2 (OH^- form); the resultant effluents and washings were evaporated to dryness on a rotary evaporator. The residues were dissolved in small volumes of distilled water (0·3 ml. per ml. original semen). In addition to the incubated semen samples, fresh uncontaminated seminal plasma[2] and spermatozoan fractions were prepared and treated in the same manner. Aliquots of 20–60 μl. were spotted on Whatman No. 1 paper and subjected to unidimensional, descending chromatography in one of three solvent systems, phenol-concentrated ammonia–water (80 gm.: 0·5 ml.: 20 ml.), ethyl acetate–pyridine–water (60 ml.: 25 ml.: 20 ml.) and *n*-butanol–acetic acid–water (60 ml.: 15 ml.: 25 ml.)[3]. Autoradiograms were then developed during two to four days with the appropriate X-ray film[4]. Authentic markers of fructose, glucose, sorbitol, inositol, fructose-6-phosphate, glucose-6-phosphate, and uniformly labelled D-[^{14}C]-glucose and D-[^{14}C]-fructose were used rather than relying on R_F values.

The specific ketose location reagent naphthoresorcinol–acetone–H_3PO_4 (ref. 5) was used to verify the formation of fructose. It was found that glucose sometimes reacted slowly with naphthoresorcinol over a few days at room temperature to give a blue colour; fructose formed a pink-brown colour immediately on heating.

The results of the chromatographic and autoradiographic studies showed that extracts of fresh spermatozoa and uncontaminated seminal fluid contained no detectable reducing sugars, but inositol was found in whole semen or seminal plasma. The sugar alcohol had previously been found and estimated (10 mgm. per 100 ml.) in cock seminal plasma (Lake, unpublished observations). Fructose always accumulated under the conditions of the experiments when cock semen was incubated with glucose, thus confirming previous observations on cock spermatozoa[1]; glucose disappeared completely from the medium after 3 hr. at 37° C. Conversely, after semen was incubated with fructose, glucose was never detected either on autoradiograms or ordinary chromatograms. Glucose and fructose were found to separate best in the phenol-concentrated ammonia–water system; a typical chromatogram is illustrated in Fig. 1.

A preliminary examination of possible pathways for the formation of fructose from glucose by cock spermatozoa was made. It was considered possible, but remotely so, that glucose was being phosphorylated, and, by phosphohexoisomerase, converted first to fructose-6-phosphate and then by phosphatase to free fructose. Such a pathway was suggested by Mann[6] for fructose formation in bull seminal vesicles. However, as no fructose could be detected after spermatozoa had been incubated for 2 hr. with fructose-6-phosphate (sodium salt; 4 mgm. per ml.) this pathway was ruled out.

King and Mann[7] presented evidence for the existence of sorbitol dehydrogenase (a ketose reductase) in ram spermatozoa which catalyses the interconversion of fructose and sorbitol; indications of a slower reduction of glucose to sorbitol were also obtained. King, Isherwood and Mann[8] also reported the presence of a small amount of sorbitol in cock semen. Hers[9] showed that glucose was irreversibly converted to fructose by ram seminal vesicle tissue: two enzymes, an aldose reductase and a ketose reductase (sorbitol dehydrogenase), were involved in a two-step process with sorbitol as the intermediary compound. If these observations could be extrapolated to cock spermatozoa they would suggest a pathway for the conversion of glucose to fructose: (*a*) reduction of glucose to sorbitol, which should be irreversible according to our observations and taking place, possibly, under conditions different from those obtaining in the ram[7]; (*b*) oxidation of sorbitol to fructose catalysed by sorbitol dehydrogenase. The latter oxidation proceeds in intact ram spermatozoa[7,10] despite an apparently unfavourable equilibrium, presumably because of a favourable ratio between oxidized and reduced diphosphopyridine nucleotide. Hers[9] suggested that the reaction glucose → sorbitol → fructose was irreversible in ram seminal vesicle tissue because triphosphopyridine nucleotide occurs almost exclusively in the reduced form and diphosphopyridine nucleotide largely in the oxidized form. Similar distributions of oxidized and reduced forms of these co-factors were found in several animal tissues by Glock and McLean[11].

With our chromatographic techniques we were unable to separate, clearly, sorbitol and fructose. Any involvement of sorbitol in the interconversion of glucose and fructose by fowl spermatozoa was therefore difficult to study. Developing the chromatograms of incubated extracts with a location reagent for polyhydric alcohols[12,13] and comparing with others developed with the silver nitrate reagent yielded ambiguous results which, however, were not inconsistent with the involvement of sorbitol. Cock semen was incubated aerobically with sorbitol and traces of fructose accumulated as determined by the resorcinol test[1]. Although the accumulation of this rapidly metabolized ketose sugar, even in traces, suggests that a route for conversion of sorbitol to fructose does exist, it is considered, at present, that the feeble activity observed is inadequate to account for the large accumulation of fructose in semen incubated with glucose.

In conclusion, the conversion of glucose to fructose by cock spermatozoa has been demonstrated to be an irreversible process. The pathway does not involve glucose-6-phosphate isomerization; a pathway involving sorbitol is possible, but remains to be convincingly demonstrated.

This investigation was supported by funds from the National Science Foundation and was conducted while one of us (P. E. L.) held a Lalor Foundation Fellowship.

INHIBITION BY PHENOTHIAZINIC COMPOUNDS OF THE EFFECT OF 2,4-DINITROPHENOL ON THE RESPIRATION OF HEART MUSCLE SARCOSOMES

By METRY BACILA and HEITOR MEDINA

Instituto de Bioquímica da Universidade do Paraná, Brasil

DURING an investigation of the effect of antihistaminic drugs on the oxidative phosphorylation of guinea pig heart sarcosomes it was found that phenothiazinic compounds inhibited the stimulation of respiration displayed by 2,4-dinitrophenol on mitochondria.

Heart muscle sarcosomes were prepared by a modification of the method of Clelland and Slater[1] previously used by us[2,3]. After homogenization and washing the heart in a medium containing 0·33 *M* sucrose and 1×10^{-3} *M* ethylenediamine tetraacetic acid, *p*H 7·4, the sarcosomes were suspended in the same medium in the proportion of 0·5 : 1 ml. of medium per heart used. The average protein content in the original suspension of heart mitochondria was 14·39 mgm. per ml. The reaction medium contained 0·33 *M* sucrose, 0·02 *M* phosphate buffer *p*H 7·4, and 0·01 *M* potassium chloride.

Respiration was measured using oxygen electrode described by Voss and Bacila[4]. It was made with a platinum electrode of the stationary type combined with a magnetic stirrer and a potassium chloride bridge. The magnetic stirrer is able to mix the reagents promptly in a closed mixing chamber with a capacity of 2·0 c.c. The inconvenience of the open cuvettes is thus completely avoided, as well as the contamination of the platinum electrode, which is coated with a cellulose tubing paper. Oxidative phosphorylation was measured according to the method of Chance and Williams[5] and the phosphorus/oxygen ratios determined as adenosine diphosphate/oxygen ratios.

The effect of phenothiazinic compounds on the normal properties of guinea pig heart sarcosomes were examined with the following: *promethazine*—10-(2-dimethylaminopropyl)phenothiazine; *chlorpromazine*—2-chloro-10-(3-dimethylaminopropyl)-phenothiazine; *neozine* — lævo-methoxy-3(dimethylamino-3′methyl-2)′-propyl-10-phenothiazine; *perphenazine* — 1-(2-hydroxyethyl)-4-[3-(2-chloro-10-phenothiazinyl)propyl] piperazine.

The main characteristic of these compounds is the presence of a phenothiazinic nucleus, besides the fact that they all have a very marked pharmacological activity some of them being of attaraxic activity and others displaying an anti-histaminic action.

The effect of one of these drugs (perphenazine) on the respiration and oxidative phosphorylation of heart muscle sarcosomes is shown in Table 1. It can be seen that the respiratory control coefficients, calculated as the ratio between the rate of respiration during the active state of respiration with adenosine diphosphate (ADP) and the control respiration after

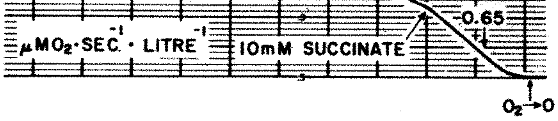

Fig. 1. Effect of promethazine on the stimulus of respiration by 2,4-dinitrophenol of guinea pig heart sarcosomes. To the aerobic mitochondria, 10 m*M* of α-ketoglutarate were added and the respiration-rate recorded (0·17 μ*M* oxygen $\text{sec.}^{-1}\ \text{l.}^{-1}$). The addition of $2 \cdot 2 \times 10^{-5}$ *M* of 2,4-dinitrophenol increased the respiration-rate (0·50 μ*M* oxygen $\text{sec.}^{-1}\ \text{l.}^{-1}$). This was followed by the addition of 5×10^{-4} *M* of promethazine; it caused a slight increase in the respiration-rate which later levelled off to the initial rate of 0·17 μ*M* oxygen $\text{sec.}^{-1}\ \text{l.}^{-1}$. The addition of 10 m*M* succinate increased the rate of respiration to 0·65 μ*M* oxygen $\text{sec.}^{-1}\ \text{l.}^{-1}$

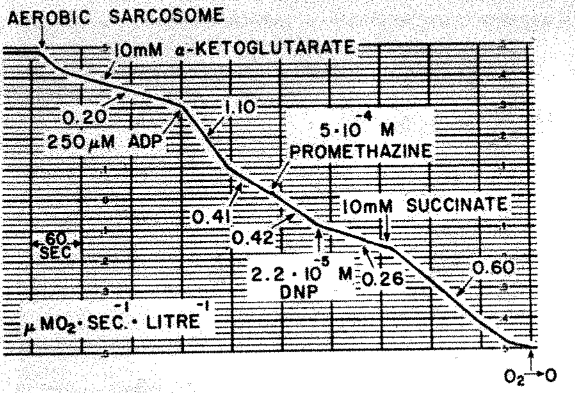

Fig. 2. Effect of promethazine on the oxidative phosphorylation and 2,4-dinitrophenol action on guinea pig heart sarcosomes. To the aerobic mitochondria, 10 m*M* of α-ketoglutarate were added and the respiration-rate recorded (0·20 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$). The addition of 250 µ*M* ADP increased the rate of respiration during the active state of respiration to 1 × 10 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$, and when the acceptor of inorganic phosphate was used up there was a levelling off of the respiration-rate to 0·41 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$. The respiratory control coefficient (ratio between the respiration-rate during the active state and the rate of the controlled respiration after ADP) was equal to 2·68 and the ADP/O ratio was equal to 2·8. This was followed by the addition of 5 × 10^{-4} *M* promethazine and then by 2·2 × 10^{-5} *M* 2,4-dinitrophenol, which did not stimulate respiration. Then the further addition of 10 m*M* succinate increased the rate of respiration to 0·60 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$

ADP, is inhibited by increasing amounts of perphenazine. Furthermore, the rates of respiration during the active state decrease in the presence of increasing amounts of perphenazine.

Table 1. Effect of Perphenazine on Oxidative Phosphorylation of Heart Muscle Sarcosomes

Perphenazine (pre-incubation)	Respiration-rate with α-keto-glutarate (10 m*M*)	Respiration-rate during ADP (active state)	Controlled respiration-rate after ADP	Respiratory control cofficient
No addition	0·27	0·62	0·27	2·3
6·2 × 10^{-5} *M*	0·24	0·62	0·24	2·5
1·2 × 10^{-4} *M*	0·17	0·50	0·20	2·5
3·5 × 10^{-4} *M*	0·21	0·47	0·26	1·8
4·9 × 10^{-4} *M*	0·19	0·29	0·19	1·5
6·2 × 10^{-4} *M*	0·19	0·19	0·00	Completely uncoupled

System contains: 1·9 ml. of aerobic medium, 0·1 ml. of sarcosome suspension, 10 m*M* of α-ketoglutarate, and suitable amounts of ADP and perphenazine. The figures for the rates of α-ketoglutarate respiration, the active state respiration during ADP, and the control respiration after ADP are given in µ*M* oxygen sec.$^{-1}$ l.$^{-1}$.

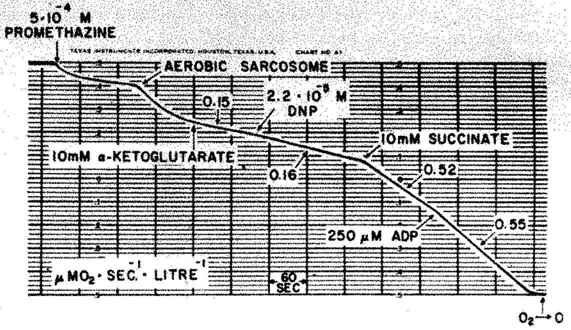

Fig. 3. Effect of the pre-incubation of sarcosomes with promethazine on the action of 2,4-dinitrophenol on respiration and oxidative phosphorylation. Sarcosomes were pre-incubated with 5 × 10^{-4} *M* promethazine for about 90 sec. Then, 10 m*M* α-ketoglutarate were added and the respiration-rate recorded (0·15 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$). The addition of 2·2 × 10^{-5} *M* of 2,4-dinitrophenol did not stimulate respiration. Then 10 m*M* succinate were added and the rate of respiration was increased to 0·52 µ*M* oxygen sec.$^{-1}$ l.$^{-1}$. Further addition of 250 µ*M* ADP did not stimulate respiration to a significant rate either

Promethazine, as well as the other phenothiazinic compounds, besides inhibiting oxidative phosphorylation of heart sarcosomes, show a very interesting effect by inhibiting the stimulation of respiration displayed by 2,4-dinitrophenol when added to a suspension of mitochondria. In the presence of suitable concentrations of promethazine, the effect of 2,4-dinitrophenol in stimulating the respiration of mitochondria fails to appear. This effect seems to be parallel to the inhibition of oxidative phosphorylation; inhibition of oxidative phosphorylation also occurs in the presence of promethazine. On the other hand, in the presence of succinate, the promethazine-treated sarcosome can respire again, even when the DNP effect and the oxidative phosphorylation are inhibited. Figs. 1, 2 and 3 illustrate this effect.

Analysis of these data indicates that phenothiazinic compounds have a very marked effect on the properties of heart sarcosomes. It was also possible to show a parallelism between the DNP effect in stimulating the respiration and the oxidative phosphorylation of the sarcosome, being both of them inhibited by these compounds. Succinate, however, can restore the respiratory activity of the mitochondria to which a phenothiazinic compound was already added.

LATEX AGGLUTINATION TEST WITH *BRUCELLA* ANTIGEN AND ANTISERUM

By (the late) Prof. L. FLECK and Z. EVENCHIK

Israel Institute for Biological Research

SINGER and Plotz[1] introduced the application of latex suspension to the serological diagnosis of rheumatoid arthritis[1]; later this method was used in other serological tests[2-4].

Hirschberg and Yarbrough sensitized red blood cells or collodion particles with various antigens derived from *Brucellae*. Successful results were obtained with extracts of *Brucellae* in trichloroacetic acid or in phenol using collodion suspensions, but not with red blood cells sensitized with the same antigens. These findings have been confirmed by us; however, the preparation of collodion is very troublesome. We have therefore replaced it by latex, which is commercially available.

The following technique has been developed: A smooth culture of *Brucella abortus*, strain 6195 or strain 544 (strain 6195 obtained from the Veterinary Institute, Ministry of Agriculture, and the strain 544 from the Veterinary Institute in Rotterdam), grown for 48 hr. at 37° C. on potato agar in bottles, was suspended in 5 ml. of saline and centrifuged at 1,500 r.p.m. for 15 min. The sediment was washed once with saline, centrifuged again and re-suspended in distilled water. The bacteria were killed by heating for 1 hr. at 70° C., whereon the suspension was ultrasonically vibrated (Raytheon, 10 kc.) for 60–120 min. The suspension was then again centrifuged for 10–15 min. at 18,000 r.p.m., and the light opalescent supernatant was used as the sensitizing antigen. The antigen could be stored for 4–6 weeks at 4° C. and the latex suspension sensitized with it for at least 4 weeks.

Sensitization of latex particles. 'Bacto-latex 0·81' (Difco) diluted 1 : 20 in 0·85 per cent saline (*p*H 6·8–7·2) was mixed with an equal volume of the sensitizing *Brucella* antigen. It was found that a solution of 1 : 5 to 1 : 10 of the antigen was optimal for the sensitization. Following an incubation of 30 min. at 37° C., the mixture was centrifuged for 30 min. at 3,000 r.p.m. the supernatant discarded, the sediment washed twice with saline and finally re-suspended in the original volume of the diluted latex suspension. This sensitized latex suspension was checked against known positive and negative sera.

Titration of anti-Brucella sera. To 0·5 ml. of inactivated serum (1 : 50–1 : 6,400), one drop of the sensitized latex suspension was added, and the tubes shaken. After an incubation of 45 min. at 37° C. the tubes were centrifuged for 15 min. at about 1,000 r.p.m., after which the reading could be carried out immediately.

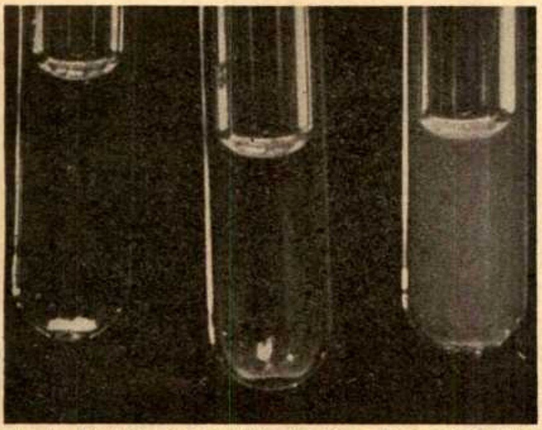

Fig. 1. Positive and negative reactions of sensitized latex suspension agglutination

Fig. 1 shows positive and negative reactions; the highest dilution of serum still showing clear agglutination represents the titre of the serum. When comparing the sensibility and the specificity between the sensitized latex suspension test and *Brucella* bacterial agglutination, no discrepancies were observed.

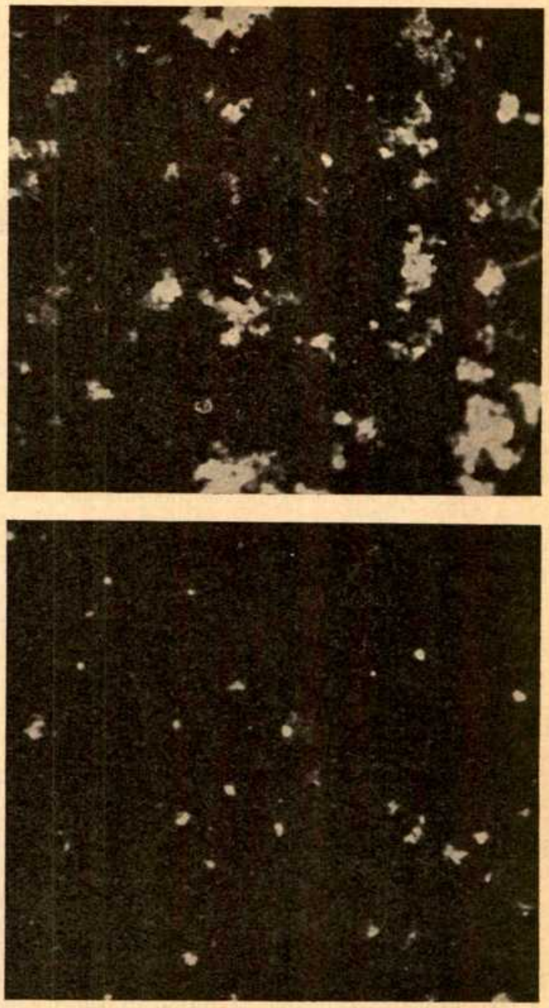

Fig 2. Top, specific fluorescence of agglutinated sensitized latex suspension (×400); bottom, fluorescence of non-agglutinated sensitized latex suspension in non-specific inhibition (×400)

Detection of small quantities of Brucella antigen by inhibition of latex agglutination. Inhibition of the latex agglutination as described here can be demonstrated with material in which *Brucella* antigen is present (Table 1).

If *Brucella* antigen is present in any clinical material tested, the inhibition index of the antigen in the material is calculated by dividing the titre of immune serum in the control test by the titre obtained when a given dilution of the tested material is added to the system. It can be seen in the case shown in Table 1 that a quantity of antigen present in 0·5 ml. of a dilution of 1 : 1,000 was still detectable. A

SLS, sensitized latex suspension

parallel precipitation test with the same antigen showed that at least a twenty-fold concentration of antigen was required for a precipitation to occur.

The application of this inhibition test is limited by the presence of many non-specific inhibitors in biological materials tested for the presence of the antigen (for example, urine). In order to distinguish between specific and non-specific inhibition of sensitized latex suspension agglutination, the fluorescent antibody technique was used. This technique was based on the 'direct' method of Coons and Kaplan[6]. Anti-*Brucella* conjugated globulin of immunized goat (agglutination titre 1 : 6,400) was used in a tube test. In a control agglutination test 0·2 ml. of a 1 per cent labelled globulin was added to an equal volume of sensitized latex suspension. The mixture was incubated 2 hr. at 37° C. and overnight at 4° C. The tubes were centrifuged for 10 min. at about 3,000 r.p.m., the sediment was washed in saline and re-suspended in a drop of phosphate buffer (*p*H 7·2–7·4). A loopful of this suspension was smeared on a slide, mounted in buffered glycerine and examined under the fluorescence microscope. Specific fluorescence of agglomerated sensitized latex suspension is shown in Fig. 2, top. In the inhibition test, labelled globulin was first incubated for 1 hr. at 37° C. with the dilutions of the antigen investigated, then mixed with sensitized latex suspension and treated as above.

In the case of specific inhibition of agglutination, the latex particles were not agglutinated and showed no fluorescence, since all antibody was bound by the inhibiting antigen. In the case of non-specific inhibition, there was no agglutination of latex particles, but they showed fluorescence (Fig. 2, bottom); the non-specific inhibitors prevent only the agglomeration of sensitized latex suspension but do not affect the adsorption of specific antibody to them.

We have been able, by introducing the sensitized latex suspension test, to investigate the antigenic fractions of *Brucella*.

The inhibition test as described above permits the detection of minute amounts of *Brucella* antigen in biological materials, while the fluorescent antibody method can be used to distinguish between specific and non-specific inhibition.

This work was supported by a grant from the Ford Foundation.

EARLY HEPATIC DYSFUNCTION PRECEDING BILIARY OBSTRUCTION IN SHEEP INTOXICATED WITH SPORIDESMIN

By P. H. MORTIMER and A. TAYLOR
Ruakura Animal Research Station, Hamilton
AND
F. B. SHORLAND
Fats Research Laboratory, Department of Scientific and Industrial Research, Wellington, New Zealand

THE mechanism of bile excretion by the hepatic cell and related physiological phenomena have been investigated by many workers. For example[1], the hepatotoxins ethionine, carbon tetrachloride and α-naphthylisothiocyanate behave differently with regard to their effects on liver cell necrosis, bile flow and proliferation of the bile ductular epithelium. Excretion of bile pigments, alkaline phosphatase and water by the hepatic cells of rabbits intoxicated with icterogenin has been followed by Heikel *et al.*[2]. Cameron and Hasan[3], in studying the effects of common bile duct ligation in rats, suggested that liver cell function is disturbed before the bile can exert its toxic action. They concluded, however, that experimental proof for this suggestion was difficult to obtain because the available techniques were inadequate. The purpose of this article is to direct attention to the possibility of using sporidesmin, a metabolic product of the fungus *Pithomyces chartarum* (Commonwealth Mycological Institute Herbarium No. 74473; Ellis[4]; Synge and White[5]), to provide experimental data on the mechanism of bile excretion and also on the events leading to biliary obstruction.

In the present experiments sporidesmin was administered orally to 56 sheep at a dose-level of 1·0 mgm./kgm. body-weight. At 2, 4, 7, 10, 14, 21 and 28 days after administration of sporidesmin, groups of 8 sheep were killed. In addition, 18 animals that had not received sporidesmin were used as controls. Serum samples were taken from all remaining sheep on the days shown in Fig. 1. The bulked gall bladder bile from each group was collected under toluene then lyophilized. Liver tissue was placed in 4 per cent (w/v) formaldehyde in isotonic saline for histological examination, was frozen and sectioned. Sections were examined for the presence of fat after staining with oil red *O* and Mayer's hæmalum. The bulk of the remaining liver was cut into thin strips and immersed in boiling ethanol within 15 min. of death. Fat was extracted from the liver tissue[6], steroids determined by the Sperry and Webb[7] procedure and lipid phosphorus by the method of Fiske and Subbarow[8] as modified by King[9]. Glutamic oxalacetic transaminase[10] and bilirubin[11] levels were determined on all serum samples. Results are summarized in Fig. 1. The solid content of gall bladder bile and the incidence of colourless bile is shown in Table 1.

Fat staining could not be found in liver sections of the control animals. However, livers of animals

△, Total liver lipid; □, liver steroids; ○, serum glutamic oxalacetic transaminase; ×, serum bilirubin. Values for control animals were closely similar to those given for day 0

killed two and four days after intoxication showed marked fat staining which was confined to the peripheral areas of the lobules. Sections from animals killed 10 days after dosing showed little or no fat staining. Livers of subsequent groups showed stainable fat in some instances, but by contrast with those of the earlier groups the distribution was mainly centrilobular. The changes revealed by the histological observations coincided with changes in the amount of extracted lipid. In addition, changes in the texture of the extracted lipid were noted. Whereas in the normal livers this lipid was brittle, two days after dosing the lipid was invariably waxy. Four days after dosing the liver lipids were also generally of a waxy texture, but in the groups killed afterwards the texture of the liver lipids was mainly friable and similar to that of normal animals. As the lipid phosphorus content of the liver remained nearly constant throughout the experimental period changes in the lipid composition must occur in the non-phospholipid fractions. Part of the increase in lipid content after two days is attributable to the steroid fraction (Fig. 1).

The increase in serum glutamic oxalacetic transaminase between days four and seven provides further evidence of hepatic cell derangement, for such increases are widely believed[12] to be associated with tissue damage and the attendant leakage of cell contents into the circulating fluids. The changes observed in gall bladder bile (Table 1) are consistent with changes in hepatic cell function, but alternatively might be accounted for by the inflammatory changes which were found in the gall bladder and in the extra-hepatic bile ducts.

The early changes just described were followed after 10 days by elevated serum bilirubin, phospholipid, and 'cholesterol' levels as well as photosensitivity. These changes were related to the biliary obstruction observed on post-mortem examination.

Thus, it seems likely that in sporidesmin intoxication of sheep (similar results have also been obtained in rabbits) injury to the hepatic cell precedes biliary obstruction.

MORPHOLOGICAL INFLUENCE OF EXUDATES OF MYCORRHIZAL AND NON-MYCORRHIZAL FUNGI ON EXCISED ROOT CULTURES OF *PINUS SYLVESTRIS* L.

By P. D. TURNER

Department of Botany, University of Hong Kong

SLANKIS[1] examined the effects of exudates from some mycorrhizal fungi on the development of excised *Pinus sylvestris* L. root cultures, and found them to be influential on the elongation and in production of dichotomous lateral roots. From these and other results he suggested a hypothesis for the morphogenesis of mycorrhizal roots[2]. These observations were of importance in understanding the influence of mycorrhizal fungi on their hosts, but it remained unknown whether this effect was confined to mycorrhizal fungi alone. The formation by soil micro-organisms of products which influence higher plants is widespread, and it seemed probable that non-mycorrhizal fungi would influence the growth of excised pine roots. A summary of work on this problem is presented here.

Exudates of 54 fungi were tested; most were obtained by direct isolation from *P. sylvestris* root tips or dichotomous roots, or from sporophores collected in coniferous plantations. The method of excised root culture was essentially that of Slankis[3], except that ferric chloride in the nutrient was replaced by iron ethylenediamine tetraacetic acid. Development occurred at laboratory temperatures, and records made of increase in length and lateral root formation. Fungi were grown on the same nutrient medium and filtrates tested when good mycelial growth had occurred. The mycelium was removed by Seitz filtration and 5 ml. of the filtrate added aseptically to each of 15 or 20 single root replicates on inoculation; 10 ml. of the same filtrate were added to each of five single replicates of older root cultures with well-developed lateral root systems.

Of all filtrates tested only four (7 per cent), *Boletus granulatus* (L.) Fr., *Boletus subtomentosus* (Schaeff.)

Table 1. TAXONOMIC SUMMARY OF THE INFLUENCE OF FUNGAL CULTURE FILTRATES ON DEVELOPMENT OF EXCISED *Pinus sylvestris* ROOTS

	Phycomycetes	Fungi Imperfecti	Basidiomycetes			
			Mycorrhizal	Non-mycorrhizal	Status unknown	Total
No. tested	7	24	7	13	2	22
No. inducing dichotomies	1 (14 per cent)	1 (4 per cent)	4 (57 per cent)	6 (46 per cent)	1	11 (50 per cent)
No. stimulating elongation	2 (28 per cent)	1 (4 per cent)	2 (26 per cent)	2 (15 per cent)	1	5 (23 per cent)
No. stimulating lateral root formation	0	0	1	1	0	2

Fr., *Mucor spinosus* van Tiegh., and *Trichocladium asperum* Harz were without any apparent effect on initial elongation of the excised radicles. Stimulation of elongation was recorded with ten (19 per cent) isolates, *Amanita muscaria* (L.) Fr., *Boletus bovinus* (L.) Fr., *Clitocybe aurantiaca* (Wolf) Studer., *Fusarium oxysporum* Schlecht. ex. Fr., *Marasmius androsaceus* (L.) Fr., *Mortierella baineri* Const., *Mucor ramannianus* Moller, two isolates of *Mycelium radicis atrovirens* and *Peniophora sanguinea* (Fr.) Bres. Filtrates of all other fungi (74 per cent) caused some reduction, slight in the case of *Mycena galericulata* (Scop.) Fr. and *Zygorrhynchus* sp., to the severe inhibition by filtrates of *Botrytis cinerea* Pers. ex Fr., *Fomes annosus* (Fr.) Cooke and *Trichoderma viride* Pers. ex Fr. Retardation of elongation was frequently accompanied by a brown or black discoloration of the roots.

The pattern of lateral root formation roughly followed that of elongation. Only two filtrates, those of *A. muscaria* and *P. sanguinea*, stimulated lateral root production; most other filtrates caused a reduction, with no formation at all with those of *Calcarisporium arbuscula* Preuss, *Cylindrocarpon radicicola* Wollenw., *Gliocladium* sp., and *Phallus impudicus* L. A number of fungi was found to produce substances in culture which induced the formation of dichotomous roots, such roots being comparable with those found associated with mycorrhizal fungi under natural conditions. Of the mycorrhizal fungi examined, differential response by root cultures to the exudate of a particular species was observed. No dichotomous roots developed in cultures containing filtrates of *A. muscaria*, *B. granulatus* and *B. subtomentosus*, although profuse development of lateral roots occurred in cultures containing the *B. granulatus* exudate. Mycorrhizal fungi found to induce dichotomy were, in order of decreasing influence, *B. variegatus* (Swartz) Fr., *B. badius* Fr., *B. luteus* (L.) Fr., and *B. bovinus*. Dichotomous roots, however, were also found in cultures containing filtrates of fungi other than those known to form mycorrhizal associations, that is, *Gliocladium deliquescens* Sopp, *M. spinosus*, *Peniophora gigantea* Mass., *Pholiota mutabilis* (Schaeff.) Fr., and *Tricholoma rutilans* (Schaeff.) Fr.

Cultured mycelium pieces of *B. variegatus*, *Collybia putida* (Fr. Kuhner and Maire, *Lycoperdon pyriforme* (Schaeff.) Pers., and *P. impudicus* were also added to well-developed root cultures. In each instance, fungal growth was markedly superior to that in nutrient medium alone, indicating a transfer of some beneficial root metabolite to the fungus. Growth of each isolate was extensive over the root surface, and finally killed the root. Dichotomous roots were produced in each culture; they were brown in colour, except those induced by *P. impudicus*, which were purple-mauve. This was additional evidence that colours of mycorrhizal roots are determined by the fungal components[4].

An examination of the data was made to determine the relationship between growth influences and ecological groups[5] of the fungi involved. Soil saprophytes, which included both specialized and unspecialized types, were almost invariably inhibitory, but exudates of one isolate induced dichotomous root production. A similar situation existed with exudates of the group of wood-destroying fungi, although a higher proportion of exudates induced dichotomies. Variable influence was also found with exudates of the mycorrhizal group of fungi, with stimulation of both elongation and lateral root formation being limited to a single isolate, and of elongation only to two others. The remaining four isolates caused reduction in varying degrees, as was previously found with *B. variegatus*[1]. Formation of dichotomous roots was not found to be characteristic of the group as a whole, but rather a property of particular individuals. A consideration of the taxonomic groups involved, however, afforded a greater correlation. No connexion was found between the degree of stimulation of elongation and lateral root formation, but this was noted in association with the production of dichotomous roots; these results are summarized in Table 1. Dichotomies were induced by exudates from one isolate of seven Phycomycetes, one of twenty-four Fungi Imperfecti, and eleven of twenty-two Basidiomycetes. It would seem that the ability to occasion production of dichotomous roots in cultures of excised roots of *P. sylvestris* was almost a characteristic of the Basidiomycete group, the number inducing dichotomies being divided equally between mycorrhizal and non-mycorrhizal isolates.

The results observed support the suggestion[6] that the study of mycorrhiza should be regarded only as a detailed part of the wider subject of root and fungus interaction. Although the great majority of fungi tested (92 per cent) produced exudates which were influential in culture, assessment of the relative importance of such exudates, if they occur naturally, to the entire plant is both difficult and largely hypothetical. The effects of fungal secretions are likely to be most pronounced at the region of the highest level of metabolic activity[7], so it is probable that only those capable of entering into the close cortical relationship would be of far-reaching significance. In addition, it was apparent from the results obtained for the seven known mycorrhizal fungi that physiologically the isolates were very different, and it seems certain that different species of mycorrhizal fungi, as well as strains of the species[8], are unequally effective in their contributions towards growth of the host plant[4].

STRONGLY CAROTENOID-DEFICIENT *CHROMATIUM*-STRAIN *D* CELLS WITH 'NORMAL' BACTERIOCHLOROPHYLL ABSORPTION PEAKS IN THE 800–850 mμ REGION

By E. C. WASSINK and G. H. M. KRONENBERG
Agricultural University, Wageningen, The Netherlands

IN the course of work on the pigment-protein complexes of purple bacteria, continuing earlier work[1,2], we endeavoured to cultivate carotenoid-deficient cells of *Chromatium*, strain *D*, by the method devised by Goodwin and Osman[3,4], using diphenylamine (DPA).

The absorption spectrum of the green cells, thus obtained, determined with a Beckman *DU* spectrophotometer by the method of Shibata[5], shows their strong deficiency in carotenoids by very great reduction of the absorption in the 450–550 mμ region of the spectrum (Fig. 1). However, the bacteriochlorophyll absorption maximum at 850 mμ is of the same order of magnitude, and in some cases even higher than that found in normally grown cells of *Chromatium*, strain *D*. The same holds for the pigment-protein complexes, present in extracts of both types, prepared by grinding (Fig. 2). In all cases the spectrum shows the shape which is usual for *Chromatium*, strain *D*, namely, with an 850 mμ maximum about 1·2–1·5 times as high as the 800 mμ maximum. The spectra of the green cells and their extracts tend to show a somewhat decreased 890 mμ absorption as compared with normally grown cells.

The occurrence of the 850 mμ maximum in DPA-treated cultures in the same way as present in normally grown cells of this strain is at variance with the observations of Bergeron and Fuller[6], who report a strong reduction of the 850 and 890 mμ absorption peaks, accompanying the decrease of absorption in the carotenoid part of the spectrum, owing to the DPA treatment. Although the concentration of DPA applied by Bergeron and Fuller[6] is higher than 12 mgm./l., at which our cells were grown, the absorption in the carotenoid part of the spectrum is equally low in both cases. We have not been successful, so far, in growing *Chromatium*, strain *D*, at DPA concentrations above 12 mgm./l. In attempts of this sort, starting from either 'red' or 'green' cultures, the medium in the inoculated bottles remains clear, the cells of the inoculum become bleached and drop to the bottom. Like Fuller (personal information), we used a pale brown preparation of DPA ('purum'). Three times recrystallization of the substance from ethanol–water mixtures yielded a white product. Using this, however, the maximum concentration at which the bacteria still multiply was not increased; it rather tended to some decrease. It seems possible that the differences in the spectra of carotenoid-deficient bacteria obtained by Bergeron and Fuller[6] and in our experiments are connected with the fact that those investigators were able to cultivate the bacteria at much higher concentrations of DPA, at which the cells may develop an absorption spectrum with lowered 890 and 850 mμ peaks. Moreover, the possibility remains of a difference in the bacteria: what is called '*Chromatium*, strain *D*' may not be fully identical in both cases.

Anyhow, the observations presented in this article demonstrate that there is not necessarily any relation between disappearance of carotenoids and disappearance of the 850 mμ bacteriochlorophyll maximum in *Chromatium*, strain *D*. As for the 890 mμ peak, we fairly consistently found this weaker in carotenoid-deficient bacteria than in those normal.

Furthermore, it occurs to us that the coincidence of disappearance of carotenoids and increased sensitivity to photo-oxidation, reported by Cohen-Bazire and Stanier[7] and Fuller and Anderson[8], and now under investigation in our laboratory, need not necessarily be explained as a direct protection of bacteriochlorophyll by carotenoids against photo-oxidation. It may as well mean that DPA inhibits the biochemical formation of carotenoids, and separately produces an enzymatic structure in the chromatophores which renders them more susceptible to

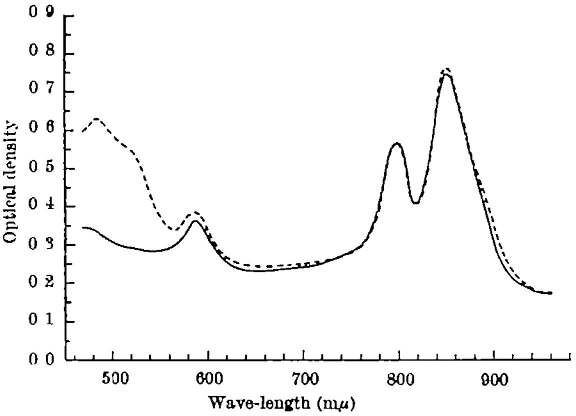

Fig. 1. Absorption spectra of *Chromatium*, strain *D*, grown in the absence and in the presence of DPA (12 mgm./l.). The 3-day-old cultures were suspended in phosphate buffer, *p*H 7·8. A sheet of filter paper was inserted into the beam to minimize the effect of scattering of the cells on the spectrum
– – –, Normal cells; ——, carotenoid-deficient cells

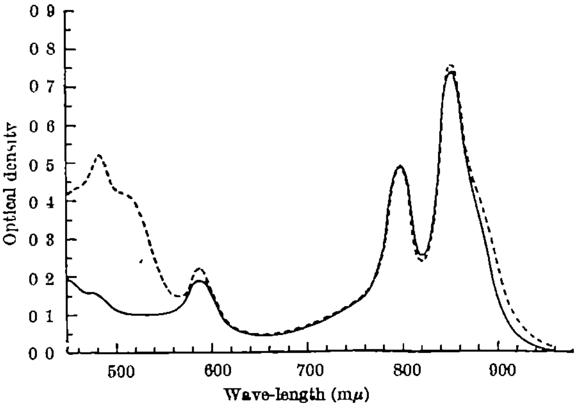

Fig. 2. Absorption spectra of aqueous extracts prepared from normal and carotenoid-deficient cells of *Chromatium*, strain *D*, by grinding
– – –, extract of normal cells; ——, extract of carotenoid-deficient cells

photo-oxidation. This change in structure may be reflected, for example, in the decrease of the 890 mμ complex. At very high concentrations of DPA, the biochemical structure of the chromatophores may be so much different from normal that the formation of the 850 mμ complex is also affected.

This work was performed under contract No. *AF* 61(052)–270 of the U.S. Air Research and Development Command.

We thank Dr. Fuller for discussions.

Note added in proof. The same holds for DPA *pro analyse*; in more recent experiments we found that, using a heavy inoculum, cultures still could be grown in solutions containing up to 20 mgm. DPA/l., without difference in the 800 and 850 mμ absorption bands

IRRADIATION EFFECTS ON STRAND SEPARATION OF DEOXYRIBONUCLEIC ACID

By H. M. KLOUWEN, A. W. M. APPELMAN and G. W. BARENDSEN
Radiobiological Institute, Organization for Health Research T.N.O., Rijswijk, Netherlands

A NUMBER of effects of ultra-violet and ionizing radiation on deoxyribonucleic acid (DNA) have been investigated from the point of view of their possible relevance to the damage produced by these radiations in living cells. Ultra-violet (254 mμ) light is mainly absorbed by the purine and pyrimidine residues and reversible hydration is considered to be the main mechanism of its action[1,2]. Recently, it has been shown that dimerization of thymine occurs when aqueous solutions of these compounds are irradiated with ultra-violet light[3,4]. Whether this effect occurs in living cells remains uncertain although Wacker *et al.* claim to have isolated thymine dimers from irradiated bacteria[5]. Ionizing radiation, on the other hand, is capable of producing several effects such as single-stranded and double-stranded breaks of the double helix structure and cross-linking[6]. Doty *et al.*[7] have shown that separation of the two strands in a DNA molecule can be achieved by heating and that recombination of the separated strands occurs when heated DNA solutions are cooled slowly. This separation mechanism is presumably very important for the replication of DNA and thus for proliferation of cells. We have investigated whether this strand separation and recombination are sensitive to irradiation.

The experiments were carried out with calf thymus DNA isolated according to the method described by Kay *et al.*[8]. Analytical data of the DNA preparation are: RNA, 0·5 per cent; protein less than 1 per cent; E_{260}/E_{280}, 1·83. Ultra-violet irradiations were performed with an unfiltered low-pressure ultra-violet source (Philips *TUV*) at 6 cm. from the lamp. The dose under these conditions was 93 erg./mm.^{2}/sec. 4-ml. samples of DNA solutions (20–25 γ/ml.; $E^{1\text{ cm.}}_{260}$ mμ, 0·380) were irradiated in Petri dishes (diam. 5·6 cm.). X-irradiations were performed with a General Electric Maxitron, 250 kV., 30 m.amp, half-value layer 2·0 mm. copper, dose-rate 250 r./min.

The DNA preparations were stored in 0·14 *M* sodium chloride (*p*H 6·5) at –10° C. at a concentration of 1·5 mgm./ml. Before use, samples were thawed and diluted with 0·14 *M* sodium chloride to a concentration of 20 or 25 γ/ml. After incubation of the DNA solutions for 20 min. in a water-bath at 89° or 95° C. the samples were transferred to cuvettes. Reading of the optical densities was started 1 min. after the samples were taken out of the bath and continued for 20 min., during which the temperature decreased to 25° C.

Two series of experiments were carried out: (*a*) those in which ultra-violet irradiation of DNA solutions was applied before heating of the samples; (*b*) those in which ultra-violet irradiation was applied between two heating periods.

(*a*) *Ultra-violet irradiation before heating.* The results of a typical experiment are shown in Table 1.

(*b*) *Ultra-violet irradiation between two heating periods.* In these experiments the DNA solutions (25 γ/ml.) were heated and cooled several times. After the second incubation period the Δ and hyperchromic shift (*H.S.*) values are increased as compared with the corresponding values obtained after the first incubation. After the third incubation, however, these values remain almost constant as compared with the second incubation. Therefore ultra-violet radiation was applied between the second and third incubation period.

Table 1. EFFECT OF ULTRA-VIOLET IRRADIATION ON DNA IN SOLUTIONS

Time of irradiation (min.)	E_1	E_{20}	Δ	*H.S.*
0	399	348	51	118
1	395	345	50	114
2	386	340	46	105
5	374	335	39	93
10	367	332	35	86
20	365	332	33	84

E_1, extinction $\times 10^3$ of a DNA solution at 260 mμ measured 1 min. after termination of the incubation; E_{20}, extinction $\times 10^3$ of a DNA solution at 260 mμ measured 20 min. after termination of the incubation; E_0, extinction $\times 10^3$ of a DNA solution at 260 mμ before incubation; Δ, $E_1 - E_{20}$; *H.S.* (hyperchromic shift), $E_1 - E_0$.

Table 2. EFFECT OF ULTRA-VIOLET IRRADIATION ON DNA IN SOLUTIONS

	Δ		H.S.	
	2–1	3–2	2–1	3–2
No irradiation	4 ± 1	1 ± 0·6	19 ± 7	6 ± 2
5 min. ultra-violet	4 ± 2	– 11 ± 3	20 ± 8	– 3 ± 2
10 min. ultra-violet	4 ± 1	– 7 ± 2	17 ± 4	– 3 ± 2

The figures represent the differences ($\times 10^3$) in extinction values: 2–1, differences between first and second incubation period, 3–2, differences between third and second incubation period.

The results summarized in Tables 1 and 2 demonstrate that ultra-violet irradiation under the different experimental conditions causes a decrease of the Δ and *H.S.* values. Even after repeated heating and cooling of DNA ultra-violet irradiation disturbs the process of strand separation and recombination. Moroson and Alexander[9] also reported an effect of ultra-violet irradiation on a hyperchromic effect in DNA. Their experiments were carried out under completely different conditions.

The effects of ultra-violet light observed disappear partially by another heating after the irradiation, especially when low doses of ultra-violet light (1–5 min.) were used. In these cases 40–50 per cent of the ultra-violet effects can be restored; heating after irradiation with relatively high doses of ultra-violet light (10–20 min.) leads only to 20–30 per cent restoration of the irradiated effects.

In experiments performed with X-irradiation, in which doses of 50–10,000 r. were applied, we did not observe a definite effect on the Δ and *H.S.* values.

Our results show that separation and recombination of the DNA double helix structure occurs less easily after ultra-violet irradiation and the effects are partially reversible. It is unlikely that under our experimental conditions appreciable rupture of hydrogen bonds occurs, because no change in extinction values could be observed after ultra-violet irradiation only. The effect observed can be explained in different ways. Dimerization of nucleotides which is known to occur might prevent proper uncoiling of the double helix and separation of the strands and this could account for the irreversible part of the irradiation effect. It is also possible that ultra-violet irradiation causes a shift towards the keto-form of the hydroxyl groups of the bases which might result in a strengthening of the hydrogen bonds and this could account for the reversible part of the irradiation effect.

It remains uncertain whether the observations described have any relation to the action of ultra-violet light on living cells.

FUNCTION OF ASCORBIC ACID IN THE CONVERSION OF PROLINE TO COLLAGEN HYDROXYPROLINE

By NEVILLE STONE and PROF. ALTON MEISTER

Department of Biochemistry, Tufts University School of Medicine, Boston, Mass.

THE synthesis of collagen, one of the most abundant animal proteins, is intimately associated with specific hydroxylation mechanisms. Thus, collagen hydroxyproline arises from proline rather than from free hydroxyproline[1,2], and lysine rather than hydroxylysine is the major precursor of collagen hydroxylysine[3,4]. Collagen synthesis therefore differs from that of other proteins, the amino-acid residues of which are derived from the corresponding free amino-acids. Collagen formation is reduced in ascorbic acid deficiency, and administration of ascorbic acid to deficient guinea pigs leads to rapid collagen synthesis[5,6]. In contrast, there seems to be no evidence that synthesis of other proteins requires ascorbic acid. The mechanism by which ascorbic acid increases synthesis of collagen is not yet known. It has been proposed that a proline-containing pre-collagen accumulates in ascorbic acid deficiency, and that ascorbic acid functions in the hydroxylation of such peptide-bound proline[6]. Failure to find peptide intermediates[5,7] has led to the suggestion that there is a separate pool of 'active hydroxyproline' derived from proline[7]. That ascorbic acid may be required for the maintenance of collagen has also been considered[8]. Mitoma and Smith[9] concluded that hydroxylation of proline is not affected by ascorbic acid deficiency, and suggested that ascorbic acid influences maturation of fibroblasts.

In an attempt to evaluate these possibilities we have examined incorporation of proline into collagen of granulomas induced in normal and ascorbic acid-deficient guinea pigs by injection of carrageenin[6]. When minces of granulomas from deficient animals were incubated with proline labelled with carbon-14, the specific activity of the collagen hydroxyproline was much lower than that of non-deficient controls. Although this suggested that conversion of proline to hydroxyproline is reduced in ascorbic acid deficiency, this result could be explained by a decreased rate of collagen synthesis. To obtain information about both hydroxylation of proline and synthesis of collagen, we have carried out experiments with tritiated proline. The use of tritiated proline would provide a new parameter for following hydroxylation if formation of tritiated water was stoichiometrically related to formation of hydroxyproline. We incubated minces of granulomas obtained from normal and scorbutic animals with media containing 3,4-ditritiated L-proline. The mixtures were then frozen and lyophilized, and the water was trapped. Collagen was isolated from the residue by extraction with hot trichloroacetic acid followed by precipitation with tannic acid. The collagen isolated from deficient and control granulomas had approximately the same amino-acid composition as that of purified gelatin. To check further the purity of the collagen, use was made of the fact that this protein lacks tryptophan. When ^{14}C-tryptophan was incubated with the granuloma, radioactivity was incorporated into non-collagen proteins but not into collagen.

When tritiated proline was incubated with granuloma obtained from deficient guinea pigs, the specific activity of the collagen proline afterwards isolated was moderately reduced as compared with the normal. In contrast, there was striking reduction of incorporation of proline into collagen hydroxyproline. Similar results were obtained with ^{14}C-proline (Table 1).

As indicated in Fig. 1 the formation of tritiated water was markedly reduced in experiments with deficient granulomas. The initial lag period is similar to that found for incorporation of proline into collagen, and may be due to the time required for proline to enter the tissue. That formation of tritiated water is a valid measure of hydroxylation was shown by the fact that the tritium incorporated into hydroxyproline and that found in the water

Table 1. INCORPORATION OF PROLINE INTO THE COLLAGEN PROLINE AND HYDROXYPROLINE OF GRANULOMAS FROM NORMAL AND SCORBUTIC GUINEA PIGS*

Isotope	Exp. No.	Incubation period (min.)	Specific activity (d.p.m./μmole) Normal Proline	Normal Hydroxyproline	Deficient Proline	Deficient Hydroxyproline
^{3}H	1	30	6,150	2,400	4,580	<100
		60	13,300	5,070	9,300	150
		120	21,300	8,700	17,800	360
^{14}C	2	30	790	695	787	<10
^{14}C	3	30	745	680	530	70

* Granuloma mince (2 gm.) was incubated with 5 ml. of medium containing 5 μc. of 3,4-ditritiated L-proline (173 μc./μmole) or 1 μc. of DL-proline-1-^{14}C (3·1 μc. per μmole) (obtained from the New England Nuclear Corporation, Boston, Mass.). Incubation was carried out at 37° under 95 per cent oxygen–5 per cent carbon dioxide. The medium contained NaCl (0·022 *M*), KCl (0 003 *M*), $MgSO_4$ (0·0012 *M*), $CaCl_2$ (0 0013 *M*), KH_2PO_4 (0·0004 *M*), $NaHCO_3$ (0 025 *M*), and D-glucose (0 01 *M*). Tritium and carbon-14 were determined by liquid scintillation counting. The granulomas were obtained after six days of growth as described by Robertson and Schwartz (ref. 6); the deficient animals were deprived of ascorbic acid for two weeks. Proline and hydroxyproline were isolated from acid hydrolysates of the collagen by paper chromatography (solvent: *n*-butanol/acetic acid/water; 4:1:1), and determined, respectively, as described by Troll and Lindsley (ref. 12) and Neuman and Logan (ref. 13).

were about the same. The ratio of the total radioactivity of hydroxyproline to the total radioactivity of the water was 1·1 ± 0·2 (average of six experiments). It appears then that about half the proline tritium was lost during hydroxylation. This conclusion was substantiated by studies on granulomas from normal animals in which ^{14}C-proline and tritiated proline were used together; the ratio of the specific activities of ^{14}C-proline to ^{14}C-hydroxyproline was, within experimental error, half that of the corresponding ratio for the tritriated imino-acids. These findings are consistent with hydroxylation mechanisms involving either a 4-keto intermediate or 3,4-unsaturation, assuming random distribution of tritium at proline carbons 3 and 4 and absence of significant isotope effects. In several experiments, glutamic acid was isolated from collagen and found to contain negligible isotope. These observations agree with those of Green and Lowther[10], and indicate that metabolism of proline to products other than hydroxyproline is not appreciable in carrageenin granulomas.

Addition of ascorbic acid to granuloma minces obtained from scorbutic guinea pigs led to a marked increase in the formation of tritiated water (Table 2). Parallel studies showed that addition of ascorbic acid also increased incorporation of tritiated proline into collagen hydroxyproline; the increase in tritiated water was equal to that of tritiated hydroxyproline. In very recent studies (published while our work was in progress), Robertson and Hewitt[11] reported that addition of ascorbic acid to deficient tissues increased the specific activity of collagen ^{14}C-hydroxyproline.

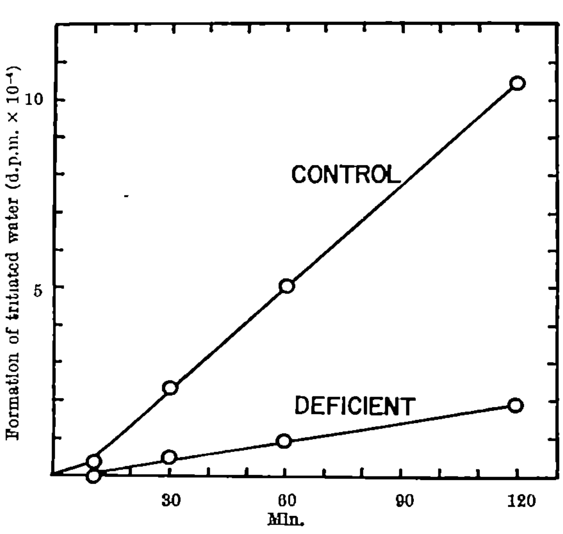

Fig. 1. Formation of tritiated water from 3,4-ditritiated L-proline by granulomas from ascorbic acid-deficient and control guinea pigs. (Conditions as in Table 1)

Table 2 STIMULATION OF THE OXIDATION OF PROLINE BY ASCORBIC ACID-DEFICIENT GRANULOMAS BY *in vitro* ADDITION OF ASCORBIC ACID

Exp. No.	Tissue	Ascorbate added (μgm./ml.)	Tritiated water (d.p.m.)
4	Deficient	None	19,700
	,,	800	45,500
5	,,	None	14,400
	,,	20	25,700
	,,	100	23,100
	Normal	None	27,200
	,,	20	30,600
	,,	100	26,500

* The experimental conditions were as given in Table 1 (with 3,4-ditritiated L-proline); after 120 min. the reaction mixtures were lyophilized and the water was trapped and counted

At least two schemes for conversion of proline to collagen imino-acids may be considered as follows:

$$\begin{tikzcd}
\text{Proline} \arrow[r, "1"] & {[(\text{pro})_x\text{-peptide}]^{\mathrm{I}}} \arrow[r, "2"] & {[(\text{pro})_{n-x}\text{-}(\text{hypro})_x\text{-peptide}]^{\mathrm{II}}} \arrow[d, "3"] \\
 & & \text{collagen}
\end{tikzcd}$$

Scheme *A*

$$\begin{tikzcd}
 & {[\text{pro}]^{\mathrm{I}}} \arrow[drr] & & \\
\text{Proline} \arrow[ur, "1"] \arrow[dr, "2"'] & & & \text{collagen} \\
 & {[\text{pro}]^{\mathrm{II}}} \arrow[r, "3"] & {[\text{hypro}]^{\mathrm{III}}} \arrow[ur] &
\end{tikzcd}$$

Scheme *B*

In *A*, proline is incorporated into collagen through a series of precursor peptides of types I and II; about half the proline residues are converted to hydroxyproline. In *B*, there are two types of proline-containing pools, of which one (I) contains proline destined to become collagen proline, and the other (II) proline that will become collagen hydroxyproline. The latter is oxidized to a hydroxyproline intermediate (III), not in equilibrium with free hydroxyproline and not yet in peptide linkage. (There may be more than one intermediate of types II and III.) According to scheme *A*, the ratio of the specific activity of collagen hydroxyproline to that of collagen proline should not exceed unity. However, Green and Lowther[10] observed ratios as high as 1·6, and we have also observed similar ratios. Robertson *et al.*[7] have stated other cogent arguments against mechanisms of type *A*.

The present findings appear to support a mechanism of type *B*. Accumulation in ascorbic acid deficiency of an intermediate (or intermediates) in the pathway from proline to collagen hydroxyproline would lead to much greater dilution of proline destined to become collagen hydroxyproline than proline which is to become collagen proline. A block at step 2 or 3 in scheme *B* would be accompanied by a decrease of tritiated water formation. However, a block at step 2, if it were between free proline and the first bound-proline intermediate, could only lead to accumulation of proline and would therefore dilute proline destined for both pathways. Accordingly, ascorbic acid appears to be required for the formation of an intermediate of type III, or possibly one of type II. (It is tempting to suggest, in line with present beliefs about protein synthesis, that I and III may be imino-acyl RNA compounds.) Reduced formation of tritiated water from tritiated proline in ascorbic acid deficiency might reflect general reduction in protein synthesis. However, such an explanation is unlikely because of the relatively high incorporation of proline into collagen proline as compared with hydroxyproline. We have also found similarly high incorporation of glycine and tyrosine into the collagen of deficient granulomas. Our results do not support a systemic ascorbic acid-mediated mechanism or the suggestions that ascorbic acid acts by stimulation of the maturation of fibroblasts or in the maintenance of collagen. The rapid increase of tritiated water formation on addition of ascorbic acid to deficient granuloma minces is consistent with the belief that ascorbic acid is involved in the hydroxylation step. According to the present proposal, hydroxylation of proline (and possibly of lysine) occurs prior to assembly of collagen peptides. Such reactions may therefore control the rate of collagen synthesis. Proof of this mechanism must necessarily depend on separation of the hydroxylation steps from protein synthesis, and on characterization of the intermediates involved. The use of tritiated proline provides a convenient tool with which to follow hydroxylation of proline, and for study of the mechanism of this reaction.

ENZYMATIC CONVERSION OF D-GLUTAMIC ACID TO D-PYRROLIDONE CARBOXYLIC ACID BY MAMMALIAN TISSUES

By PROF. ALTON MEISTER and MARTHA W. BUKENBERGER

Department of Biochemistry, Tufts University School of Medicine,
Boston, Mass.

It is known that when DL-glutamate is administered to rats most of the D-component is excreted in the urine as D-pyrrolidone carboxylic acid[1,2]. Sarah Ratner suggested in 1944 that this conversion was probably enzymatic in nature[1], and recent work on rat tissue slices[2] is consistent with this view. In the course of work in this laboratory on the mechanism of the enzyme-catalysed synthesis of glutamine, evidence for the formation (in the presence of adenosine triphosphate and Mg^{++}) of activated enzyme-L-glutamate and enzyme-D-glutamate complexes was observed when ammonia was rigorously excluded[3-5]. Although the enzyme-L-glutamate complex reacts readily with small amounts of ammonia to yield L-glutamine, the reaction of the enzyme-D-glutamate complex with ammonia is very slow with low concentrations of ammonia. Mild heating of either complex gives pyrrolidone carboxylic acid. These observations suggested the possibility that the enzyme that catalyses the synthesis of L-glutamine might also be responsible (in the presence of low physiological concentrations of ammonia) for the formation of D-pyrrolidone carboxylic acid from D-glutamic acid.

To test this hypothesis, we incubated the purified glutamine-synthesizing enzyme from sheep brain[6] with D-glutamate under various conditions; although some D-pyrrolidone carboxylate formation occurred with large amounts of enzyme, this reaction did not occur at a significant rate at 37° with catalytic quantities of enzyme. It thus appeared probable that another enzyme activity was present in animal tissues that was able to catalyse the conversion of D-glutamate to D-pyrrolidone carboxylate. We therefore examined several mammalian tissues for such an activity and found it in the kidney and liver of the mouse, rat and man. In each case, the activity per gram of tissue was higher in the kidney than the liver.

Since homogenates of mouse kidney are somewhat more active than those of the other tissues examined, we purified the activity (about thirty- to fifty-fold) from this source. Approximately two-thirds of the activity was found in the supernatant solution after centrifugation of the homogenate at 100,000*g* for 2 hr., and most of it precipitated between 30 and 60 per cent of ammonium sulphate saturation at *p*H 7 and 0°. After separation of the protein from ammonium sulphate by passage through a column of 'Sephadex', further purification was achieved by adsorption of impurities on alumina $C\gamma$ gel.

The purified fraction catalysed the conversion of D-glutamate to D-pyrrolidone carboxylate in the presence of Mg^{++} or Mn^{++}. The reaction was conveniently followed with ^{14}C-D-glutamate by using paper chromatography; thus both disappearance of glutamate and formation of pyrrolidone carboxylate were observed (Fig. 1). Disappearance of D-glutamate has also been followed by use of the ninhydrin colour reaction. The formation of D-pyrrolidone carboxylate was shown conclusively by isolation of the product in a large-scale experiment; crystalline pyrrolidone carboxylate was obtained in analytically pure state. Hydrolysis of this material in 2 *N* hydrochloric acid for 3 hr. at 100° gave glutamate quantitatively. The glutamate thus obtained was not susceptible to the action of L-glutamic acid decarboxylase of *Clostridium welchii*.

Under the conditions used, no reaction occurred in the absence of enzyme or with heat-inactivated enzyme (Table 1). Little conversion occurred in the absence of added Mg^{++} or Mn^{++}. The *p*H optimum was about 8·3 with mouse kidney and liver preparations and Mg^{++}; at this value of *p*H, Mn^{++} was more effective than Mg^{++} when these metal ions (as magnesium chloride and manganese chloride) were compared at concentrations of 0·008–0·142 *M*. Addition of adenosine triphosphate (0·015 *M*) had either no effect or slightly inhibited the reaction. Addition of ammonia (0·005 *M*) with or without adenosine triphosphate did not affect the rate significantly, and the enzyme preparation did not catalyse the synthesis of either L- or D-glutamine. Incubation of the purified mouse kidney fraction (1 mgm.) with ribonuclease (50 μgm.) for 30 min. had no effect on activity, while all activity was destroyed by incubating the preparation with trypsin (50 μgm.). Treatment of the enzyme with charcoal did not affect the activity.

Table 1. ENZYMATIC CONVERSION OF D-GLUTAMATE TO D-PYRROLIDONE CARBOXYLATE

Reaction mixtures*	Pyrrolidone carboxylate formed (mμmoles)
Enzyme + D-glutamate + Mg^{++}	17 5
Enzyme + L-glutamate + Mg^{++}	0
Enzyme + D-glutamate + Mn^{++}	58·1
Enzyme + L-glutamate + Mn^{++}	0
Enzyme + D-glutamate	3 4
Enzyme† + D-glutamate + Mn^{++}	0
D-Glutamate + Mg^{++}	0
D-Glutamate + Mn^{++}	0

* Each experiment contained buffer and other components in the concentrations given in Fig, 1, except that 0 25 mgm. of enzyme preparation was used; incubated for 30 min. at 37°.

† Heated at 100° for 5 min.

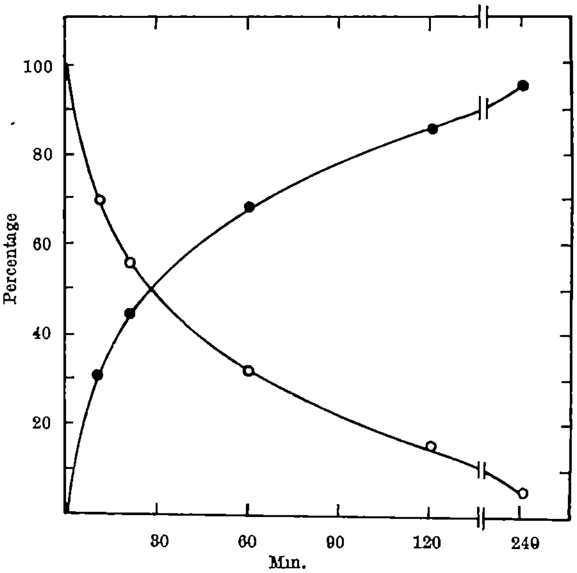

Fig. 1. Time course of the enzymatic conversion of D-glutamate to D-pyrrolidone carboxylate. The reaction mixtures consisted initially of purified enzyme from mouse kidney (0·5 mgm.), D-glutamate-1-^{14}C (0 07 μmole, 70,000 c.p.m.), $MgCl_2$ (4 μmoles), and 2-amino-2-(hydroxymethyl)-1,3-propanediol-HCl buffer (20 μmoles; *p*H 8·3); final volume, 0·12 ml.; 37°. The reaction was followed by paper chromatography (*n*-butanol/acetic acid/water; 4 . 1 : 1) of deproteinized reaction mixtures, and determination of the radioactivity found in the areas corresponding to glutamate (open circles) and pyrrolidone carboxylate (closed circles); ordinate represents per cent of total radioactivity found in each area

Under the conditions given in Fig. 1, the reaction went to approximately 95 per cent completion. The position of equilibrium is thus similar to that observed in studies on the non-enzymatic cyclization of glutamic acid[7]. That the enzymatic reaction is reversible was shown by incubating ^{14}C-D-pyrrolidone carboxylate in the system described in Fig. 1; under these conditions, about 5 per cent of the added substrate was converted to glutamate. In the presence of higher concentrations of D-glutamate (for example, 0·01 *M*) and Mn^{++}, the initial reaction-rate was approximately forty times greater than in the experiment described in Fig. 1.

The purified mouse kidney fraction did not catalyse the disappearance of L-glutamic acid, L-glutamine, D-glutamine, D-α-aminoadipic acid, D-homoglutamine, D-aspartic acid, or L-aspartic acid. On the other hand, when D-α-methylglutamic acid, DL-α-methylglutamic acid, DL-β-methylglutamic acid, and DL-α-aminotricarballylic acid were incubated with the enzyme, there was disappearance of amino-acid (never exceeding 50 per cent of the total with the racemic mixtures) as determined by the ninhydrin colour reaction. These findings constitute presumptive evidence that the enzyme acts on certain substituted D-glutamic acid derivatives.

The enzyme activity appears to be present in sufficient amount to account for the observed *in vivo* conversion of administered D-glutamate to D-pyrrolidone carboxylate. At the present time there is no evidence that D-glutamic acid or other D-amino-acids are of significance in mammalian metabolism. The enzyme activity that catalyses the conversion of D-glutamate to D-pyrrolidone carboxylate seems therefore to occupy the same uncomfortable metabolic status as that of D-amino-acid oxidase. It is of interest that both these enzymes are found in the kidney and liver, the former being more active in each case. Although it cannot be excluded that other as yet undiscovered more 'natural' substrates for these enzymes exist, it may be speculated that their functions are to destroy ingested D-amino-acids and those formed by the bacterial flora (and possibly by other reactions). It seems unlikely that they are artefacts of isolation since their catalytic actions appear to be reflected *in vivo* when D-amino-acids are administered. While many D-amino-acids are converted to their respective α-keto acid analogues (which may be re-aminated by L-specific systems), D-glutamic acid is removed from the organism by an intramolecular acylation reaction, analogous in some respects to the mechanisms for removal of benzoic and phenylacetic acids. The possibility that the enzyme described here acts on D-glutamate ingested in the diet or formed by the bacterial flora is consistent with the presence of D-glutamic acid in a number of lower forms. If such is the case, one might expect to find D-pyrrolidone carboxylic acid in the urine of mammals. It is of interest that human urine contains a considerable quantity of 'bound' glutamic acid[8], although a fraction of this can be accounted for as phenylacetylglutamine[9], some D-pyrrolidone carboxylate may be present. (We found that samples of human kidney and liver obtained at necropsy (8–14 hr. post-mortem) were 50–80 per cent as active as rat kidney and liver, respectively. Putnam *et al.*[10] found no ^{14}C-pyrrolidone carboxylic acid and only ^{14}C-glutamic acid in the urine after intravenous injection of ^{14}C-DL-glutamic acid to a patient with multiple myeloma; however, the patient had extensive renal damage and may also have had impaired liver function.)

Apart from the question of the physiological significance of the enzyme, the mechanism of this optically specific cyclization and the role of metal ions in the reaction pose interesting problems. Finally, the enzyme may, like D-amino-acid oxidase, have practical value in biochemical investigations.

SALT-MARSH BACTERIA

Bacteria of a Developing Salt Marsh

IN a study of the bacterial flora of a salt marsh at Gibraltar Point, Lincolnshire, numbers of heterotrophic aerobes were estimated by colony counts on ZoBell's sea-water agar medium No. 2216[1]. Numbers increased with passage up the shore from uncolonized to colonized areas. The lowest counts were obtained from samples taken at the edge of the channel cut by the River Steeping through the bare mud flats, higher counts from the mature marsh and the highest from the *Salicornia* zone. This area also showed the greatest seasonal variation in numbers. Samples from areas dominated by *Spartina* often gave even lower counts than those taken from the bare mud flats at a point between the Steeping site and the first colonized zone. It is interesting to compare these results with the distribution of fungi reported for the same marsh by Pugh[2], who observed a comparable decrease in the *Spartina* zone but found the highest numbers of fungi in the mature marsh.

Colonies selected at random from the plates were isolated and purified by repeated streaking on ZoBell agar. 320 isolates were obtained over a period of four months, 40 from each of eight sampling sites, namely, the two uncolonized sites referred to above, which are flooded by most high tides; areas of the immature marsh dominated by *Salicornia* and *Spartina* and flooded only by spring tides; and four sites in the mature marsh dominated by *Halimione*, *Agropyron*, *Puccinellia* and *Limonium* and flooded only by exceptionally high spring tides. The isolates were preserved as desiccates until they were to be examined, when moist slopes on ZoBell agar were prepared. After 24–48 hr. growth these were examined microscopically, and used for inoculating media for physiological tests. The chief characters so far determined are given in Table 1, which shows for each test the percentage of isolates which gave a positive reaction.

Only 11 per cent of the isolates were Gram-positive, most of these being found in the mature marsh. Whereas Gram-positive rods, especially *Bacillus* spp. and mycelial forms, were almost confined to this area, cocci were more evenly distributed. Gram-negative rods, often pleomorphic, predominated in the marsh as a whole, and especially in the immature marsh. These results differ from those of Wood[3], who found the bacteria of coastal muds in Australia to include 23 per cent of Gram-positive rods, 28 per cent of cocci and only 49 per cent of Gram-negative rods. However, he pointed out that the numbers of *Bacillus* spp. and of cocci varied in different areas, also that seasonal changes and different techniques would affect the numbers recorded. Other workers, including ZoBell[4], have found up to 95 per cent of the bacteria of marine muds to be Gram-negative rods. Taylor[5] reported similar findings for fresh water muds. In drier soils, although Gram-negative forms predominate, Gram-positive forms seem to be rather more numerous[6] than in these water-logged muds, which agrees with the finding that the Gram-positive forms of the marsh were found mostly in the drier areas.

A third of the isolates were pigmented, whereas Wood found only 15 per cent of pigmented forms. Those from the mature marsh included a higher proportion of pink forms and some with the diffusible green fluorescent pigment usually associated with *Pseudomonas* spp., while the immature marsh yielded more isolates with yellow or orange pigments. 9·5 per cent of the isolates, all from uncolonized area and immature marsh, were colourless at first but later developed an orange-brown pigment in the centre of the colony.

Acid was formed from glucose under aerobic conditions by 42 per cent of the isolates, but only 7 per cent were active under anaerobic conditions. This and other biochemical activities, for example, the hydrolysis of starch and gelatin, were shown by a higher proportion of the mature marsh isolates, those from the immature marsh being for the most part rather inactive. Surprisingly, in view of the widespread blackening of the muds, only 22 per cent of the isolates produced hydrogen sulphide from peptone. Obligate anaerobes, including sulphate-reducers, must presumably be responsible for most of the sulphide production.

In many respects the bacterial flora described by Wood showed characters intermediate between the

Table 1. CHARACTERISTICS OF SALT MARSH BACTERIA

	Percentage of isolates showing character		
	Uncolonized areas and immature marsh (frequently flooded)	Mature marsh (more rarely flooded)	Whole marsh
Gram-positive reaction	6	16	11·0
(*a*) Rods	1	4	2·5
(*b*) Mycelial forms	0	8	4·0

typical floras of soil and of marine mud. The flora at Gibraltar Point seems to resemble the latter more closely. While this may be due merely to the waterlogged nature of the muds, it is of special interest since there is evidence[7] that considerable amounts of sandy silt are swept in from the sea in this area. It is possible that a high proportion of the organic debris, especially in the lower part of the marsh, is of marine origin and may encourage the growth of marine bacteria.

Effect of Salinity on the Growth of Certain Salt-marsh Bacteria

A COMPARISON of media made up with sea-water and with river-water (to be published) showed that the former was more satisfactory for the enumeration and isolation of bacteria from certain salt-marsh muds. Samples of saline mud from colonized and uncolonized areas at Gibraltar Point, Lincolnshire, gave rise to 6–90 times as many colonies on ZoBell's sea-water agar medium 2216 (ref. 1) as on a variant of the same medium made up with river-water. Comparable samples of river-mud gave about three times as many colonies on the river-water medium as on the sea-water medium.

The effect of salt concentration on the growth of bacteria isolated from the sea-water agar plates has been investigated. Forty isolations were made from mud samples from each of three areas, namely, the Halimionetum, the Salicornietum and an uncolonized area on the edge of the River Steeping as it crosses the bare mud-flats. Twenty isolations were also made from fresh-water mud from the River Steeping above the level of tidal influence. A few isolates from each group later failed to grow, for unknown reasons. The actual number of isolates from each group which were tested is shown in the tables.

The method used was similar to that used by Tyler, Bielling and Pratt[2]. The test media consisted of 0·1 per cent tryptone (Oxoid) in demineralized water, with the addition of mineral salts to give concentrations equivalent to those in sea-water (sodium chloride, 24·0 gm.; potassium chloride, 0·7 gm.; crystalline magnesium chloride, 5·3 gm.; crystalline magnesium sulphate, 7·0 gm. per litre), and similar tryptone solutions containing the same salts in half, twice, four times and six times the above concentrations. Tyler *et al.* varied the concentration of sodium chloride only; but it was decided in this experiment to vary the concentrations of all the mineral salts since the bacteria in the muds, which are exposed during low tides to the effects of evaporation and dilution by rain-water, would have been subjected to variations in concentration of all the salts.

The bacteria were grown on artificial sea-water—tryptone agar slopes with about 2 ml. of 2·4 per cent sodium chloride solution added. After two or three days incubation at 25° C. the bacterial suspension at the base of the slope was transferred to a sterile spectrophotometer tube and the optical density of the suspension was adjusted to 0·30 ± 0·05 with sterile 2·4 per cent sodium chloride solution. Conical flasks containing 30 ml. quantities of the test media were inoculated with 0·1 ml. of this adjusted suspension.

Growth was measured after two days incubation at 25° C., in terms of the optical density of the cultures at 500 mμ in a Unicam *SP* 1400 prism absorptiometer. The optical densities observed are recorded elsewhere[3]; but the results are summarized in Tables 1 and 2.

Table 1. PERCENTAGE OF ISOLATES CAPABLE OF GROWING AT ANY GIVEN DEGREE OF SALINITY

	Salicornietum mud	Halimionetum mud	River steeping uncolonized mud	Non-saline mud
A.S.W.* × 6	53	2	19	0
A.S.W. × 4	66	30	59	0
A.S.W. × 2	87	95	92	17
A.S.W.	100	97	97	55
A.S.W. × ½	89	92	97	78
Demineralized water	3	22	11	94
No. of isolates tested	38	40	36	18

*A.S.W., artificial sea-water.

Table 2. PERCENTAGE OF ISOLATES SHOWING MAXIMAL GROWTH AT ANY GIVEN DEGREE OR DEGREES OF SALINITY

	Salicornietum mud	Halimionetum mud	River steeping uncolonized mud	Non-saline mud
A.S.W.* × 6	0	0	0	0
A.S.W. × 4	18	0	5	0
A.S.W. × 2	58	17	33	0
A.S.W.	60	60	53	17
A.S.W. × ½	18	47	27	22
Demineralized water	0	0	0	89
No. of isolates tested	38	40	36	18

Note. Where an isolate showed equally good growth at two or more different concentrations of salts, it has been included in more than one set of figures.
* A.S.W., artificial sea-water.

A far larger proportion of the isolates from the Salicornietum, which was frequently flooded by the tide and where the chloride content has been found to reach high values (up to 57 gm. per kgm. of soil-water), grow albeit feebly, at a salinity six times that of artificial sea-water, that is, 53 per cent, compared with 2 and 19 per cent from the other sites. The organisms tested in this manner included pigmented and non-pigmented Gram-negative rods, and eighteen isolates which produced an orange-brown pigment in the centre of the colony after prolonged incubation. Fifteen of this latter type were among the organisms which grew at the highest salt concentrations. In the preceding communication it was noted that these organisms were confined to the more frequently flooded areas of the marsh. Most of the isolates tested grew poorly, if at all, in the medium with no added salts and showed maximum growth in the normal artificial sea-water medium. In contrast, the isolates from the fresh-water site grew best in the medium with no added salts and only half of them grew at all in the normal artificial sea-water medium.

Thus, within a saline area, variations in the salt tolerance of bacterial populations occurred, which may be related to the amount of tidal flooding to which they are subjected. This might be due to either a change in the species or to the selection of salt-tolerant variants of forms common to both environments. Furthermore, adequate comparisons of the numbers of bacteria in saline and non-saline parts of a river cannot be made using a single medium because of the wide range of behaviour of the bacteria in respect of salinity.

THE GENE-FOR-GENE CONCEPT

By DR. CLAYTON PERSON*, DR. D. J. SAMBORSKI and DR. R. ROHRINGER
Plant Pathology Laboratory, Canada Department of Agriculture, Winnipeg

THE gene-for-gene hypothesis, propounded by Flor in 1942[1] to account for genetic interrelationships between flax (*Linum usitatissimum* L.) and flax rust (*Melampsora lini* Desm.) has in recent years been applied to a number of different parasitic systems[2,3]. According to Flor's interpretation, for each resistance gene in flax there is a specific and related gene for virulence in those rusts to which it is susceptible. There is, however, no apparent uniformity among pathologists as to the criteria by which gene-for-gene relationships are identified, or as to the tests by which such relationships can be unequivocally demonstrated. There are several reasons for this: owing to the specificity of the relationship, a gene in either member of the host : parasite system is identifiable only if the specific gene in the other member, with which it interacts, has been previously identified and is available for carrying out the identifications; there is also the fact that the genetic ratios that are obtained in segregating populations, either of the host or of the parasite, are in large part determined by the genotype of the tester stock or strain that is used, with the result that a manofactorial ratio, when it is obtained, need not indicate that the characteristic being studied is determined by a single genetic factor[3].

Along with the difficulties that may be encountered in carrying out genetic analyses for gene-for-gene relationships there is the fact that the gene-for-gene concept has not been clearly defined; and lacking a clear definition it is also difficult to assess the limits within which such relationships are likely to occur, or to recognize systems in which a search for gene-for-gene relationships is likely to be successful. There are systems, for example, in which the parasite is obligate during part of its life-cycle only, and those in which it is alternately obligate on two, and occasionally more, hosts; there are other systems, involving hyperparasitism, that are more complex than these. To meet with such a variety of situations, it is apparent that a clear definition of the gene-for-gene concept is needed. Our attempts to formulate a definition are recorded here.

In formulating our proposed definition we have found it necessary to take into account the processes by which gene-for-gene relationships arise and are maintained in biological systems. In natural populations selection pressure can bring about changes in gene frequencies at certain loci while at the same time existing frequencies at other loci remain unchanged. Given that populations do respond to changes in selection pressure, it follows that where the pressure is specific, and where the population under pressure makes an adjustive response, the response is also specific. The genes for production of penicillinase that are brought forward in penicillin-treated populations, and those for DDT-dehydrochlorinase in DDT-treated populations are cases in point: the action of these genes is specifically directed toward the agency which brought about the change. In the same way, the introduction of new genes for resistance into host populations, either by mutation or through the activities of plant breeders, usually brings about adjustive changes in the parasitic population and the effects of the new genes for virulence that are brought forward in these populations are specifically directed toward the resistance genes that have been introduced. An example of this sort is given by Turner[4], who has provided evidence that the pathogenic specificity of *Ophiobolus graminis* var. *avenae* toward oats is due to its capacity to produce avenacinase, an enzyme which destroys the biological activity of avenacin, which is a glucosidic inhibitor present in the oat plant. Turner, in ascribing pathogenic specificity to this mechanism, directs attention to the fact that a mutation in the parasite which inactivates the host inhibitor would be of great survival value. The survival of such a mutant gene in a parasitic population would, however, be maintained only so long as the genetic conditions in the host that determine its survival value remain unchanged. A gene for virulence in a parasitic population will become ineffective following the subsequent appearance of new resistance genes in the host. In summary: with the introduction of new resistance genes in a host population, specific and related genes are brought forward in the population of the parasite; these remain effective and are maintained in the parasitic population only so long as the related genes for resistance are present in the host.

Since the operation of selection pressure, either in maintaining or in bringing about changes in gene frequencies, is not limited to parasitic systems we have next to consider whether gene-for-gene relationships are likely to arise, through selective processes in other biological situations. A clear example is seen in these situations that involve mimicry, where the genes for colour and pattern which are to be of selective value to the mimic are predetermined by those genes for colour and pattern that have become established in the organism which is mimicked. We are convinced by this, and by other examples, that if the gene-for-gene concept is to be defined solely in terms of selective mechanisms then, owing to the ubiquity of these mechanisms, the concept would be applicable to most if not all biological situations in which organisms come into contact with, and exert selection pressure on, one another. We conclude that the definition must include some further qualification if the gene-for-gene concept is to be stated in such a way that the limits of its applicability are clearly defined.

To date, the gene-for-gene concept has been applied only to parasitic systems. Since parasitism is a form of symbiosis, we have extended our inquiry to include other forms of symbiosis, in order to determine whether the gene-for-gene concept applies to these also. We shall consider here mutualistic symbioses, in which it is considered that both members of the association profit by the presence of the other. In such systems it can be presumed that a mutation in one member that threatens the continued survival of the other, from which it profits, will not have been preserved. On the other hand, a mutation in one member that favours the other can be preserved only if at the same time it favours the organism in which it had occurred. A mutant gene is not likely to persist in an organism that derives no benefit from it. It is seen that genes accumulate in symbiotic systems because they are beneficial to the organism in which the mutations have occurred; the fact that the symbiotic partner also benefits is purely incidental. So far as the gene-for-gene concept is concerned, this illustrates that: (1) a mutation in one organism the sole action of which is to benefit another organism is not likely to persist; for those mutations that do persist, if they benefit another organism they do so accidentally; (2) since the new gene poses no threat to the organism that accidentally profits, it evokes no adjustive response and therefore there is no basis for specific gene-for-gene relationships.

Evidence for lack of genetic specificity between symbiotic partners had been provided by Pant and Fraenkel[5], who have shown that yeast symbionts taken from the gut of two beetle genera, *Stegobium* and *Lasioderma*, can be interchanged; the yeasts retain their morphological and physiological characteristics after being provided with new symbiotic partners. A similar case showing lack of specificity involves certain symbionts of the genus *Triatoma*; these may be transferred to sterile individuals of the genus *Rhodnius*, where they provide the latter with the necessary micronutrients for development[6]. In these cases, at least, there is no evidence of the high order of specificity, based on gene-for-gene relationships, that is so characteristic of parasitism. Quispel[7], in commenting on the relations that exist between symbionts, asserts that "Two organisms don't enter into symbiosis to give something to the partner, but in order to take as much advantage of the partner as possible". To this it can be added that it is only when the advantage taken by one works to the disadvantage of the other that an adjustive response is required, and a gene-for-gene relationship can arise; but when this occurs the symbiosis is no longer mutualistic but antagonistic or, to use the more common description, one organism has become parasitic on the other.

The consideration of symbiosis shows that gene-for-gene relationships arise only when the relationship between the symbiotic partners becomes antagonistic. Symbiosis frequently involves a high degree of intimacy in the association between partners; there can therefore be nothing in the intimacy of the association, *per se*, that necessarily leads to gene-for-gene relationships. The earlier example, mimicry, showed that the processes leading to gene-for-gene relationships can take place even when the relationship between the participants is relatively remote. But the intimacy of the relationship between host and parasite does provide a distinction that may be useful in coming to a precise definition. To take the example given earlier, it is possible to study the genetics of colour and pattern in one organism, and at the same time be quite ignorant of the fact that the pattern being studied is a mimic pattern. With parasitism, however, it is not possible to study resistance to infection independently of the parasite, or to study virulence of the parasite independently of the host. Both organisms must be present in the study. This is a necessary condition, since one and the same morphological expression, the reaction-type, provides the needed information, whether it is the genetics of the host or of the parasite that is being studied. If this is taken into account, a definition can be formulated that does not violate the gene-for-gene concept as it is presently held and at the same time places rather precise limits on its applicability. The concept thus defined would be limited to parasitism. Quispel[7] finds no distinct dividing line between mutualistic and antagonistic symbioses, and points to the fact that any given symbiotic pair can exhibit both kinds of relationship. Where this occurs it is our opinion that the antagonistic part of the relationship will have its basis in gene-for-gene specificities; in fact, we believe that where doubt exists the demonstration of such specificities is likely to be the surest diagnosis of an antagonistic symbiosis.

These considerations have brought us to the following definition of the gene-for-gene concept:

A gene-for-gene relationship exists when the presence of a gene in one population is contingent on the continued presence of a gene in another population, and where the interaction between the two genes leads to a single phenotypic expression by which the presence or absence of the relevant gene in either organism may be recognized.

The lack of clear definitions in biology can be expected to lead to confusion. An example relating to Flor's gene-for-gene concept has been given recently by Flangas and Dickson[8], who contend that some sort of structural homology at the sub-genic level is required of the units that interact in a gene-for-gene relationship. We believe, on the other hand, that functional specificities between related genes need neither imply nor require any structural specificities between the genes concerned. Speculations concerning the mechanisms by which related genes interact have therefore been considered irrelevant to the problem of formulating a definition of Flor's gene-for-gene concept.

LETTERS TO THE EDITOR

ASTRONOMY

Expansion of the Universe

In a recent issue, Dr. Alastair Ward[1] suggests an interesting experiment to check whether or not the universe is expanding. By using the Mossbauer effect we can study photon interactions and attempt to produce an increase in wave-length λ that is proportional to distance r. This would then explain the Hubble law ($\delta\lambda/\lambda \sim r$) as derived from the red shift in the spectra of distant galaxies. But physicists should bear in mind the uncertainties in the astronomical data. For example, it is quite possible that the red shift, and hence the apparent velocity of recession, increases as distance squared.

Fig. 1 shows the most comprehensive collection of red shift values available at the present time for field galaxies[2]. The logarithm of the observed red shift is plotted against the observed bolometric magnitude M which has been corrected for absorption within the local galaxy. Most of the scatter among the points is due to intrinsic differences in absolute brightness and random motion of galaxies. There are many types of galaxies from *E0* to *Sc*, and each type has a characteristic magnitude. Deviations also occur in the brightness of galaxies within a single classification.

In a flat space-time with no intergalactic absorption the apparent magnitude M_0 of a galaxy at a distance r kiloparsecs is given by:

$$M_0 = M_{\text{abs.}} + 10 + 5 \log r \qquad (1)$$

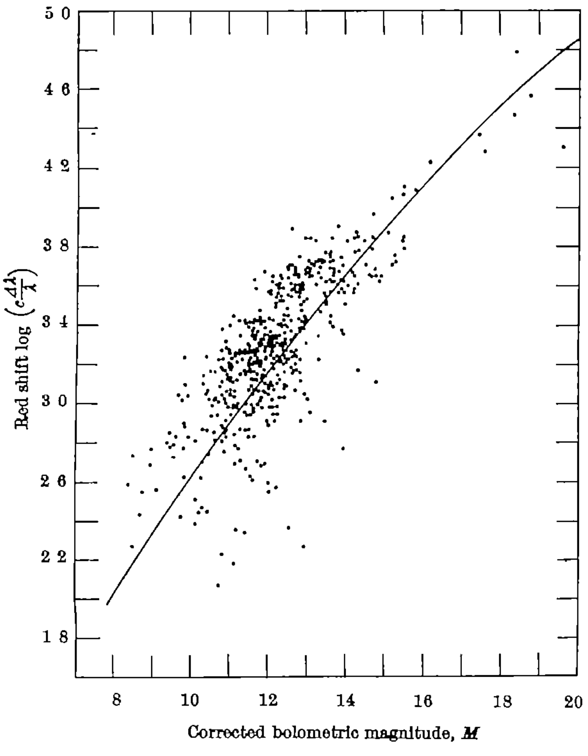

Fig. 1. Red shift for field galaxies

where $M_{\text{abs.}}$ is the absolute magnitude of the galaxy. As a first approximation we may follow Humason, Mayall and Sandage[2] and assume that $M_{\text{abs.}}$ is the same for each field galaxy. We would then expect to find the relation:

$$M = 5 \log \frac{c\delta\lambda}{\lambda} + \text{constant} \qquad (2)$$

If a least-mean-square solution of the form of (2) is fitted to the points in Fig. 1 then a gradient of 3·03 is obtained. If the analysis is restricted to the 430 galaxies with magnitudes brighter than + 14 (91 per cent of the sample) then the line of best fit is:

$$M = 2{\cdot}26 \log \frac{c\delta\lambda}{\lambda} + 4{\cdot}63 \qquad (3)$$

A gradient of 5 corresponds to a linear law while a gradient of 2·5 corresponds to a quadratic law. Thus the measurements for field galaxies are more consistent with a quadratic law, and in particular (3) gives:

$$\frac{\delta\lambda}{\lambda} \sim r^{2{\cdot}21} \qquad (4)$$

A linear law can only be obtained from these data by postulating that systematic biases, such as selection effects, exist, and by weighting the observations in some way so as to remove the suspected bias.

Intergalactic absorption may also be present, dimming the galaxies and displacing the points to the right. A galaxy of absolute magnitude $M_{\text{abs.}}$ will be dimmed by δM, where:

$$\delta M = \alpha \log_{10}^{-1} \{0{\cdot}2(M_0 - M_{\text{abs.}} - 10)\} \qquad (5)$$

and where α is the absorption coefficient in magnitudes per kiloparsec. In the Milky Way the interstellar density is 10^{-24} gm. cm.$^{-3}$ and the dust produces a coefficient of $\alpha = 1$. Between the galaxies[3] the density of material may be as high as 10^{-27} or 10^{-28} gm.cm.$^{-3}$ and values of $\alpha \sim 10^{-4}$ might be expected. The theoretical curve in Fig. 1 corresponds to a red shift which increases as r^2 and with a slight amount of absorption present ($\alpha = 6 \times 10^{-5}$ mag./kpsc.). The absolute magnitude[2,4] of a field galaxy was taken as $-$ 20·07. It can be seen that the theoretical curve is a tolerable fit to the data. Humason, Mayall and Sandage[2] have pointed out that more significance can be given to the points in the upper half of the diagram since these represent the larger galaxies and there is less likelihood of observational selection taking place. The theoretical curve forms a satisfactory envelope for these points when displaced to the left by 2·0 magnitudes to allow for the increased absolute magnitude of the brightest galaxies.

The curve may also be tested with the data from clusters of galaxies. Humason, Mayall and Sandage have given the red shift measurements for a number of clusters as shown in Fig. 2. The magnitude corresponds to the brightest cluster member and for the brightest member Humason, Mayall and Sandage[2]

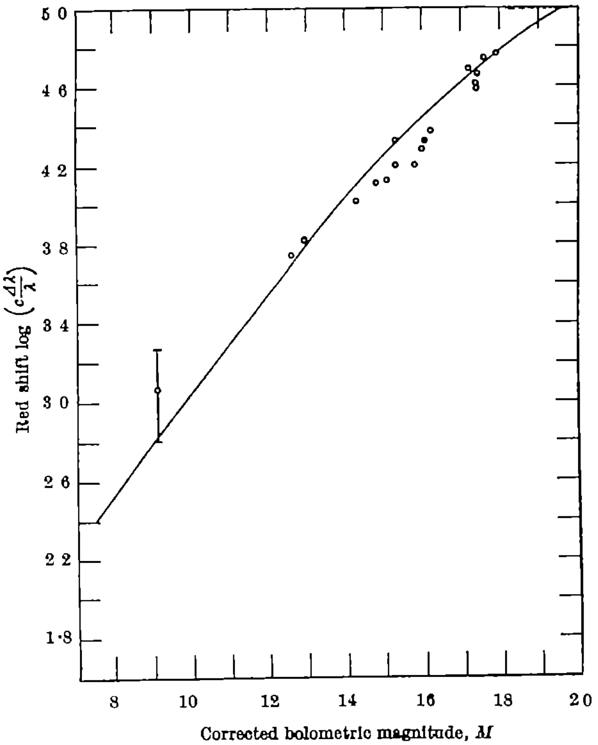

Fig. 2. Red shift for brightest members of clusters

and Sandage[4] give $M_{\text{abs.}} = -21{\cdot}64$. The curve was derived using the same values of density and absorption as for the field galaxies ($\alpha = 6{\cdot}0 \times 10^{-5}$ mag./kpsc., $\rho = 6{\cdot}6 \times 10^{-27}$ gm.cm.$^{-3}$). A bar has been placed on the point for the Virgo cluster to indicate the standard deviation of the red shift among the members of the cluster.

Thus it is premature to assume that the Hubble law is linear and that the apparent velocity of recession increases proportionally with distance. Indeed a quadratic law adds weight to the argument of a non-expanding universe and increases the need for interpreting the red shift as due to some cause other than the Doppler effect. If $\delta\lambda/\lambda \sim r^2$ in all directions of observation then a Doppler interpretation puts us at the origin of a parabolic velocity field and leads towards the unpalatable conclusion that the Milky Way is at the centre of the universe ! A quadratic law is best interpreted in terms of a static universe where the red shift is caused by some propagation effect. Mechanisms similar to the photon interaction proposed by Dr. Ward are interesting in this respect. Alternatively a quadratic law can be derived from the formulation of general relativity[5-7] using a static model as proposed by the author.

PHYSICS

Hydromagnetic Heat Transfer

Consider the convective transfer of heat between an electrically conducting viscous fluid (of density ρ, shear viscosity μ, thermal conductivity $\varkappa$, specific heat at constant pressure C_p, and finite electrical conductivity σ) and a boundary surface at a different temperature and with characteristic length L, possibly associated with a complex geometry, in the presence of a steady externally applied magnetic field of magnitude B. A full mathematical analysis of general validity for this situation is still not available and it is useful to consider elementary dimensional arguments in this connexion. It will be seen that such arguments provide the possibility of determining the gross electrical conductivity of a continuous fluid in terms of a chosen standard fluid.

For forced convection, let the fluid be caused to move past the surface with steady speed v. The boundary temperature will be assumed to be greater than that of the main fluid by an amount $\Delta T (\neq 0)$; but the opposite situation could equally well apply. Difficulties over the detailed specification of ΔT will be avoided in the usual way by using the logarithmic mean temperature difference across the boundary layer region.

If a quantity of heat q passes from unit area of the boundary into the fluid per unit time then dimensional analysis leads readily to a functional relation between the relevant parameters of the flow. Defining the Nusselt number, Nu, Reynolds number, Re, and Prandtl number, Pr, by:

$$Nu = \frac{qL}{\varkappa\Delta T}, \; Re = \frac{\rho v L}{\mu}, \; Pr = \frac{\mu C_p}{\varkappa} \qquad (1)$$

and the dimensionless grouping $\xi = \frac{B^2\sigma L^2}{\varkappa\Delta T}$ (Gaussian units), then it follows that:

$$Nu = f_1(Re) f_2(Pr) f_3(\xi) + C \qquad (2)$$

where f_1, f_2, f_3 are three as yet undetermined functions. C is a constant associated with conductive heat transfer, and can be regarded as remaining independent of the magnetic field to very good approximation. Equation (2) then implies the condition $f_1(Re) \rightarrow 0$ as $v \rightarrow 0$, since in this limit $Nu = C$. Some information about the limiting form of f_3 for vanishing ξ is easily deduced when it is noted that $B^2\sigma L^2$ refers to the fluid-magnetic field coupling. When this coupling is zero (that is, $B = 0$) the heat transfer is purely hydrodynamic so that $f_3 (\xi) \rightarrow 1$ as $\xi \rightarrow 0$. Although it is unphysical in the present context it can be noted that if the coupling were ever complete (that is, $B^2\sigma L^2 \rightarrow \infty$) the fluid and field would be frozen together, the heat transfer then being by conduction relative to the field.

In the limit $\xi = 0$, empirical knowledge of equation (2) is already available[1]. Thus it is known that now many situations of practical interest are well described by the substitution $f_1(Re) f_2(Pr) = D(Re)^n (Pr)^m$, where (D, n, m) are flow parameters. For liduiq metals[2] $Pr \sim 10^{-2} - 10^{-3}$, $n = m$ and C in equation (2) is of the order 10; for turbulent conditions $D \sim 10^{-2}$ and $n \sim 3/4$. Making the reasonable assumption that the separation of the functions f_1 into independent hydrodynamic and magnetic contributions is valid, and introducing the Peclet number,

Pe, according to $Pe = Re \times Pr$, then equation (2) can be written generally:

$$\frac{Nu - C}{D(Pe)^n} = f_3(\xi) \qquad (3)$$

for hydromagnetic laminar or turbulent conditions.

Measurements of heat transfer for a known geometrical and magnetic arrangement allow the data $f_3(\xi)$ as function of ξ to be determined for a chosen fluid, which could conveniently be mercury. With the function f_3 known for one representative fluid this information is applicable to other fluids within the continuum approximation, and under comparable heat transfer conditions. If the geometry and magnetic field are known then ξ can be determined for some other fluid of interest by making heat transfer measurements and using the empirical data for f_3 in equation (3). By this method, equation (3) can be used to determine σ for one fluid in terms of a standard fluid; the method may have some merits in connexion with fluids that are difficult or dangerous to handle, since equation (3) can be applied to a closed loop system.

The same approach can be applied to natural convection where the gravitational acceleration g and the fluid density volume coefficient of expansion β are relevant while the fluid velocity is not. In this case Re is replaced by the Grashof number $Gr = \dfrac{\beta \Delta T g L^3}{\nu^2}$ and Pe by the Rayleigh number $Ra = Gr \times Pr$.

Finally, the fluid may be in steady rotation with angular speed Ω. In this case the right-hand side of equation (2) is multiplied by the additional function $f_4(Ta)$, where $Ta = \dfrac{\Omega L^2}{\nu}$ is the Taylor number. For free convection without a magnetic field f_4 has been found experimentally[3] in one instance to be reducible to a linear form if L is suitably defined, but almost no general data are at present available.

GEOLOGY

Age of the Cuddapahs, India

IN discussing the age of the Cuddapahs, India, Dr. U. Aswathanarayana[1] includes lead isotope analyses of the Cuddapah galenas.

The extremely low lead-207/lead-204 ratios of these samples in comparison with their other ratios have attracted our attention since they are not readily explained by any of the now accepted lead isotope models with parameters that are in the range of those usually used. When we brought these unusual abundances to his attention, Dr. Aswathanarayana sent us his original spectrograms so that we could carry out our own measurements on them. We did this with results that were substantially different from those obtained in India, as can be seen here. It is to be emphasized that our values are not from our own measurements but are merely recomputations of some of the Indian spectra.

Table 1. ZANGAMRJUPALLE GALENA (WALTAIR MEASUREMENTS)

Calculated by	^{206}Pb/^{204}Pb	^{207}Pb/^{204}Pb	^{208}Pb/^{204}Pb
Aswathanarayana	15·86	14 49	34·70
Russell and Ostic	16·0	15 1	34 8

We have made considerable effort to try to determine the nature of the discrepancy between the two calculations, which results primarily from the different way in which base lines are drawn under the peaks at the two laboratories. It appears that the smaller resolution of the Waltair instrument exaggerates the effects of tailing of the peaks due to scattering of the ions in the analyser tube. It has been our practice to apply corrections for this tailing, which for our own spectrograms can change the results by as much as 0·5 per cent. To make this correction three numbers are required. These are the proportions of a peak observed at distances from its centre equivalent to one-half mass, one mass and two mass units respectively. These values vary approximately proportionally to the pressure in the analyser tube and may change with variations in the source conditions such as caused by the replacement of a filament, etc. Even with good resolution it is quite difficult to estimate the magnitude of these correction factors. However, we have tried to estimate representative values from lead tetramethyl spectra we have available from different laboratories. These estimates are given in Table 2 with sufficient other information about each spectrum to indicate the importance of adequate resolution in carrying out this type of measurement.

The way in which these terms enter into the calculations depends, of course, on the way in which base lines are drawn under the peaks. We draw the base line under the 249 mass by joining the minima on either side of it with a straight line. The base lines for the three major peaks are drawn by joining, with a straight line, the corresponding base lines measured well beyond the limits of the trimethyl group of the spectrum. This is similar to the procedure carried out at the University of Toronto. With this measuring procedure the ratio lead-207/lead-204 is that most critically affected by the tailing correction, the correction amounting to not less than the tailing at half mass plus twice the tailing at one mass distances. This figure is also given in Table 2 although we do not imply that any measurements are in error by the amount listed, since judiciously drawn base lines can allow for much of the tailing, particularly under the mass 249 peak.

We direct attention to this source of uncertainty in these measurements because, as Dr. Aswathanara-

Table 2. ORDER OF MAGNITUDE OF TAILING CORRECTIONS ESTIMATED FOR MASS SPECTROMETERS OF DIFFERENT RESOLUTION

Laboratory	Resolution	Collector slit width	Beam width at collector	Estimated tailing $m + \frac{1}{2}$	$m + 1$	$m + 2$	Correction of ^{207}Pb/^{204}Pb (per cent)
British Columbia	470	$1·7 \times 10^{-3} R$	$0·4 \times 10^{-3} R$	~ 0 002	~ 0·001	~ 0 0002	~ 0 4
Toronto	310	$2\ 3 \times 10^{-3} R$	$0\ 9 \times 10^{-3} R$	~ 0·01	~ 0·002	~ 0·0004	~ 1 4
Andhra	290	$2·0 \times 10^{-3} R$	$1\ 5 \times 10^{-3} R$	~ 0·02	~ 0·005	~ 0·0007	~ 3·0

R, Radius of curvature of the instrument.

yana points out, these samples may have an important bearing on understanding the geochronology of India, and the uncertainty in isotopic composition suggested by the present comparison is equivalent to a factor of two difference in age of the two samples as calculated in the paper cited. (We also contend that the calculation of the age of galenas by any technique requires some *a priori* evidence that the sample dated can be expected to satisfy the model used, but this is another matter.) Moreover, the analyses originally quoted suggest the primary development of lead isotopes in terrestrial systems having a uranium/lead ratio which we feel to be improbably low. We are also anxious to direct attention to the importance of pressure scattering as a source of uncertainty in lead isotope analyses since it does not seem to have been given sufficient attention by the laboratories carrying out such measurements.

We thank R. G. Ostic and E. R. Kanasewich for carrying out a number of calculations related to the present discussion and for their critical comments on this manuscript.

---

[1] *Nature*, 193, 470 (1962).

Russell and Slawson have clearly brought out, presumably for the first time, the significance of the pressure-scattering correction which may change the lead-207/lead-204 ratio by about 3 per cent when low resolution mass-spectrometers are used for the isotopic analysis of lead. This correction, coupled with differences in the mode of measurement of peak heights, is responsible for the discrepancies in lead isotope ratios given by Russell and Slawson and those given by me[1]. It is possible that the correction may improve the accuracy of the lead isotope ratios, but this requires to be corroborated. The objective of this communication is to discuss the conclusions that flow from the revised model age of the Zangamrajupalle galena.

The corrected isotopic constitution of the lead of Zangamrajupalle (see preceding communication) (lat. 14° 45′ 22″ N.; long. 78° 51′ 33″ E.) galena, which occurs as veins in the Cumbum shales of the Upper Cuddapahs, and its model ages are given below in Table 1.

Table 1

^{206}Pb/^{204}Pb	^{207}Pb/^{204}Pb	^{208}Pb/^{204}Pb	Model ages (m.y.)		
16·0	15·1	34·8	1,400*	1,460†	1,470‡

* ^{206}Pb/^{204}Pb and ^{207}Pb/^{204}Pb age—Houtermann's formula, constants of Russell and Farquhar (ref. 2).

† ^{206}Pb/^{204}Pb and ^{207}Pb/^{204}Pb age—Houtermann's formula, constants of Moorbath (ref. 3) (read from the unpublished tables (No. 5) of R. P. C. Pockley).

‡ ^{208}Pb/^{204}Pb age—formula of Russell, Farquhar and Cumming (ref. 4).

The revised model age (1,400–1,470 m.y.) of the Zangamrajupalle galena has far-reaching implications. Thus the Cuddapahs may not be the time-equivalents of the Delhis, since the post-Delhi pegmatites were found to be 735 m.y. old[5]. This view has been advocated by Holmes[5]. The Cuddapahs may belong to the end phase of the Eastern Ghats cycle (1,600 m.y.) and the period immediately following[5,6]. As pointed out by Holmes[5], the two may be related in the same way as the Indo-Gangetic alluvium is related to the Himalayas.

It must be emphasized that the foregoing conclusions are tentative and require to be substantiated by further work, which is in progress.

I thank Prof. C. Mahadevan for his helpful criticism. This work was aided by the Council of Scientific and Industrial Research (India).

Occurrence of Graywacke in the Lower Siwaliks, Simla Hills

SIKKA *et al.*[1] have reported the occurrence of graywacke in the Nahan Series (Lower Siwaliks) near Kalka, Simla Hills, Panjab. The rock has been described as "a grey to greenish micaceous 'sandstone' type" in the hand specimen which in thin sections is seen to consist of "angular grains of quartz (approximately 50 per cent) embedded in a matrix composed of fragments of slate, schist, quartzite, chert, felspar, chlorite and authigenic sericite". The authors appear to be of the opinion that the presence of this rock type in the Siwaliks casts doubts on their fresh-water origin since "it is generally accepted that the graywackes are characteristic of the geotectonic belts".

It is well known that the two distinctive features of a graywacke are its texture and composition. The authors made no precise mention of the texture of the rock although, according to Pettijohn[2], "it alone distinguishes graywacke from all other sandstones". The description of the composition of the rock is also confusing since rock fragments and felspar grains have been regarded as the constituents of the matrix. It is clear that rock fragments and felspar grains do not constitute the 'matrix' but form an integral part of the framework of the graywackes. Since the grain/matrix ratio is important in defining these rocks, it is essential that the amount of 'true' matrix is indicated separately. If this distinction is not clearly brought out, the graywacke proper cannot be distinguished from the sub-graywackes which have a different origin and geologic significance. From the description given by Sikka *et al.*[1], it is not at all clear whether the rock is a graywacke or a sub-graywacke.

Krynine[3] had noted the occurrence of graywacke in the Siwaliks of north-western India and considered them non-marine. It is interesting to note, however, that the same author redefined the term in 1945[3] and created two types of graywackes—low-rank and high-rank. The low-rank graywacke of Krynine so far as composition is concerned is equivalent to the sub-graywacke as defined by Dapples *et al.*[4] and Pettijohn[5].

It is more than likely, therefore, that much of the so-called graywacke of the Siwaliks may, in fact, turn out to be sub-graywacke (the low-rank graywacke of Krynine) if a proper petrographic study is made. If this is the case, the notion that the Siwaliks are entirely of fresh-water origin may still be true because the sub-graywackes are neither necessarily marine nor are they characteristic of the geotectonic belts.

The presence of cross-bedding and ripple-marks, the moderate sorting of the Siwalik sandstones and their profuse richness in plant remains (even in the Nahans themselves) and in the mammalian fauna of the Upper Siwaliks suggest their deposition under shallow water conditions. Indeed their nature and mode of formation are identical with those of the sub-graywackes and they may well have formed on flood plains or in deltas in the coastal plains. The presence of red shales and numerous bands of conglomerates also supports the existing view that they were deposited under subaerial conditions. Moreover, in the vast thickness of the Lower Siwaliks not a trace of marine fossils has been found, nor any other evidence suggestive of geosynclinal conditions. The molluscan fauna wherever found suggests fresh-water conditions.

A Pedunculate Cirripede from the Upper Silurian of Oesel, Esthonia

The discovery of a pedunculate cirripede in Silurian rocks carries the history of that order a long way back; for until now the earliest record of a pedunculate is from the Rhætic, and that of the goose-barnacles (Lepadidae) is from the Pliocene. Some fifty of these fossils were discovered when etching out the chitinous skins of *Eurypterus fischeri* Eichw. from the Upper Silurian limestones of the Island of Oesel in Esthonia. Some were still attached to the legs of the *Eurypterus*, clustering on them as do the young *Lepas* on bits of sponge, cuttle-bone, etc.

I name this fossil *Cyprilepas holmi* gen. et sp. nov. (Fig. 1). As the figure shows, there is a capitulum of two valves united on one side and resembling the shell of the Recent ostracod *Cypris* and of the *Cypris*-larva of all cirripedes; and a cylindrical peduncle with one or more annular constrictions and, in a few cases, with a terminal attachment-disk. Their total length ranges from 2·2 mm. to 4·8 mm. The chitin is virtually structureless and devoid of growth-lines; but in two cases it displays a small patch of hexagonal markings quite similar to those left on the chitinous covering of the Recent goose-barnacle *Lepas* when its calcareous plates have been dissolved. This may be evidence of the existence of a pair of calcareous plates before the fossil was etched from the rock; but there is nothing to suggest that there were five plates, as in *Lepas*. The chitin of the stalk appears, in some examples, to be covered with minute papillæ. This feature and the terminal disk can both be matched in very young post-larval *Lepas*.

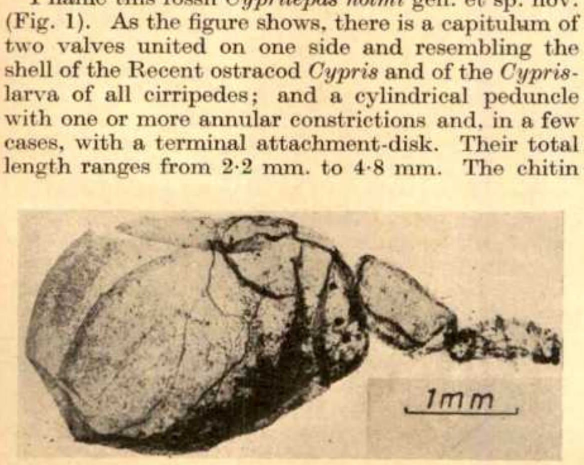

Fig. 1. *Cyprilepas holmi* gen. et sp. nov.; the holotype, *B.U.*743

Duplicates are available for distribution to interested individuals and museums.

GEOCHEMISTRY

Nitrate and Iodate in Antarctic Salt Deposits

Antarctic salts have been described by Ferrar[1], Ball and Nichols[2] and several other authors, but nitrates and iodates have not previously been reported. Although Jensen's[3] analyses showed small amounts of nitrogen, presumably in ammoniacal form, he specifically mentions the absence of nitrate. He considered this deficiency due to nitrifying bacteria being unable to survive in the cold climate, and believed it to be an important factor in preventing plant life.

Salt pans, efflorescent crusts on rock faces, and salt layers within the moraine were sampled by the 1959–60 Victoria University Antarctic Expedition during its study of the 'ice free' Victoria Valley region[4] (situated opposite Ross Island in the Victoria Land mountains). We report here the presence of considerable amounts of nitrate and iodate in two samples obtained 30 miles west of McMurdo Sound.

The salts contained some acid-insoluble mineral matter, but consisted largely of calcium sulphate and carbonate, and sodium sulphate, nitrate and chloride either as single salts or as mixtures in various combinations.

Of the eighteen samples examined, all showed nitrate in quantities ranging from a trace to as much as 90 per cent sodium nitrate in one sample. The analysis of this latter sample is given in Table 1. Nitrate, first identified by optical methods, was later determined by the phenoldisulphonic acid method, with the estimation being made spectrophotometrically.

Table 1. Analyses of Salts containing High Iodate and Nitrate Respectively

Victoria University of Wellington sample No.	Location	Description	Composition (per cent)	
10567	¼ mile south-west of Lake Vashka	Surface sample from salt-filled depression	$CaSO_4.2H_2O$ $CaCO_3$ $NaIO_3$ $NaNO_3$	85 14 0·13 trace
10569	3 miles south of Lake Vashka on Range west of Balham Valley (ref. 4)	Encrustation on Beacon sandstone cliff	$NaNO_3$ $CaSO_4.2H_2O$	90 10

The important 'caliche' deposits of Chile have not yet been adequately explained despite the many theories advanced[5]; the existence of nitrate in the Antarctic is even harder to explain. Iodate is associated with the nitrate in the Chile deposits but is also found with other salts in Victoria Valley.

Iodate to the extent of 0·13 per cent sodium iodate was found in one sample (Table 1) which consisted mainly of calcium sulphate, with small amounts of calcium carbonate and traces of sodium chloride and nitrate. Another specimen composed largely of sodium sulphate contained 0·02 per cent sodium iodate. Waters from the nearby Lake Vashka also contain iodate.

The iodate was determined by addition of potassium iodide to an acid extract of the salt, followed by titration with standard phenylarsenoxide, using starch as the indicator. Iodate was established as the oxidizing agent by reduction with sulphite, followed by nitrous acid oxidation, when extraction with chloroform gave the characteristic coloration for elementary iodine.

An explanation of the existence of iodine in an oxidized form can be made on thermodynamical grounds, since at neutral *p*H values the atmospheric oxygen-iodine potential is such that some oxidation may occur, and subsequent hydrolysis will give iodate as the stable form[6], as is found in sea water[7-9].

Uranium in Recent Japanese Sediments

Considering the amount of work that has been done concerning the uranium content in recent marine or lacustrine sediments, especially during the past decade, the available data are rather less than for uranium of rocks or mineral assemblages[1-3].

Very little is known about the uranium content of sediments from various environments in Japan. The primary purpose of an investigation that we recently made was to determine the uranium in such sediments, but with regard to non-contaminated areas, and thus to obtain a figure for the ground-level of uranium for natural environments in Japan.

Samples of sediments, of which two were marine, three from inlets, four sections of a core obtained from a brackish lake, one from an oilfield and one from a gasfield, were examined. The locations of the samples are shown in Fig. 1. The microquantities of uranium present in the samples were determined colorimetrically by complexing with dibenzoylmethane[4,5].

Uranium was isolated from the leached solution of 1 or 2 gm. of sediment with a liquid–liquid extraction of ethyl acetate, followed by treatment with anion exchange resin ('Amberlite *IRA*-400', 80–100 mesh) which was used in a column of 8 mm. diam. and 5 cm. long. The uranium was afterwards eluted with 1 *M* perchloric acid, and the effluent evaporated to dryness.

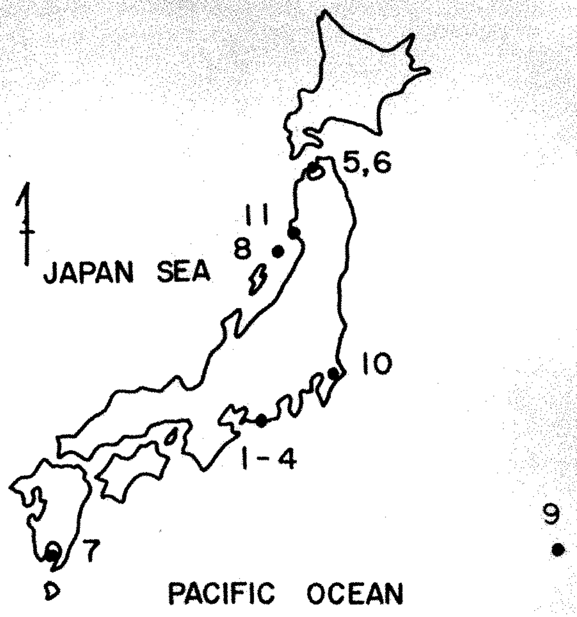

Fig. 1. Location of sediments sampled

The small residue of uranium resulting from the chemical separation was dissolved in nitric acid and analysed by measuring the maximum absorbance at 420 mμ of the complex formed with dibenzoylmethane.

The results are summarized in Table 1. It can be seen that the sediments from Lake Hamana (samples No. 1–4) and Kagoshima Bay (sample No. 7) show higher values of uranium than the others. This discrepancy is probably due to the fact that the bottom layers of Lake Hamana and of the Kagoshima Bay present reducing conditions, so that tetravalent uranium is quickly adsorbed or precipitated as a hydrolysate, and accumulated in the natural environment.

Table 1. Uranium in Recent Japanese Sediments

No.	Sample remarks	Water depth (m.)	Uranium (μgm./gm.)
1	Lake Hamana St. 4, No. 3	6	$14{\cdot}2 \pm 0{\cdot}3$
2	No. 4		$17{\cdot}9 \pm 0{\cdot}4$
3	No. 5		$8{\cdot}3 \pm 0{\cdot}2$
4	No. 6		$18{\cdot}1 \pm 0{\cdot}4$
5	Mutsu Bay *E*-16	50	$2{\cdot}6 \pm 0{\cdot}0_5$
6	*E*-25	50	$2{\cdot}1 \pm 0{\cdot}0_4$
7	Kagoshima Bay St. 10	200	$8{\cdot}7 \pm 0{\cdot}2$
8	Japan Sea (off Sakata)	200	$3{\cdot}5 \pm 0{\cdot}0_7$
9	Pacific red clay	6,215	$1{\cdot}3 \pm 0{\cdot}0_3$
10	Tohgane gasfield	—	$1{\cdot}7 \pm 0{\cdot}0_3$
11	Funakawa oilfield	—	$3{\cdot}7 \pm 0{\cdot}0_7$

However, fairly constant values of uranium were obtained in samples from elsewhere in Japan. Kulp *et al.*[6] summarized the uranium values of various types of sediment as follows: shelf, hemipelagic and pelagic, containing 3·0, 2·5 and 1·0–1·8 μgm. of uranium per gram of sediment respectively.

In comparison with the uranium content of average igneous rocks (3·5 μgm./gm.)[1], the uranium contents of recent Japanese sediments are slightly less, but are of the same order of magnitude as those in the classification given by Kulp *et al.*

An approximate estimation of the uranium values of recent Japanese sediments is given as an average of

2·5 p.p.m. (excluding those sediments with an extraordinary content of uranium).
